MR. THOMAS ANNANDALE, of Edinburgh, said that he had two good reasons for not speaking: first, he had arrived but half an hour ago from the steamer, and second, that unfortunately he had not, owing to that, been able to hear the papers or much of the discussion. As he had been called upon to speak, he might be permitted to give his opinion in regard to the treatment of intestinal obstruction. Now, in regard to treatment, he thought it was very important to divide these cases into acute and chronic. In regard to the acute cases, it is perfectly right that everything medicine can do should be tried, but should not be tried too long. As soon as it has been tried for forty-eight hours then the case belongs to the surgeon, and the sooner he opens the abdomen the better. If possible, open the intestine and form an artificial anus.

In regard to chronic cases he thinks one might wait in fact until the symptoms have become acute, and then if the symptoms of a chronic intestinal obstruction become acute, then he should operate at once. He had heard his friend, Mr. Durham, speak of lumbar colotomy in cases of cancer of the rectum. He has learned to prefer inguinal colotomy in the left inguinal region, because it is not a serious operation in the matter of risk, if properly done, and is certainly a simple one in a large majority of cases.

DR. SENN, in closing, said that he could assure Mr. Durham that hydrogen when injected into the intestinal canal never forms an explosive, as the canal naturally contains hydrogen gas. It has been tried hundreds of times on animals and at the bedside without an explosion. One of the first experiments he made was on himself.

In reference to colotomy, he would say that he did not mean to condemn this operation. He advocated its use in several cases, but he did repeat the statement that lumbar colotomy might become obsolete. The operation is done for the purpose of securing to the bowel perfect physiological rest, which cannot be done by a lumbar colotomy.

WEDNESDAY EVENING, SEPTEMBER 19TH.

DR. CHARLES K. MILLS, of Philadelphia, opened the discussion on

CEREBRAL LOCALIZATION IN ITS PRACTICAL RELATIONS.

He began by referring to the fact that from the clinical observation of practical physicians sprang the conceptions out of which developed the science and art of cerebral localization. Allusion was made to the discoveries of Bouillaud and of Broca on speech localization; to the announcement by J. Hughlings Jackson in 1864, that certain convolutions superintended the delicate movements of the hand which were under the immediate control of the mind, and to Hitzig's researches having originated from his observing certain ocular movements during galvanization of the heads of his patients. Brief reference was made to the history of American work in

localization; to the investigation in 1874 of the New York Society of Neurology and Electrology; to Putnam's discovery that irritation of the white matter beneath the definite cortical centres produced movements similar to those caused by irritation of the centres themselves; to the labors of Wood and Ott on the heat centres, and to the light thrown by these investigations upon the mechanism of fever, and the action of drugs upon different forms of high temperature.

Before taking up the surgical aspects of the question, he briefly discussed some of the practical results wrought by cerebral localization for psychological medicine and medical jurisprudence; for general symptomatology and diagnosis, and for medical therapeutics and technique.

Trephining for cases of insanity, particularly when guided by the rules of localization, was briefly considered. Two of the recent cases of brain operation, reported by Bennett and Gould and by Macewen, were cited as possibly opening a new field for surgical interference in insanity, the excision of cortical areas as a method of treatment when certain subjective phenomena, such as hallucinations of sight or hearing, can be given a local habitation in the brain.

In turning to the surgical aspect of cerebral localization in its practical relations, Dr. Mills stated that his remarks would be chiefly concerned with questions of diagnosis. He considered, first, the forms of disease and injury in which cerebral localization is a valuable aid to diagnosis; and, secondly, the topographical diagnosis of the parts of the brain accessible to surgical interference, with some sources of error in such diagnosis. The forms of disease in which such diagnosis has been used are intracranial tumors, cysts, fractures, hemorrhages, abscesses, and discharging cortical areas.

In considering the localization of brain tumors, Dr. Mills referred to twenty cases of autopsies occurring in his own personal experience, in about one-half of which the tumors were in surgically accessible areas, and in at least one-fourth of which successful operations might have been performed. He advocated, from experience, the excision of old gummata, and also, in special cases, of tubercular growths. The value of localization was shown in cases of fracture in which the extent of the unseen damage could not be told by the position and character of the visible lesions.

Of the different forms of intra-cranial hemorrhages, subdural, cortical and intra-cerebral, were most amenable to localizing diagnosis. The rules for the local diagnosis of these forms of hemorrhage were then given. Dr. Mills advocated the performance of trephining in exceptional cases of hemorrhage into the ganglia and capsules—cases in which symptoms indicated that the bleeding had not broken into and inundated the ventricles. From his dissections, the best site for operation in such cases, all things considered, would be in the anterior portion of the first or second temporal gyre. He favored Hughlings Jackson's suggestion of excising localized cortical areas, even when coarse lesions could not be made out, in cases of spasm, beginning locally and deliberately.

The inaccessible areas had been narrowed down by the venturesome surgical explorer until reduced to the middle regions of the base and its bordering convolutions, the corpora quadrigemina and the pons-oblongata.

The characteristics of localizing symptoms were described as phenomena of irritation, destruction, instability, pressure, invasion, and reflex action. Signal symptoms and the serial order of motor phenomena were discussed. Briefly, in certain regions of the brain an accurate topographical diagnosis could be made with great certainty from positive localizing symptoms. These brain areas include the entire motor zone, in which are embraced the motor or emissive speech area—the region of Broca; the visual area in the cuneus, giving lateral hemianopsia, and the intracerebral visual tracts, possibly also the angular gyre, and the lateral surface of the occipital lobe. In other regions of the encephalon the topographical diagnosis could be made with sufficient accuracy, even for surgical purposes, by the study of the positive symptoms, with, in addition, the application of processes of exclusion and successive differentiation. Particular stress was here laid upon the importance of pressure and invasion symptoms. These areas for approximately certain topographical diagnosis include the cerebellum, the prefrontal lobe, the temporal lobe and even certain cranial nerve districts, as the auditory and facial, when the lesion would be localized within the cranium between the superficial origin of the nerves and their entrance into their foramina or canals of exit.

Motor localization has become almost an exact science The latest physiological research bearing upon the subdivision of the motor area and the light thrown upon the question by surgical operations were discussed. It was held to be imperative for the neurologist and surgeon to have exact knowledge, not only of the anterior and the posterior limits, but also of horizontal subdivisions of the motor zone.

The old method of subdividing the motor zone into three elliptical or circular areas from above downward was considered insufficient, but the neurologist should be able to locate for the surgeon from a study of motor phenomena at least seven or eight positions for trephining, these positions being selected by a close study of the initial or signal symptoms, the serial order of movements, and also of the amount and character of the temporary paralysis after the seizure and the method of extension of the persisting palsy. Reference was made to operations performed through accurate localization in these areas.

The view of Ferrier as to the localization of the centre for ocular and head movements in the second frontal gyrus was concurred in, and observations were cited in its support; when turning of the head and eyes was the starting-point of the spasm, this localization was sometimes indicated. The fact that cortical oculo-motor palsies were not present as a persistent condition, even with definite lesions of the second frontal gyre, was explained by the intimate and peculiar connections of the oculo-motor nuclei at the base; they do not persist for the same reason that paralysis in the upper distribution of the facial nerve is so seldom permanent. He believed that there was a special centre for the orbicularis palpebrarum movements, probably below and adjacent to the oculo-motor centre.

Dwelling upon the sources of error in motor localization, the questions of reflex spasm, of unilateral convulsions due to uræmia, lead, and other toxic agents, and hysteria and hystero-epilepsy were briefly discussed. Sufficient diagnostic difficulties are still present to make it important, in the light of the tremendous impetus toward operation, to examine carefully all questions of

differential diagnosis. In certain spasmodic affections, the resemblance between those clearly of reflex origin and those as demonstrably central, was very striking. Trigeminal epilepsy, whether dural, facial, dental, nasal, pharyngeal, laryngeal, or of whatever local origin, might cause unilateral convulsions or even mono-spasm. Dural epilepsies are especially worthy of attention, as shown by the researches of Dupuy, Brown-Sequard, Burdon Sanderson, the New York Society of Neurology and Electrology, Duret, Bochefontaine and Francois-Franck. Franck has made a careful comparison and contrast of cortical epilepsies with those which are reflex and toxic, including those which are due to irritative lesions of the dura mater.

He then referred to five cases in his own experience in which operations had been performed for epilepsies apparently reflex in character; two in which spicules of bone had been removed from the dura mater, one in which an old inflammatory lesion of the membranes and cortex from traumatism was present, and two in which scalp cicatrices were removed. While fearing with Franck, that we were not always able to make a trenchant separation between reflex and cortical epilepsies, some points of separation were indicated.

True Jacksonian epilepsy, Dr. Mills believed, was sometimes reflex in origin, that is, that it was established by intense, persistent peripheral irritation, and even after the irritation had been removed, the cortical discharge continued; herein, perhaps, lay the explanation of Jacksonian spasm without coarse lesion, and herein also, perhaps, was to be found the justification for the excision of cortical discharging areas. He referred to a case in which epilepsy, clearly of Jacksonian type, was just as clearly due to a fibroma involving a nerve trunk on the palmar surface of the hand, and in which the patient was cured by removal of the growth.

With reference to sensorial localization, cutaneous and muscular, the views of Horsley and Schäfer with reference to the limbic lobe were accepted in part. He believed that the evidence is becoming stronger every day in favor of the existence of a zone for the sensations of touch, pain, and temperature separate from cortical motor areas. Collections of cases, such as those of Starr, Petrina, and others, which were supposed to indicate that the sensory areas coincide largely with those of motion, were not regarded as overcoming the positive evidence of decided destructive lesions of the cortical motor zone without any sensory disturbance. From a study of his personal cases, he had concluded that they did not support the doctrine that the motor and sensory areas coincide. Notes of these cases were given and also cases from other reporters. He believed with Bechterew that the loss of sensation in animals which have had the motor area destroyed was apparent and not real. Some light had been thrown upon this disputed question by careful examination of patients after operation, particularly when certain definite cortical areas had been clearly excised. Reference was made to the cases of Horsley, Weir and Seguin, Lloyd and Deaver, and others. The speaker believed that these observations and experiments pointed clearly to the theory that the motor zones are motor alone in function. His view was that the region for general sensation including touch, pain, temperature and perhaps pressure, location and muscular sense could be divided into special areas for the various distinct portions of the body and that these centres lay alongside and had close anatomical and morphological relations with corresponding motor centres, but that they were not identical with them. He located these sensory areas in the gyrus fornicatus, the hippocampal gyre, the precuneus, and the lateral postero-parietal region.

The practical conclusion was that the neurologist and surgeon must depend upon motor symptoms alone in fixing the site for operation in cases in which the motor lesions are definite. When positive sensory symptoms are present, they may sometimes serve to aid in locating more exactly the position for operation, but the data are not sufficient for positive reliance.

The question of morphological peculiarities of the human brain was briefly alluded to as having some practical bearing upon the subject under discussion. The position of the so-called angular gyre and aberrations in the parieto-occipital region were more particularly discussed. Even the fissure of Sylvius, the central and the parieto-occipital fissures sometimes present considerable variation, but, as a rule, such aberrations are not confusing in operating on the motor region after the method of Broca, Thane, and others.

Dr. Mills concluded by saying that the discoveries in cerebral localization with the achievements in antiseptic surgery constitute the greatest triumphs which adorn the history of the noble science and art of medicine.

DR. ROSWELL PARK, of Buffalo, spoke as to the surgical aspect of the subject, and omitted consideration of those cases in which operation is dictated by a study of the subjective rather than of the objective features.

Cerebral topographical anatomy. The areas which most concern the surgeon are those which cluster around the fissure of Rolando. A few bony prominences deserve attention in this connection—that at the point of the nose known as the glabella, the external occipital protuberance, known also as the union; the point of the vertex half way between these two—the bregma; the external angle of the orbit, the tip of the mastoid process and the lower border of the alveolar process of the upper jaw. The fissure of Rolando has its upper end about five centimetres back of the bregma, but does not run quite in the middle line, its lower end lies about one-half centimetre behind the auriculo-bregmatic line and a little above an imaginary line projected backward from the superciliary ridge, thus the lower end of this fissure will be found about six centimetres above and a little behind the external auditory canal; or about an inch behind the bifurcation of the fissure of Sylvius. In regard to the convolutions, it must be stated that lesions of the dura mater overlying motor areas are not always to be distinguished from lesions in the cortex beneath. It is enough for the surgeon that a lesion of some kind can be located with reasonable accuracy. It matters not whether this is an old, irritative lesion; an acute suppurative process between the bone and the brain, or an abscess or tumor of the brain itself. The indication for exploration is just as strong in either case.

When and where can one trephine with safety? The safest rule is first to apply the trephine over those areas which do not overlie large vascular channels. Afterward the opening may be extended in any direction and to any required extent. The greatest hesitation is with regard to opening one of the sinuses. Two dangers

attend such an accident, one fatal air embolism, the other profuse hemorrhage. The former danger is almost a theoretical one, and the other may be overcome by plugging the sinus, or closing its wound with a fine needle and suture.

Cerebral and cerebellar abscess. Bergmann has shown that abscess of the brain has but one result—death—and that the surgeon's knife offers the only relief. So far as we know, there is no such thing as idiopathic abscess of the brain; it is always the result of some external wound of the head or some extension from diseased surrounding bone. The only exceptions to this statement are to be found in the case of pyæmic or tuberculous abscess. The symptoms of deep brain abscess may be divided into three groups according to causes: 1. Those which are inseparable from indications of suppuration. Such are those disturbances which may follow any deep-seated foreign body. 2. Symptoms of increased intra-cranial pressure and of disturbed relations. 3. Special symptoms by which the locality of the disturbance may be ascertained. As long as the gray matter is undestroyed, the collection of pus may assume large dimensions, and still no intense motor symptoms appear. Local elevation of temperature over the abscess is a symptom of importance when present, but its absence need not negative a diagnosis, if made on other grounds. Wernicke has stated that there is a peculiar disturbance of speech which points to lesion of the temporal region. This is the confusion of correct with incorrect words. In the general diagnosis of cerebral abscess, it is to be remembered that there usually is a latent period which may continue for an indefinite period. The stage of active symptoms is usually ushered in by more or less headache; slight rise in temperature; local or motor symptoms can only be expected when the abscess is in the motor area of the brain.

In operating for abscess of the brain, operators, until recently, have satisfied themselves with incising the dura and doing nothing more. With the introduction of aspirating methods, the hollow needle came to be used for brain exploration. The dangers of this procedure are certainly small. The danger of hemorrhage has been over-estimated. A temporary tampon will control deep hemorrhage, while, in bleeding from the pia mater, the vessels may be secured with ligatures or serre-fines. In brain abscess consequent upon middle ear disease the best point to trephine, according to Bergmann, is above and behind the ear. Macewen proposes a second counter-opening on a level with the floor of the abscess.

Brain tumors. The principal features of these growths which produce symptoms are location, size, character, rapidity and manner of growth, and extent to which they affect surrounding brain tissue. Considered in their surgical relations, we may, with Bergmann, divide them into (*a*) the circumscribed or encapsulated, and (*b*) the infiltrated or diffuse, around which, as a rule, there is a zone of softening. A third class may be mentioned, *i. e.*, those growing from the interior of the cranium, from the bone or dura.

If a reasonably satisfactory diagnosis can be made, it must be, indeed, an extensive growth of the cranial vault which shall contraindicate operation. The question of what and how many brain tumors are operable has been best answered by White. He found in one hundred brain tumors met with in the dead room of Guy's Hospital that only nine could have been removed—one tuberculous nodule, four sarcomas, two undetermined tumors, one cyst, and one myxoma. Nine per cent. could have been attacked, providing a fairly accurate diagnosis had been made. Of these nine tumors, five were located in the cerebellum, one in the frontal lobe, and one in the extremity of the occipital. It is doubtful whether these seven could have been recognized accurately enough during life to justify operation; while the myxoma was impossible to diagnosticate. It is thus seen that by no means all tumors which can be diagnosticated can be deemed suitable for operation.

Operation for intracranial tumors. The head should be shaved two or three days before operation, washed with green soap and ether, and antiseptic compressors applied. Chloroform should be, as a rule, the anæsthetic, on account of its contracting influence on the vessels of the brain. Morphia, hypodermatically, and ergot may be resorted to for the same purpose. The author suggested that, after localizing the lesion, a small, disinfected headless tack be driven through the scalp into the bone at the point determined upon. After the dissection of the external flap this will point out accurately the point to be first attacked. In order to prevent hemorrhage the author had found a spray of antipyrin solution (1 : 40) of service. The semilunar flap is the proper shaped one to raise. Its apex should be in such a position as to allow of drainage with the patient on his back. The periosteum should preferably be raised with the flap. The use of the trephine is preferable to the hammer and chisel. Since Macewen has taught us how to preserve the fragments of bone and restore them to their place, his method has been widely tried and universally commended. The dura mater should be incised around a large part of the area at a distance of one-eighth to one-quarter of an inch from the edge of the bone The appearance of the dura is sometimes a guide to trouble beneath. In recent cases it is sometimes highly vascular; in old cases it may be yellowish or discolored. Whenever adherent it should be freely excised. Horsley claims that marked protrusion of the dura indicates pathological intra-cranial tension. The color of the brain should be noted, remembering that the cerebellum has normally a different appearance from the cerebrum. Sometimes, where there is uncertainty as to which convolution is the desired one, the battery may be employed. When no indication of lesion is found, further exploration may be conducted with a small aspirating needle or a blunt probe.

Should a tumor be discovered, the incisions for its removal shonld be made perpendicularly to the cortex for the purpose of avoiding hemorrhage and division of the conducting fibres. Removal of a layer of cortex, whether normal or abnormal, does not leave, as one might fear, a prominent gap with vertical sides, since, in a short time, the depressed portion is made to bulge almost to the level of the intact parts surrounding. In addition the cut edges are also slightly everted, and, if less brain is removed than bone, the edges are extruded into the opening in the skull; thus there is a continual normal tendency to hernia. Bergmann and others have shown that this tendency to hernia cerebri is in inverse ratio to the area of bone removed. Experience has taught that it is wise to remove brain tissue to an extent greater than was at first considered justifiable. In all operations

or epilepsy the portions of cortex nearest the evident lesion should be freely removed.

The matter of drainage must be determined according to the circumstances of the case. An abscess must be drained as long as pus is discharged. After the antiseptic removal of a tumor, the cavity should seldom be drained for more than twenty-four hours. The provision for drainage may be removed on the second day, and the wound dressed with reasonable pressure over the flap. Exudation naturally collecting in this cavity will be retained and will give rise to some pain and disturbance, but so long as the symptoms from this are not severe, the wound may be left with confidence that the fluid will be reabsorbed, and that the pressure will be the best check to protrusion.

Dangers of the operation. The principal immediate dangers are two: hemorrhage and œdema. Hemorrhage from the pia or from the brain substance is usually readily controlled, but disastrous hemorrhage may occur from unexpected sources. When there is bleeding, a temporary tampon of iodoform gauze may be applied. The dural and skin flaps are laid over this, and an absorbent dressing applied. At the end of forty-eight hours this may be removed and sutures inserted.

The second danger, that of acute brain œdema, may be brought about either by increase of intra-arterial pressure or by obstruction of the venous channels of escape. Under this accumulation the brain becomes more sodden. Removal of a portion of the cranium is virtually a diminution of the pressure normally exercised on its contents and is often followed by reaction with production of excess of fluid.

He had collected reports of 63 cases which were presented in summary and tabular form, 17 of these terminated fatally, although only 5 of these deaths could properly be attributed to the operation; 15 of the cases were abscesses, subdural or subcortical. In 11 cases the lesion was a tumor, exclusive of tubercular nodules. Of cysts, properly speaking, there were 12. The 25 other cases were of a miscellaneous nature. In 3 cases, the true character of the lesion was not revealed during the operation, and was only discovered at the autopsy. In 2 cases, in which no palpable or visible lesion was discovered at the time of operating, the symptoms which led to the performance of the operation were nevertheless relieved, though nothing but careful exploration was practised.

Of the 63 operations, 17 were performed by American surgeons. Those who have themselves operated more than once are, with the number of their operations: Macewen, 12; Horsley, 11; Bergmann, 4; Weir, 3; Keen, 3; and Park, 3.

DR. D. FERRIER, of London, said he had listened in common with every one else in the room with the very greatest pleasure and profit to the extremely able papers which have been read before the Congress, and in which were so clearly expounded the principles of cerebral localization and of the surgical treatment of cerebral disease. He took especial personal pride in the fact that the question of cerebral localization and its practical application had been assigned a very important place in this gathering of the profession of America. It had been for many years a cherished idea with him, long before it had taken any definite shape or crystallization, that the accurate determination of the functions of the brain would in time lead to the successful treatment, by surgical means, of the most distressing ailments to which our fellow creatures are subject. Regarding the results of his experiments upon monkeys and other animals, he sounded several of his surgical colleagues with a view to obtain from them assistance in cases which he thought might be the subject of successful surgical procedure, but received little encouragement from them. He was told that men were not monkeys, though they may be descended from them.

About five years ago, at a meeting of the Medico-Chirurgical Society of London, he ventured more boldly to advocate the surgical treatment of cerebral disease, but he was honored with a denunciatory leading article in the *Lancet*, and thought this was so curious that he took note of it at the time.

If one bears in mind the brilliant results of Macewen, Horsley, Keen, Weir and others, he thought he would see that cerebral surgery has amply vindicated itself as a justifiable branch of the art of surgery. When we consider the numerous cases of tumor that have been successfully removed, of abscesses evacuated, of epilepsy permanently cured by surgical procedure and in cases which have been clearly indicated from the localizing symptoms alone, then he thought one would say there is likely to be a great future before the cerebral surgery of to-day. He thought, however, we must be cautious, because in our newborn enthusiasm we may be apt to do things our better judgment and larger experience may not consider justifiable. He did not think the dangers of cerebral surgery to be altogether due to septic inflammation. There have been cases which have not been successful. He has seen several of these that have occurred in his own practice. That, however, is not more than is true of any great surgical operation.

He thought that the cases of recovery are distinctly much larger in proportion than those in which evil results have followed. He confessed that in some respects he had been disappointed in regard to some of the cases. He alluded more particularly to those cases which Dr. Mills referred to as being the subjects of Jacksonian epilepsy. In these cases we have reason to believe there has been an irritative lesion directly localized in a definite portion of the brain. Cases of this kind have been operated upon, the discharging lesion has been removed, and certain cases have been permanently cured. Nevertheless, from the fact that some have recovered, he thought it would be well to give the patient at least the benefit of the doubt. In endeavoring to cure our patient we may also inflict a greater evil, and he, himself, shared very largely Mr. Macewen's opinion that to render a patient hemiplegic would be a very questionable cure for unilateral convulsions.

There is still a good deal of work to be done, both in regard to determine the function of the brain and also in determining the accurate diagnosis of cerebral disease. We know now a great deal more than was known a few years ago, but still there are regions which are practically to us a *terra incognita*, and it will require much laborious work before we can say we have gained a thorough knowledge of the functions of the brain. There are a good many differences still prevailing among those who believe thoroughly in the doctrine of localization in regard to the exact limits of the region supposed to be endowed with specific functions. These differences are regarded by the opponents of localization as signs of a

divided household. He did not think so. He regards them as signs of healthy activity. They are only family jars.

As there were several speakers to come after him, who were to address the Congress this evening, and particularly his distinguished colleague, Mr. Horsley, who has done so much for cerebral surgery, he would no longer trespass upon the patience of the audience, but would thank them for their very great reception of this evening, with which they had favored him.

MR. HORSLEY remarked that, in the course of what he had to say, he should have occasion to refer to numerous experiments. These experiments have been performed by himself in conjunction with other observers, and therefore when he referred to them as his own work he wished they should understand that he was simply the spokesman of his colleagues, Prof. Shäfer, Beevor, Gotch, and Dr. Semon. The subject is so enormous, he was at the greatest difficulty to know in what way he could be of any service to the meeting. It occurred to him that he had better take up a distinct line and give in detail, so far as he was aware, the latest points that have occurred in that line. He would, therefore, give some facts and ask them to take on trust the observations on which these facts, in a great measure, rest. He would confine his remarks entirely to that region which Prof. Ferrier was the first to map out, viz., the so-called motor region.

He believed in the so-called motor region they had three functions clearly represented:

1. Slight tactile sensation.
2. The so-called muscular sense.
3. Movement.

He would ask them to remember the yet more fundamental principles which underlie our information on this subject. They must understand that these three functions are wrapped up closely together, and that in each particle of the cortex there are represented all the segments of the body in a varying degree. If they adopt the views of Dr. Hughlings Jackson, of course they all believe that in the corpuscles of the fourth layer is the seat of representation movement. It seemed to him that they cannot refuse to believe that the small corpuscles are similarly the seat of representations of 1 and 2, *i. e.*, sensory representations. The evidence upon which this belief is founded is to be found in experimental evidence and clinical observations. Facts of this kind he has published at length.

Passing from the representation of a tactile and muscular sense, he would say a word or two upon the needs of representation of movement in this so-called motor cortex. It seemed they must consider this very closely if they were to gain an accurate knowledge of the representation of the different segments of the body. Prof. Ferrier was the first to give them a correct map of the representations of the face, arm and leg. Dr. Mills has stated that Prof. Shäfer and himself showed that the trunk was represented on the mesial surface of the hemisphere. Dr. Beevor and he believed it would be perfectly possible by laborious investigation to split up these centres very minutely. The method adopted was as follows: They divided this so-called motor area into squares two millimetres in length, and they excited each square of the cortical surface with a very weak faradic current—in fact, the weakest stimulus that would produce any movement at all.

He would illustrate the general result of the observation, and would take for that purpose the representation of the movement of the thumb. The representation of the thumb is focussed in front of the lower end of the intracranial sulcus, and it extends over a great deal of the upper limb area. This representation gradually diminishes in intensity of representation as we pass from the focus upward. The shoulder and the thumb form the two most important parts of the upper limb. The shoulder is represented in exactly the opposite part of the upper limb area to that of the thumb, and it conversely diminishes in intensity downward. The question of the limitation of the whole area of representation of any given segment is most important.

DR. FERRIER has always held that these areas are limited by hard and fast lines, and that no one area trenches upon another. Unfortunately, he could not follow his honored teacher in this belief. He was perfectly sure these were what may be called border centres, and in one portion of the brain Dr. Ferrier himself drew attention to the fact that in one spot we have representation of the two limbs. The representation of the face at its upper border merges into the representation of the upper limb. So if they have a focal lesion at that spot there are two "signal" symptoms. For diagnostic purposes it is absolutely necessary for us to be aware of the relation of one focus to another.

He would now turn to the question of the representation of the character of movement. Dr. Ferrier, in his monograph published in 1874, pointed out that in certain parts of the so called motor region there were certain movements represented. Dr. Beevor and himself carried this further, and could trace gradation of representation of different movements. He would give two examples. At the upper part of the upper limb region extension of the elbow is represented, whereas, in the lower part of the same region flexion is represented, and between the two there is confusion. This practically holds true of the various segments of the body.

He would give one more example, which gives him special pleasure. It is an example of the representation of extension of the wrist which Dr. Keen referred to in his cases before the Surgical Association. In his diagnosis he had figured the exact spot where, according to Dr. Beevor, extension of the wrist is most represented, that is the anterior border of the upper limb region. This point is specially interesting to them, because they are in a position to show that extension of the wrist must precede every fine movement of the limb. This brings to a conclusion what he had to say of representation of movement. The facts referred to as being observed by Dr. Beevor and himself are in harmony with the facts observed by Prof. Shäfer and himself. There are minute points of difference due to the species of monkey employed. During the past two years they had employed but one species of monkey, viz., macacus sinicus.

He would now speak of cortical epilepsy. Cortical epilepsy consists of several stages of a preliminary aura, then a tonic stage, then a latent period, then the clonic stage, and then, finally, the stage of exhaustion or paralysis. For five years he has been making observations respecting the possibility of finding out which of these kinds of spasms in a muscle are due to the cortex cerebri alone. Here they must look upon the convulsion from two points of view. The connection between the cortex

and the spinal system is, of course, brought about by the pyramidal tract. Now, obviously, if they investigate the convulsed muscles by the ordinary graphic method, they should obtain a tracing, the uprising of which indicated the tonic stage, then a pause and a fall; then little waves to indicate the clonic convulsions which suceeeded the tonic stages. It might be thought the whole of these convulsions was due to the cortex, or the tonic stage to the cortex alone and the clonic to the spinal cord alone. Gotch and he had found it possible to tap the pyramidal in the dorsal region and then to stimulate the cortex and measure with a very delicate electrometer changes in the pyramidal tract. The variations indicate the impulses coming down from the cortex streaming down the pyramidal tract. It is perfectly justifiable to assume that these variations exactly correspond with the nerve impulse. Of course, they know nothing of nerve energy itself except its speed of transmission. Therefore, they investigate its character by means of the concomitant negative variations which attend the passage of nerve impulses. They had thus found that the whole of the character of the convulsion is entirely due to the cortex; with this electrometer it is possible to photograph a record, and the photographed record is given under the graphic record on this diagram. And they can see they correspond in character.

He would now conclude with a few remarks upon the so-called practical part of the subject—he meant cerebral surgery. There are a few points of special character, and to these he would allude. He had nothing to add on the subject of his previous papers.

The bone is marked with a fine drill through the scalp. He would urge the cutting out of a piece of bone by an inch drill. Then quickly, with a circular saw, open a large area by almost cutting through the skull, then with a very careful brim forceps quickly cut away the area marked out. Before, of course, such forceps are applied to the skull it is best to separate the dura mater. The dura being exposed if we perform exploratory operations, it is, he thinks, a terrible thing for the patient if the dura is not opened. He was perfectly aware that the risk was greatly increased if care is not used in the preparation of antiseptics for the operation.

With regard to faradism this is a point upon which the activity of his American colleagues had gone further than in Europe. Many interesting practical points are to be gained from faradism of the cortex if it is exposed.

He now passed on to hemorrhage. He believed the parenchymatous oozing may be stopped by the use of morphia and ergot, as Dr. Keen has suggested. But the ligature must always be applied, if possible. The wound should never be plugged, as it is disastrous to do so. The method of ligation is with catgut, applied by exactly even and gentle traction on the two ends, so as to avoid cutting through or tearing the delicate vessel.

He would refer to a source of regret in this kind of surgery, viz., the death of the patient. He would say that it is exceedingly dangerous to operate upon a patient who is under the influence of drugs and especially the bromide of potassium. They should endeavor, as far as possible, to take the patient from under influences of that sort.

Another regrettable point is the failure of the object for which the operation was undertaken, viz., recurrence of the epilepsy. He believed this was almost invariably due to incomplete operations. Cases in which he had completely removed not only the lesion but also at least one centimetre of the surrounding brain substance remained free from epilepsy. The cases in which the epilepsy recurred he did not remove, to his entire satisfaction, all the damaged brain substance around the lesion.

The prognosis of a case after operation must be guarded. If we operate upon such cases, it must be early. He thought there was some danger of doing too much in certain cases. He believed, on the other hand, that they stood in considerable danger from statistics.

In conclusion, he begged to thank the members for the very kind manner in which they had received him to-night, and also for the generous feeling of hospitality and friendship with which they greeted him on his visit to this country.

DR. KEEN, of Philadelphia, said that we distinguish in the body three cavities, the cavity of the heart, the cavity of the chest, and the cavity common to the abdomen and pelvis. In the chest and the abdomen and pelvis we recognize a large number of separate and distinct viscera with separate and distinct functions. We can investigate the diseases of each viscus and locate them according to the physical signs and the symptoms presented by the history of the case. Until very lately the head was regarded as a cavity containing one viscus acting in its entirety like the liver, spleen, or kidney. If it were affected, we were not able to distinguish one part from the other, but in his opinion we ought to regard the brain cavity precisely as we regard the chest cavity or the abdominal cavity, as a cavity containing a number of viscera, fused physically but separate physiologically.

If we recognize this fact that the head cavity is a cavity containing a number of viscera, and that each viscus has its appropriate function, we shall at once have a much clearer conception of the functions of the head and its viscera, and, therefore, of their diseases and injuries.

He was very glad that a warning note had been sounded to-night, both by Dr. Ferrier and Mr. Horsley, as to over-rashness. We are only just beginning to find out what operative surgery can do in the brain. We are in danger of very greatly overdoing it, while on the other hand we must be equally cautious in the other direction. We must take, in the head cavity, a warning and an encouragement from the history of the surgery of the abdominal cavity. The timidity with which surgeons approached the abdominal cavity, was somewhat remarkable in the early days of abdominal surgery. Their boldness now is almost appalling, and the success equally gratifying. He was very glad to hear Dr. Parks, to-night, advocate exploratory operations. We must do with the head cavity just what we do with the viscera of the abdomen. We must sometimes open the abdominal cavity in a case of intestinal obstruction, in order to make a diagnosis, and we must do so in the case of the head. We have all got to learn the limitations of operative interference from experience, and at present we have to make the experience.

A very good illustration of this was furnished to him recently. A gentleman consulted him with reference to an intense headache in the back of the head, presumably the result of a fall. He called Dr. Mills and Dr. Oliver to examine the case, and they found no localizing symptoms. He declined to operate on the ground that he could find no localizing lesion. The patient afterward

went to Dr. Weir. Dr. Weir trephined him, basing his operation on the point of the focus of the headache, and he cured his patient. He did not suppose Dr. Weir understood anything more about the nature of the trouble than he did, but he did better with his patient. This is a simple illustration of what boldness will sometimes accomplish.

Dr. M. Allen Starr, of New York, said that it was evident, from the statements to which they had listened, that cerebral surgery has a great future, but that it is largely dependent upon neurology. The surgeon is ready to proceed when the neurologist can indicate the way. The responsibility for future progress rests with physicians. It is to be met by the careful observation of cases, their thorough examination, their collection and analysis; for it is by this method that progress has always been made in the past. The examination of cases has not always been complete, and needs careful preparation. This was especially true of the cases assigned him for discussion, viz., disturbances of speech.

In the history of aphasia there have been three epochs. First, that of Broca, when it was established that lesions in the posterior part of the third frontal convolution of the left side in right-handed and of the right side in left-handed persons caused aphasia. Secondly, the epoch of Wernicke, in which a broad distinction was made between motor aphasia, the variety described by Broca, and sensory or amnesic aphasia, the lesion of which Wernicke showed to be in the first temporal convolution. Thirdly, the epoch of Charcot. Charcot says "a word is a complexus; in it one can discover four distinct elements: the auditory memory-picture, by whose means we are able to grasp the sense of words heard; the visual memory-picture, which enables us to comprehend the words written or printed; and also two motor elements—that is to say, the motor memory of articulation and the motor memory of writing: the first developed by the repetition of movements of the tongue and lips necessary to pronounce a word; the second, by the practice of motions of the hand and fingers necessary for writing." These memories, then, joined by anonation, form the mental substratum of language. But since they are distinct, each may be lost, while the others remain.

The loss of visual memories results in word-blindness; the loss of auditory memories, in word-deafness; the loss of motor memories, respectively in agraphia and motor aphasia. Individuals differ widely in the development of various mental powers, some remember things seen better than things heard, faces rather than names; others write down what they wish to remember. In these different persons aphasia presents different features; the student suffering more from word-blindness than the laborer.

Each of these clinical distinctions has a pathological basis. Motor aphasia is due to lesion of Broca's centre, and this is easily accessible to the surgeon in case the disease is open to his interference. The lesion in agraphia is still undecided. The situation of the lesion causing word-deafness is in the first and second temporal convolutions in their posterior two-thirds. (A diagram was shown, on which all the cases of pure sensory aphasia hitherto published were laid down (forty-three in number), and the situation of the lesion was shown.)

Word-blindness was also discussed, and shown to be due to a lesion in the angular gyrus. This symptom is often attended by psychical blindness, in which the patient can see but cannot recognize objects. The lesion in these cases is deep, involving the association fibres beneath the angular gyrus. It may be possible in future to select lesions of other association tracts beneath the cortex if cases are properly tested—such acts as repeating words after one another, copying, writing at dictation, involving the action of these tracts.

Pure aphasia of any of these varieties is rare. The usual form is mixed aphasia, both sensory and motor elements of speech being affected. Here the lesion is in the Sylvian region, and involves both temporal and frontal lobes. Here it is accessible to surgical interference, and the indications are plain. For though we can no longer speak of the speech-centre, we can speak of the centres of motor and sensory and mixed aphasia, and each offers a sufficient guide to the surgeon, as definite as motor spasm or hemianopsia.

Dr. Robert F. Weir, of New York, said that he had been always very handsomely treated by physicians, and he had been very handsomely treated to-night by Dr. Keen.

It had been his good fortune, commencing in 1883, to have practised what is now called brain surgery in ten instances: three times for tumors, three times for cerebral abscesses, twice for hemorrhage into the cerebrum where there was no external hemorrhage, once for epilepsy, and once for cerebral pain.

His last case of brain surgery, which had been made the subject of a paper by Dr. Seguin and himself in the *American Journal of the Medical Sciences*, is exemplified in the brain he would pass around for inspection. This case illustrates a point of some importance. It was so deep that in exposing the brain they were within an ace of not recognizing the tumor. It was only detected after some difficulty, deep in the brain substance. Bergmann has stated that an operation for the removal of a brain tumor should not be undertaken, first, when the tumor is large; and, second, when the patient is in a state of coma. Dr. Keen removed a tumor over four ounces in weight, and recovery took place. Mr. Horsley removed a four and a half ounce tumor from a man in a state of coma. So he thinks facts are at variance with this theory of Bergmann.

In the first case of tumor upon which he operated there was an error of diagnosis. The brain was opened and no tumor found. The bone was replaced, the skin was fastened, as advised by Horsley, and the patient recovered. The headache disappeared altogether, paralysis improved, and the patient lived two months. Another case was reported by Mr. Heath, of London, in which the tumor was attached to the bone at the base of the skull, and was not removed. The headache was relieved, paralysis improved, and epilepsy ceased for a time.

In cases of hemorrhage threatening life his plan is to do the operation as an exploratory one, take away a portion of the skull, and if he finds the blood-clot remove it.

He had gone over the brain a year and a half ago to see how much could be done in the way of surgery, to find out whether the longitudinal sinus and lateral sinus were things we could avoid. He found he could strip them up from the anterior surface of the skull to a goodly length. He had stripped the lateral sinus from its bed

to a distance of about an inch. He had stripped up the dura upon a living subject in ear trouble to a distance of one and a half inches. He had been able to raise up the frontal sinus until the anterior glenoid processes were exposed. He had been able to feel the foramen magnum. He had recently tapped a cerebral abscess on the under surface of the sphenoid bone just anterior to the foramen rotundum and ovale being led to these regions by necrosis. He believed one can reach very many portions of the brain providing our neurological friends give us information thereon.

AMERICAN SURGICAL ASSOCIATION.

Annual Meeting,

Held in Washington, September 18, 19, and 20, 1888.

TUESDAY—MORNING SESSION.

The Association was called to order, at 10 A.M., by THE PRESIDENT, D. HAYES AGNEW, M.D., of Philadelphia.

The first business was the delivery of

THE PRESIDENT'S ADDRESS.

(See page 316.)

DR. JOHN ASHHURST, JR., of Philadelphia, presented

A CONTRIBUTION TO THE STUDY OF EXCISIONS OF THE LARGER JOINTS,

based upon the records of 120 cases in which excision of the larger joints have been required; embracing 10 of shoulder-joint; 19 of elbow-joint; 40 of hip-joint; 51 of knee-joint; and 6 of ankle-joint excisions.

The large majority of the excisions had been performed without any of the so-called "antiseptic precautions," and the wounds had been dressed with simple oiled lint, or with lint saturated with dilute alcohol. For more than a year past, however, he had employed the antiseptic method in almost all his large operations, using also antiseptic dressings in their after-treatment, and with benefit; though as regards the ultimate welfare of the patients he has not noticed any gain. His best series of consecutive successes had been obtained under old methods, and he had not obtained any diminution of mortality by the adoption of the new. At the same time he had seen no ill results which could be attributed to the use of antiseptic measures; their use shortens the period of convalescence, and they have the merit on account of the infrequent change of dressings needed, that they greatly lessen the surgeon's labor.

DR. F. S. DENNIS, of New York, called attention to cases of excision of knee-joint for disease beginning in abscess in the condyle. In these cases the abscess cavity breaks down after recovery, leading to the production of deformity. In these cases he takes away all of the abscess-cavity, saws away a corresponding piece from the tibia, and brings the oblique surfaces together.

He has been in the habit of employing antiseptic dressings, removing the drainage tube on the third day, allowing the first dressing to remain five or six weeks.

In excision for injury, only enough bone to allow of free drainage should be removed.

SIR WILLIAM MACCORMAC, of London, had heard with some surprise that the tendency seemed to be to postpone excision of hip-joint until all other measures had failed. This is not the practice in regard to any other joint. In England the disposition is to perform the operation at an earlier period. Another point that he had not heard mentioned in the paper was in reference to the performance of operation in cases of old dislocation of the joint. He had performed this operation with success in old hip-joint dislocation, and reported the case of a sailor coming under observation three years after the occurrence of dislocation of hip-joint which had not been reduced. After the operation he could use the limb perfectly. He had been much interested in the recommendation of Dr. Ashhurst that a long incision be made to reach the subcrural bursa, a suggestion which he had not heard mentioned by any other surgeon.

DR. E. M. MOORE, of Rochester, had been somewhat surprised to hear a certain amount of indifference expressed toward the use of antiseptic surgery. He had found in his practice the greatest improvement follow the use of antiseptic dressing in these cases of excision. He cited several cases showing the result obtained.

DR. JOHN E. OWENS, of Chicago, agreed to the value of the wire cuirass, and referred to a modification of this apparatus consisting in the substitution of a frame of gas-pipe conforming to the outlines of the body. On this the body is supported by means of flannel stretched between the two sides of the frames. Extension may be applied, if desired, by the use of adhesive plaster, counter-extension being provided for by elevating the foot of the frame. After keeping patients in bed for thirty days, he tries to get them into the open air. He had found great advantage in keeping up a certain amount of extension after the patient was allowed to get up. By removing pain this enables the patient to move the joint more freely, and thus tends to far greater mobility of the part. He thought that there was no comparison between the antiseptic methods and those formerly employed.

DR. FRED. LANGE, of New York, referred to a class of cases in which the disease of the hip began in the tissue outside of the joint, the articulation becoming involved at a later stage of the affection. In these cases he recommended early operation with the hope that in this way necessity for opening the joint would be avoided.

AFTERNOON SESSION.

DR. NICHOLAS SENN, of Milwaukee, read a paper on

THE RELATION OF MICROÖRGANISMS TO INJURIES AND SURGICAL DISEASES.

At the present time no argument is required to show that many special conditions are due to the presence of bacteria. In regard to the so-called hereditary transmission of disease, the author held that the specific microbes of the specific diseases are transmitted directly from parent to child. In evidence of this he referred to cases of so-called hereditary osteomyelitis in newly born infants. In other cases, while this same origin may be inferred, we have as yet no direct evidence that such is the case. In regard to the question whether or not pathogenic microörganisms exist in the healthy body, while the results of some observers point in this direction, the results of others are opposed to the existence of pathogenic organisms in the healthy body. The conclusion was that under certain circumstances pathogenic

organisms might be present. There is proof of this in cases in which, after accidental injury, there is localization of these pathogenic organisms. Acute suppurative infectious osteomyelitis, following slight injury or exposure, was cited as an illustration of this fact. This localization is favored by certain anatomical conditions. The antagonism among microörganisms was being considered when the time of the author expired.

DR. ROSWELL PARK, of Buffalo, had done some work in this direction. He had examined pus from fifty-two sources, and presented a table showing the number of cases in which pyogenic bacteria were found. He had also prepared culture media with various antiseptics in different proportions, includlng carbolic acid, iodoform, iodine, naphthaline, hydro-napthol, resorcin, trichlorphenol, creolin, sulpho-carbolate of sodium, boric acid, perchloride of iron, antipyrin, antifebrin and quinine. Almost the only one of these antiseptic jellies as thus prepared which has prevented all growths was hydro-napthol, 1 : 100. This shows that hydro-napthol can be relied upon as an antiseptic. Many of the bacteria grow freely on iodoform jelly, 1 : 100. Those which grew abundantly on iodoform jelly grow slightly on oxide of zinc jelly 1 : 100. Oxide of zinc was considered a better solid antiseptic than iodoform. The author thought that our present knowledge permitted us to associate certain bacterial forms with definite pathological lesions. In conclusion he presented the report of a case of abscess of the face in which he found the micrococcus tetragens. So far as he knew, this microörganism had never before been found in phlegmon in man.

DR. WM. H. CARMALT, of New Haven, remarked that there was only one point to which he wished to refer, that was in reference to the alleged microbic origin of tumors. A great deal has been said in regard to the microbic origin of cancers and other tumors. He thought that the division of Virchow's class of granulomas into a class of tumors by themselves, known as infectious tumors, is correct. This class includes tubercle, syphilomes, lepra, lupus, actinomycosis, and myelitis. These growths should be taken out of the class of tumors and assigned to a class by themselves. He had been unable to convince himself that tumors proper have a bacteriological origin.

DR. N. SENN, in concluding the discussion, said that the diseases, enumerated in his paper, included only those in which the specific cause had been isolated, cultivated outside of the human body, and in which the injection of this culture produces identical lesions. When these three things are done we have furnished positive proof that the disease is due to specific germs. Another class of diseases had been alluded to in the paper in which there was reason to believe from analogy that the affection was due to specific germs, althongh the three conditions above referred to had not as yet been fulfilled. So far no one had been able to show that the supposed bacillus of syphilis was the specific bacillus. That it is a specific disease connot be doubted; that it is due to a microbe cannot be doubted, but to establish this positively, experimenters must do what Koch did before he announced the specific origin of tuberculosis.

He was firmly convinced from his observations that tumors in the true sense of the word were not due to microbes. He had made tumor implantations for many years in animals, and in justifiable cases in man, both close to the original seat of disease and at remote points, without obtaining the least evidence of the *microbic origin* of disease.

DR. W. W. KEEN, of Philadelphia, then read a paper entitled

THREE CASES OF BRAIN SURGERY.

The first case was one of removal of a large tumor from the brain; the second, trephining for old depressed fracture followed by epilepsy, with removal of underlying brain substance; the third was the removal of the cerebral motor centre for the left wrist and hand, for epilepsy. The three patients were presented, and his paper will be found in full in the October number of *The American Journal of the Medical Sciences*.

AMERICAN GYNECOLOGICAL SOCIETY.

Thirteenth Annual Meeting,
Held in Washington, September 18, 19, and 20, 1888.

SEPTEMBER 18TH.—MORNING SESSION.

THE PRESIDENT, DR. ROBERT BATTEY, of Rome, Ga., called the Society to order.

DR. S. C. BUSEY, of Washington, then made an

ADDRESS OF WELCOME.

He alluded to the courtesy of the Boston Fellows in yielding their claim to the meeting, which had been appointed for their city, thus allowing Washington to entertain the Society at the same time with the other societies of the Congress, of which he felt that this Society should be a part. The object of that Congress was to unite men of high professional standing in the various departments of medicine from all parts of the country. The American Gynecological Society had many eminent members, and the Congress was incomplete without them. The Society had furnished thirteen volumes of transactions in the course of its existence, the character of which testified to the good its members had done, and to their advanced scientific standing.

DR. FORDYCE BARKER moved to reconsider the action which had been taken at the last meeting, and to accept the report of the committee which recommended

JOINING THE CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

This was seconded and carried unanimously.

DR. FORDYCE BARKER was appointed a committee to inform the executive committee of the Congress of this action of the Society.

DR. HOWARD A. KELLY, of Philadelphia, read a paper on

URETERITIS, ITS DIAGNOSIS AND SYMPTOMATOLOGY.

Catheterization of the ureters is a proceeding which is very useful in the diagnosis of disease of the ureters and the pelvis of the kidneys. Ureteritis is probably more common than has usually been supposed. While this method of procedure is of comparatively recent date the disease—ureteritis—was recognized years ago by Rayer and by Cruveilhier. It may be either descending or ascending; perhaps it is more commonly secondary and descending. It may also be ascending, following gonorrhœa and other diseases which affect the bladder. The ureter may also be diseased from the passage of renal

calculi, and as a complication of many forms of disease of the uterus and its surroundings. Hence it is important that the functions and the condition of the ureters should be carefully ascertained in any suspicious case. These and other facts suggest that more careful study of renal and bladder troubles is now in order for scientific gynecologists.

Examination of the ureters may be made by inspection, by palpation, and by catheterization. The first may be practised by splitting the vesico-vaginal septum at the proper level, then turning the opening into the vagina, as suggested by Dr. Thomas Addis Emmet. This may be done by pressure from without, or by pressure through the rectum, as suggested by Dr. Polk. By palpation the course of the ureter is to be followed by delicate touch, compression being exercised both through the abdominal wall and the vagina. If the ureter is dilated, its course may not infrequently be traced by this means. The method of catheterization is, however, the most practical, and the method of Pawlik, that of free-hand catheterization, is believed to be the most applicable. To perform this operation the patient is placed in the dorsal position, the perineum is retracted with Simon's speculum, and Pawlik's fine silver catheter is introduced into the bladder, the base being searched by it until the depression at the mouth of the ureter is felt, when the catheter will slip in, guided by the eye and the finger. Once in the orifice it may be pushed along as high as the level of the crest of the ilium, beyond which it is not safe to go.

In three cases of supposed bladder trouble he found that it was the diseased ends of the ureters which were causing trouble, the trouble disappearing when these were cured. Other cases were also narrated to prove the value of this method of procedure. The literature of this subject is not extensive and includes, in addition to the papers of Pawlik and Simon, the theses of Bonnet and Chaumont, and the recent paper of Silbermann.

DR. POLK found the subject one of great interest, and had given much time to its consideration, both upon the living and the dead subject. The method of examining the ureters which was most commonly referred to was Pawlik's. He had made many trials of it, but usually without much success. He had found more satisfaction in making a buttonhole fistula at the base of the bladder as recommended by Dr. T. A. Emmet, and then by suitable pressure the ends of the ureters could be made accessible. In palpating for the ureter it is to be remembered that it is between the line of the uterus and the brim of the pelvis. For a catheter he preferred one of broad curve like a prostatic catheter, and after this had been entered another instrument should be passed into the rectum, with which the onward course of this instrument in the ureter could be traced.

DR. H. D. BYFORD, of Chicago, had practised palpation of the ureters in one hundred cases, desiring to find a simple method of determining its course. If the uterus is taken as a centre and the finger in the vagina be made to radiate from it along the pelvic roof, a line would at length be reached where a gentle resistance of a cord-like body would indicate the presence of the ureter. This line having been determined, it would not be difficult after a little practice to find the mouth of the ureter and introduce a catheter, the catheter being guided by the finger in the vagina.

DR. W. H. BAKER, of Boston, thought that very few obtained sufficient skill to catheterize the ureters. He believed the method was of value, however, in enabling one to give a diagnosis as to the extent of diseases of the bladder, etc. It must not be forgotten, in all these manipulations, that there might be displacement of the ureter as had occurred in his experience.

DR. H. C. COE, of New York, found in three autopsies that pressure was exercised upon the ureters two inches from their endings by cicatricial nodules which were associated with uterine disease. This condition might have caused dilatation of the ureters which would have admitted of their determination by palpation.

DR. BACHE EMMET had found that as good results as by any method could be obtained as to determining the position of the ends of the ureters, by making a fistula in the base of the bladder then pressing in the median line of the abdomen, then varying the pressure to one and then the other side. He believed that ureteral trouble complicated various uterine troubles, and that a diagnosis of pelvic disease could hardly be considered complete until the condition of the ureters was known. He did not believe that disease of the ureters was a very common complication of bladder disease.

DR. KELLY, in closing, detailed the experiments of Tuchmann, Silbermann, and others in catheterization, and showed the value of the operation. He thought disease of the ureters could not be called uncommon, that it might be due to inflammatory deposits, displacements, etc., and that examination of these organs was eminently simple and practical.

DR. THOMAS ADDIS EMMET, of New York (by Dr. Duncan Emmet), read a paper entitled

CAUSE AND TREATMENT OF URETHROCELE.

This condition is generally considered as due to a loss of support in consequence of laceration of the perineum, but it is never found after first labors unless the rupture has extended through the sphincter ani. It always exists after serious double laceration of the cervix in consequence of severe labor, which may have been either rapid or tedious. The former is the more common cause, the latter sometimes acts as a cause when ergot has been given or when the labor has been instrumental. The trouble is usually in the lower or vaginal part of the urethra. In some cases the accident is doubtless prevented when a few ounces of urine are in the bladder during the expulsion of the head, the urine acting as a cushion and only being discharged as the space is required. This is contrary to the long accepted dictum that the bladder must be empty when the head is delivered. The laceration may be transverse or longitudinal, and a few fibres or many may be ruptured. There is seldom a rupture through the vaginal mucous membrane. Urethrocele must be differentiated from the thickened condition of the urethra in which there is no rupture. In urethrocele the length of the urethra is diminished, a pouch being formed in which the urine collects. Serious reflex symptoms may be excited by such a condition as is shown in a very aggravated case narrated in the paper. He repeated his opinion expressed in his paper before the Society in 1882, as to the value of the buttonhole fistula operation, which is the means by which urethrocele also may be effectually treated.

Dr. Priestly, of London, referred to a paper written by him in 1869, in which he referred to sebaceous cysts of the urethra which he thought formed a condition somewhat analogous to that referred to by Dr. Emmet in his paper. He thought such conditions as Dr. Emmet treated of might be due to other causes than labor; for example, a sebaceous cyst of the urethra which he had seen had arisen entirely independently of labor.

Dr. Skene, of Brooklyn, thought that cystocele and urethrocele were very apt to be confounded. In his experience it was not the lower portion of the urethra which was apt to be involved as the result of severe labor. Complete dislocation of the urethra, the latter being torn from its attachments at the pubic arch, was a more common accident of labor than the sacculated condition to which Dr. Emmet referred, and he believed the longitudinal or transverse ruptures of the fibres of the urethra to be relatively rare. The buttonhole operation would be of no use in cases of dislocated urethra, but for the sacculated condition it would apply. Bozeman had described the dilated condition of the urethra following labor ten or fifteen years ago, and had suggested the opening of the urethra as a means of relief.

Dr. Lusk, of New York, had found Emmet's operation very efficient in a very troublesome case which had long been under his observation, and had, finally, been cured by Dr. Emmet. Since then he had performed the operation in several cases with great satisfaction.

Dr. Kelly referred to a case of urethrocele which had been reported by Dr. Skene Keith, and upon which he had performed Emmet's operation with marked success. Urethrocele should be differentiated from false urethrocele or pouting of the urethra, which was often caused by straining in urination.

Dr. Sutton, of Pittsburg, read a paper on

THE TREATMENT OF PELVIC ABSCESSES.

He referred to those abscesses which often resulted from pelvic cellulitis, though this condition did not usually terminate in abscess. There are septic and aseptic forms of this condition; in other words, there is one class of cases in which the septic element is well marked, and another in which it is not well marked. Sepsis may be due to dirty instruments, dirty fingers, etc., during labor, or from inoculation by the lochial discharge. Septic material may also be introduced in other ways and set up inflammation in the cellular tissue, the lymph vessels or the veins. Peritonitis may also accompany such conditions. Abscess may also occur in virgins and in those who have passed the menopause, without any appreciable septic origin. Such cases are commonly called idiopathic; they may arise from exposure to cold, sudden stoppage of the menses, etc. The treatment for such cases is usually hot douches, opium and poultices. He believed that a blister was better than poulticing, or an ice-bag might be applied to the abdomen. If there were tympanites, he prescribed an enema of hot soapsuds, or a dose of sulphate of magnesia. Of the febrifuges he preferred quinine, though he had had no experience with mercury, the salicylates, etc., for this condition. In spite of all care septic symptoms would sometimes appear, and bye and bye there would be fluctuation in the rectum, the vagina, or the iliac region. To evacuate the pus he used a knife, a trocar, or the actual cautery, irrigated the cavity, and then introduced a drainage tube. Accompanying conditions were usually hard masses in the pelvis, fixation of the uterus, and the pressure of pus in the vagina, rectum, or bladder. The most favorable location for evacuating the pus was the vagina. Pus in the Fallopian tubes was best treated by laparotomy, the same being true of large abscesses elsewhere in the pelvis. If a sinus opened upon the skin counter-openings should be made in the vagina, and drainage effected by this avenue if possible. The entrance to the sinus should be dilated, and the sinus curetted and irrigated. If the opening were in the rectum it should be dilated and the cavity washed out with bichloride solution 1 : 1000, the rectum having first been irrigated. The general health of patients with such conditions often rendered the prognosis bad. Bitter tonics, alcohol and malt liquors should be given, and the patient should be fed as freely as circumstances will admit. The cases not infrequently end in tuberculosis and death.

Dr. Goodell, of Philadelphia, had never seen pelvic abscesses arise from gonorrhœal poisoning, though often from septic influence of other character. It was not rough treatment during operations which led to these abscesses, but uncleanliness. Such abscesses in virgins are associated with the catamenial period, and are aseptic. He preferred to open such abscesses with a blunt instrument, such as a pair of scissors, dilating and then draining. If the opening be in the rectum, it is better to insert a probe in the direction of the vagina and then make a vaginal opening. If the rectal opening is enlarged, there is danger that feces and poisonous gases may enter the sinus, and then poisoning will result. If the abscess can be felt *per vaginam*, an opening should be made in the vagina and a drainage-tube inserted, but some abscesses never become large enough for such treatment. If laparotomy be performed, and the conditions are such that the wound cannot be well drained, it is better to make another opening into the vagina and drain in that direction. For irrigating sinuses in the rectum, he preferred permanganate of potassium to the bichloride. A vaginal opening is always to be preferred for drainage, if it can be secured.

Dr. William H. Parish, of Philadelphia, thought that abscesses in the pelvic areolar tissue after labor were almost always septic, and should not be operated upon early. An aspirator should never be used for such abscesses, except for purposes of exploration, and he seldom used them for any purpose. If the abscess pointed low in the vagina, a superficial incision should first be made, then a grooved director should be thrust in, and the incision enlarged by cutting upon this. It is not safe to wait until the abscess becomes a tumor sufficiently large to be apparent in the abdomen. In some cases he had succeeded in following the track of the abscess with his fingers, enlarging and breaking down the cavity as he proceeded, then draining, without opening the vagina at all.

Dr. T. Gaillard Thomas, of New York, differed with the reader in respect to treatment. He recognized three varieties of abscess: one described by Bennett as an inflammation of the tissue between the layers of the broad ligament, a second occurring in the tissue posterior to the uterus, and a third in the tissue anterior to the uterus, between the uterus and the bladder. Yet another form was that which was associated with pyosalpinx, and may frequently be reached by a vaginal incision, thus avoiding

laparotomy, which must always involve the greater danger. The sooner these abscesses are opened the better for the patient. Without being too definite, it is safe to say that a phlegmon which has existed for a month should be explored. It is not safe to wait for fluctuation, for that may never appear. There is a decided difference in the rapidity of development of abscesses which are associated with parturition and those which arise from other causes; the former develop rapidly, the latter slowly. It is not wise to wait for the appearance of constitutional symptoms before operative treatment is begun. He believed there are only two passages by which pus should be evacuated from the pelvis—the vagina and the abdomen. One should never open into the rectum or bladder. His method of operating upon the different forms of abscess was then described. If the abscess points at the abdomen, a long incision should be made along Poupart's ligament, which should be irrigated and drained, but the vaginal opening should always be preferred if possible.

DR. T. GILL WYLIE, of New York, thought that the theory of cellulitis as a cause of abscess had been greatly overrated. Excluding acute abscesses arising soon after labor, he believed that almost all pelvic abscesses originated in salpingitis and ovaritis. He believed that too much stress was laid on treating such abscesses by the vagina, and too little by laparotomy. The disease was not usually treated radically until the abdomen had been opened and the tubes, which were the centre of the disease, removed. Should the abscess point in the vagina it may be opened there, but, frequently, one gains a clearer knowledge of the case and is able to treat it more intelligently if the abdomen also is opened, and the condition thoroughly investigated.

DR. POLK, of New York, found in 100 cases of pelvic abscess that had been attributed to cellulitis that such was not the cause, but that the cause was salpingitis, hence he had abandoned the common theory and gone back to that of Bernutz, which regarded tubal disease as the most frequent cause. With regard to the influence of septicæmia in such cases, the same principles obtain with respect to the uterus which hold in respect to other parts of the body. In those cases in which the abscess can be treated outside of the peritoneal cavity, laparotomy is not indicated, in all other cases laparotomy is urgent, that the condition may be radically disposed of and pyogenic membrane removed. In all the cases which the speaker had investigated since his change of belief he had found pyosalpinx, and for such a condition laparotomy is the only proper treatment. Should the abscess point in the vagina there is no objection to opening it there and draining.

DR. H. D. BYFORD, of Chicago, objected to the teaching that pelvic abscesses always resulted from pyosalpinx. He had not found that such abscesses point at the skin or in the vagina alone, nor even in the majority of cases. His plan was to open them by the most direct route, whether that might be into the bladder, or the rectum or elsewhere. The greater number of his cases had opened into the rectum, and most of the patients got well. They presented symptoms of diarrhœa, and examination would show pus in the discharges. He thought that there more recoveries from cases which opened into the rectum than from those which opened into the vagina.

DR. HOWARD A. KELLY had found that good results followed opening of pelvic abscesses with Paquelin's cautery. He had also used the method described by Dr. Goodell, the cavity being opened with blunt scissors, and the opening enlarged as the scissors were withdrawn. He did not consider it necessary to enucleate the walls of an abscess, as suggested by Dr. Polk, if only antiseptic measures were used to encourage the closure of the cavity.

DR. JOHNSTON, of Danville, believed that a better understanding of this subject would be obtained if the condition were compared with croupous pneumonia, with which it presented strong analogy. He had found no cases in which chronic cellulitis *per se* existed in the pelvic cellular tissue. Such an inflammation should follow the same law which it observed in the cellular tissue elsewhere, which was to undergo resolution after a longer or briefer period of time. He believed that the trouble in pelvic abscesses was primarily in epithelial structures, the natural development of which had been interfered with. The *rete mucosum* was the part which was involved—that is, the inflammation was primarily in the ovaries or the tubes.

DR. BALDWIN believed that pelvic abscesses were always due to inflammation of the tubes and ovaries, and that the only correct way to treat them was by laparotomy. By so doing, we could get directly at the diseased structures, and were not treating them in the dark. Even if the abscess can be conveniently reached by the vagina the period necessary for a cure is a long one, a mass of hardened tissue being left, which is long in disappearing. Removing the diseased structures by the abdomen a radical cure would be quickly effected.

DR. REAMY, of Cincinnati, admitted that the origin of the disease might often be in the tubes, but was unwilling to concede that it should never be treated per vaginam. Besides, it must be remembered that it was not always desirable to take away the possibility of offspring if the disease could be cured without unsexing the patent. He was positive that cases could be cured by vaginal incision and be able to bear children subsequently, as was proven by an interesting case which was narrated.

DR. SUTTON, in closing, recapitulated the various means by which infection might take place, and concluded that the old views, which assumed that pelvic abscess was caused by cellulitis, were passing away.

CORRESPONDENCE.

THE CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

(*From our Special Correspondent.*)

I WRITE to you in the midst of work now going on in the various societies constituting the first meeting of the Congress of American Physicians and Surgeons; which societies, by the way, some will persist in calling "Sections," recollecting, perhaps, the constitution of somewhat similar bodies in the past, and finding it difficult to realize the distinctive features of this Congress. As I desire you to have an early report for your next issue, of course I cannot embrace all the salient features of the Congress.

Rain, rain, outpouring and persistent in the beginning of the week, promised ill for the comfort of those who

came to Washington to attend the Congress, and even on the night preceding its opening, when so many assembled around the banquet table to welcome the foreign guests, the bad weather still persisted. But Tuesday opened bright and clear, and now, with the thermometer at 80°, and with pleasant air stirring, the atmosphere is quite bearable for those who do not make undue exertion. The breezes come from those flats which Dr. Busey says in his address of welcome, have for forty years furnished him with life-giving air, with every southern wind, and have not furnished him with the malaria of the correspondent or casual visitor—whose excesses, under another name, unlike the rose, would be better identified.

The Committee of Arrangements selected an admirable location for the Congress, and for a number of the societies, in the building erected by the Grand Army of the Republic; high, well ventilated, and with capacious rooms well adapted for the purpose in their acoustic properties. It is directly opposite to Willard's hotel—the place for registration and headquarters. It is, moreover, in full view of, and a short distance from, the celebrated Potomac marshes, and the Government improvement of the same, but the American Climatological Society—being located on one of the lower floors—unfortunately did not get the full benefit of their surroundings.

As these various meetings recur year after year, in the heat of the summer and early fall months, one cannot help asking the old question, why medical men will make themselves so uncomfortable at these seasons, to come back from cool summer resorts, with their early hours, simple diet, and light clothes, to the hot, dusty streets and hotels of a city, put on dress-suits, eat and drink what does not agree with them at the best of times, and keep late hours, scarcely seems in accordance with the canons of hygiene. New York, or even Boston, is not attractive at this season, much less Washington; while in a few weeks from now all of these cities will be at their best. Perhaps there is, however, some retributive justice in it; the school children who have had to come home from the seashore and country, to drone over their tasks in the hot school-room, have wondered why their family physician does not exercise his authority and come to their aid; perhaps they take some pleasure in seeing how the doctors like it themselves.

The banquet was really the affair which opened the Congress, although it was intended to be unofficial in its character, so far as it was possible under the circumstances. It preceded the Congress, and was a spontaneous welcome to the foreign guests by those who wished to participate, and to meet each other socially. It was served in the large dining-room of Willard's hotel.

At one end of and across the hall was a table at which were seated Dr. S. C. Busey, Chairman of the Committee of Arrangements, and at his right and left, respectively, Prof. von Esmarch, Sir Spencer Wells, Dr. William Pepper, Dr. John S. Billings, Sir William MacCormac, Dr. William H. Draper, Surgeon-General Moore, U. S. A., Surgeon-General Browne, U. S. N., Dr. D. Hayes Agnew, Prof. Annandale, Prof. MacCullum. At either end of this table were long tables extending down the length of the dining room at which the remainder of those present were seated; they were all medical men and honored the occasion by their presence, but there were far too many to name in a letter like this. Prof. Ferrier, Dr. Ord, Mr. Horsley, Mr. Durham and Dr. Pye Smith were among the foreign guests interspersed at the tables with their American colleagues. The menu was very prettily engraved in the usual form, and embraced the usual variety and mixture of English and French terms, which have become so familiar to us from long usage. A band of music played at intervals during the evening.

There were but very few toasts, some six or eight short speeches being made. Prof. von Esmarch gave a very pleasant address partly in English and partly in German, and Sir Spencer Wells and Mr. Ord made some very acceptable remarks. The others were mostly by our American physicians in response to calls. All who participated spoke of the occasion as a very enjoyable one, and when the formality was over and cigars were lighted, neighbors found very agreeable company in each other.

On Tuesday work began in earnest. The various Societies appeared to be well attended, by the members, there were few outsiders present, and each Society accordingly was more or less represented in the degree of the size of its roll of membership. The Surgical Society was quite full, the Society of Physicians was well filled, while, on the other hand, the Physiological Society had a scant attendance; that, however, may be accounted for in more ways than one, it was its first annual meeting, and it held its sessions in the Army Medical Museum, away from the city centres occupied by the other Societies. A great deal of honest, earnest, and satisfactory work was done in the Societies, which will, of course, be reported in due time, and through the proper channels.

The Congress organized as a body by Dr. Pepper calling it to order, in which, among other things, he stated that the idea of a conjoint meeting had taken definite shape before any preparations had been made for the meeting in this country of the International Medical Congress, but had been deferred so as not to interfere with that meeting. He expressed himself as being, with a large proportion of the members, warmly attached to the American Medical Association, and determined to exert influence to maintain and promote its success, and thought the plan of organization of the present Congress did not interfere in the least with that Association. At the close of his address he introduced Dr. Billings as the President. Dr. Billings did not make any formal address, as on Thursday night he closes the Congress by his address, but, after a few words introduced Dr. Busey who, as the Chairman of the Committee of Arrangements, welcomed the members. Dr. Busey's address was very well received and his labors were evidently highly appreciated, as they certainly deserve to be, his task having been a very onerous one. Rules for organization were submitted and accepted, one important rule being that the Congress meet triennially in Washington.

Tuesday evening the subject of "Intestinal Obstruction in its Medical and Surgical Relations" was before the Congress, and papers were read by Dr. Reginald H. Fitz, of Boston, and Dr. Nicholas Senn, of Milwaukee, and it was intended that Dr. William Pepper, Dr. J. Collins Warren and Dr. Thomas G. Morton, with others, should take part in the discussion, but the papers read took up so much time that, at their close, Dr. Pepper, when called upon, very happily expressed the desire of hearing some of the foreign medical men present upon

the subject, and he was gracefully seconded by the President who called up in turn Dr. Durham, Dr. Ord, and Mr. Annandale. Dr. Warren having also followed Dr. Pepper in yielding the floor.

This proved to be a very enjoyable part of the discussion. Dr. Fitz's paper was carefully prepared and well received, and Dr. Senn illustrated his paper with valuable pathological specimens, and was very eloquent upon the subject of the ileo-cæcal valve, etc.; but the foreign guests, with their earnest and off-hand treatment of the subject, added very much to the interest shown. They were all men who have paid special attention to the subject. Dr. Durham especially, having, as he stated, furnished Quain with his article on the subject for his Dictionary. Dr. Durham made quite an address and was very forcible in his remarks; and while he complimented highly the American profession, and expressed his great pleasure at his reception here, like a true Britisher, he did not hesitate to contradict forcibly some views that had been previously expressed. Dr. Durham is tall and spare, with a clear-cut, pleasant face, and has the appearance of being an earnest and hard worker.

Dr. Ord, who succeeded him, was a smaller man, rather inclined to be stout, smooth face, muddy complexion, and a fair type of the Englishman, with a very genial, comfortable manner and expression. His remarks were easy and to the point. Dr. Ord is a prominent London practitioner and is connected with St. Thomas's Hospital.

Mr. Annandale, who was the last speaker, made but a few remarks, having only just arrived in Washington, his steamer having been delayed by its encounter with the recent cyclone.

At the close of the Congress the members passed across to Willard's, where a very satisfactory collation was ready for them, and the remainder of the evening passed in eating a little and smoking and talking a great deal. Everybody was in a good humor and glad to see each other, and matters were freely discussed. One pleasant feature of the evening was the presence of so many of the local profession and their evident intention to enjoy themselves and help make the occasion a pleasant one for the visitor.

Professor von Esmarch is, of course, one of the most distinguished of the foreign visitors, and is of interest also to the general public as being the husband of Princess Henrietta, of Schleswig-Holstein, who is also aunt to the present Empress of Germany. He is of medium height, with a full, gray beard parted in the middle, and has something of a military bearing. His manner is very pleasant and cordial.

The discussion of Wednesday evening on Cerebral Localization in its Practical Relations was looked forward to with a great deal of interest, especially as Dr. David Ferrier and Mr. Victor Horsley were to take part.

This evening a reception will be held at the Army Medical Museum, and it promises to be very enjoyable. The hall of the library is being draped in a very artistic manner.

Before closing, I must mention one feature which is very striking—not a drug vender, instrument dealer, book or medical journal agent, is to be seen about the Congress, registrating rooms, or any of the Societies, nor are there any circulars of the same distributed.

WASHINGTON, THURSDAY, SEPTEMBER 19TH.

NEW INVENTIONS.

A NEW FORM OF GALVANO-CAUTERY SNARE, ETC., FOR NASAL, THROAT, AND EYE-WORK.

BY JOSEPH A. WHITE, A.M., M.D.,
SENIOR SURGEON OF THE RICHMOND (VA.) EYE, EAR, THROAT, AND NOSE INFIRMARY.

IN the treatment of throat and nose affections the galvano-cautery is of such general utility that any improvement in the apparatus used for its application must necessarily be of interest to all who are engaged in this work. Most of the handles I have seen are too heavy to admit of rapid and skilful manipulation; and in using the snare and wheel attachment, for removal of polyps, growths, etc., in the nose and post-nasal space, I have found it clumsy and cumbersome, usually requiring *both hands*, if we wish to regulate the electric current and tighten the loop at the same time. To obviate these difficulties I have had a new form of handle, with snare attachment, made for me by Mr. Otto Flemming, the well-known electrician, of No. 1009 Arch Street, Philadelphia, which, after nine months' daily use, I can safely present to the profession as superior to any other I know of. This handle, with canula and snare attached, is represented in the accompanying cut.

The length of the handle (A) is 14 centimetres, its breadth 1 centimetre, its width 6 millimetres and its weight less than one ounce. Set into the handle along its whole length is a small ratchet on which runs the slide (C), to which are attached the ends of the platina loop passing through the canula (D). The slide (C) which catches on the ratchet, as it is pulled down, can be instantly released by pressing a spring at its lower part and the loop thereby loosened, if necessary. At the upper end of the hand there is a movable joint, into which the canula and electrodes are fastened, which can be fixed at any angle by the fixation screw (E).

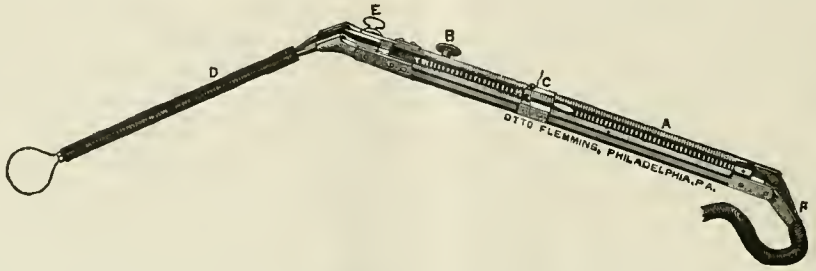
The conducting cords are fastened together by a spring (F), which can be attached or detached from the handle instantly, thus doing away with the two fixation screws, usually used for this purpose. At B is a spring and button, for current breaker.

The advantages of this handle and snare are apparent. It is so light and delicate, it is more easily manipulated, and with the slide and ratchet the snare can be more rapidly applied to growth. The movable joint at the top, by which the snare and electrodes can be regulated at any desired angle, is, in many cases, a decided advantage, and the doing away with the binding screws, at the bottom, an economy of time.

In post-nasal work this instrument is of great value, because it can be used with one hand, whilst the other holds the mirror in the throat, the thumb manipulating the slide (C) carrying the snare, and the forefinger regulating the current, by the button (B), then turning it off and on, as may be needed, whilst watching the operation in the mirror. With my *Post-nasal Speculum* (Self-retaining Palate-retractor) in position, the mirror in the left hand, and the handle in the right, every step of a post-nasal operation can be seen as easily as the removal of a growth from the skin.

I not only use it as a galvano-cautery snare, but also as a *cold* snare. Since I have had it I have almost en-

tirely discarded the Jarvis's and similar snares for infranasal operations. It is as light and delicate, as easily applied and the *cold* snare can, in a moment, be converted into a *hot* one, if desired. For removal of nasal polyps it is superior to any instrument I have ever used. If it captures the polyp about the *body*, gentle traction will usually break the pedicle, and then it can be cauterized; if about the *neck* the current can be turned on and



the polyp removed and root cauterized at the same time. For lower turbinated hypertrophies, it is superior to Jarvis's snare, as no transfixion with needles is ever necessary. If it does not grasp them as a *cold* snare and slips off, if the loop is pressed down about the hypertrophy, and the current turned on, a groove is made by the *hot* snare, and the loop firmly fixed by running the slide on the ratchet. The operation can then be completed with cold or hot snare as preferred. I have used it to remove turbinated hypertrophies, nasal polyps, growths from the septum and post-nasal space, including two fibroids from the vault of the pharynx. I have also removed adenoid tissue by its help, when the third tonsil was sufficiently large.

I also have a snare attachment for laryngeal work and I have successfully removed papillomata with its help. Every kind of electrode used in throat and nasal work, for linear cauterization, destruction of granulations, cauterizing ulcers, etc., can be attached to the same handle. I have half a dozen or more kinds. Moreover, I have had made for it several tiny points for *eye-work*, such as cauterizing ulcers of the cornea, destroying granulations of the conjunctiva, grooving the tarsal cartilage in entropion, etc. In this application the handle is held as a penholder and almost as easily manipulated.

410 EAST GRACE STREET, RICHMOND, VA.

NEWS ITEMS.

Transmission of Syphilis.—The Paris law courts have just decided a case in which the parents of a child suffering from hereditary syphilis, which communicated the disease to its nurse, have been condemned to pay £80 damages to the woman. Each of them has also had to pay a fine of £4. The decision was grounded on the clauses of the Code providing for the punishment for wounds or other injuries inflicted through carelessness. It appears that the parents were aware of their child's condition.—*British Medical Journal*, September 1, 1888.

Saccharin not a Food.—The Consulting Committee of Public Hygiene, in France, has officially approved the report of MM. BROUARDEL, POUCHET, and OGIER, relating to the use of saccharin. These gentlemen conclude that saccharin is not a food and cannot replace sugar. Its use retards the digestion of starchy and albuminous substances. It is extremely liable to augment intestinal troubles, and even cause those troubles which it was originally intended to cure. Its use is, of course, too recent to formulate decided views; but it seems to be settled that its effects on the digestive organs are harmful. —*L'Union Médicale*, August, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM SEPTEMBER 11 TO SEPTEMBER 17, 1888.

PAGE, CHARLES, *Colonel and Assistant Surgeon-General, Medical Director of the Department*, will proceed to Forts Riley and Hays, Kansas; Post near Denver, and Forts Crawford, Lewis and Lyon, Colorado, and return, on public business. The travel enjoined is necessary for the public service.—*S. O. 114, Headquarters, Department of the Missouri, Fort Leavenworth, Kansas*, September 7, 1888.

NORRIS, BASIL, *Lieutenant-Colonel and Medical Director*, will proceed to Fort Klamath, inspect the Medical Department at that post, and, upon completion thereof, return to these Headquarters. —*S. O. 103, Headquarters, Department of the Columbia, Vancouver Barracks, Washington Territory*, September 3, 1888.

CALDWELL, DANIEL G., *Major and Surgeon.*—Is granted two months' leave of absence, from September 14, 1888.—*S. O. 210, A. G. O.*, September 10, 1888.

AINSWORTH, FREDERICK C., *Captain and Assistant Surgeon.* —Will, by direction of the Secretary of War, proceed to Kennebec Arsenal, Augusta, Maine, on public business connected with the Medical Department of the Army; on completion thereof, will return to his station in this city.—*S. O. 211, A. G. O., Washington, D. C.*, September 11, 1888.

BANISTER, JOHN M., *Captain and Assistant Surgeon* (U. S. Army).—Is granted two months' leave of absence, with permission to apply for an extension of one month, to take effect when his services can be spared.—*S. O. 211, A. G. O.*, September 10, 1888.

By direction of the Acting Secretary of War, NORTON STRONG, *Captain and Assistant Surgeon*, will report in person, at 11 o'clock A. M., October 18, 1888, to Brigadier-General John R. Brooke, President of the Retiring Board in session at Omaha, Nebraska, to give testimony in a case pending before the Board. Upon completion of this duty, he will return to his proper station.—Par. 9, *S. O. 212, A. G. O.*, September 12, 1888.

JARVIS, NATHAN S., *First Lieutenant and Assistant Surgeon.* —Is granted one month's extension of leave of absence, on surgeon's certificate of disability.—*S. O. 210, A. G. O.*, September 10, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING SEPTEMBER 15, 1888.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LIII. SATURDAY, SEPTEMBER 29, 1888. NO. 13.

AMERICAN CLIMATOLOGICAL ASSOCIATION.

THE PRESIDENT'S ADDRESS.

Delivered September 18, 1888.

THE CLIMATE AND ENVIRONMENT BEST SUITED TO OLD AGE IN HEALTH AND DISEASE.

BY A. L. LOOMIS, M.D.,

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE IN THE UNIVERSITY OF THE CITY OF NEW YORK.

AGAIN the pleasant duty devolves upon me of welcoming you to an Annual Meeting of the American Climatological Association. Our fifth anniversary finds us a strong, well-organized, working body. Our records for the past four years show much good work done, and the programme for our present meeting is a guarantee for the future.

Three years ago, under similar circumstances, it was my privilege to say that this Association was organized that representative medical men from different sections might come together and, from their combined views and experiences, endeavor to determine the therapeutic value of the various localities which were claimed to have the power of arresting or curing chronic diseases of the respiratory and vascular organs; and I then expressed the hope that in the near future it would be a place where good workers could meet on a common ground with no medical politics or ethics (except such as one scientific worker is always willing to accord to his fellows), and there discuss in a scientific spirit those questions in etiology and therapeutics which are now engaging so largely the mind of the profession.

My hopes and prophecies have been more than realized, for our Association has not only made a scientific record for itself, but it has stimulated the profession in this country to harmonious work in the important field which we occupy, and has given such a prominence to climatology and hydrology in this country that our springs and health resorts are being placed on a more intelligent and scientific basis, so that English and French physicians are already sending their phthisical and rheumatic patients to those American resorts which have received the sanction of this Association.

The fact that the subjects for investigation and experimentation, as well as the clinical studies which come within the scope of our labors, are becoming more and more important each year, and in all parts of the world are engaging the attention of some of our best medical workers, should stimulate this Association to a still higher standard of work.

With these few words of congratulation as an introduction to that which is before us, I will invite your attention to some thoughts connected with the climatology of age.

In studying the therapeutics of climate, and its effects upon diseased processes, one soon realizes that *age* is a factor which enters very largely into the climatic problems which we are endeavoring to solve—much has been written on the climates best suited to the management of different diseases, but the literature of *the climate and environment best suited to old age in health and disease* is meagre and conflicting. I have thought that it might not be without interest, if I should at this time give you some of the results of my experience and observations on this subject.

The life of man is naturally divided into four periods—infancy, youth, manhood, and old age; each period has its mental and physical characteristics, each its diseases, and each its therapeutics. There are conditions of environment and climate which not only are especially adapted to the development and vigor of each, but which influence largely the immunity from those diseases liable to occur at these different periods, often arresting or curing them after their development.

Most men begin to show signs of decay between fifty and fifty-five, while the favored few retain the vigor of manhood at seventy. Original conformations, heredity, habits of life, climate, anxieties, and temperament, unquestionably influence very greatly the commencing period of old age. Some men are old at forty, while others are young at seventy.

There are certain physiological and anatomical characteristics of old age, which especially interest us in the study of those conditions which are best suited to the fuller development and prolongation of life. The more prominent of these are: defective secretions and excretions, imperfect metabolism, feeble respiration, which interfere with complete oxidation, the excretory organs being more or less weakened withdraw from the body less perfectly the results of tissue metamorphosed. The nutritive functions, digestion and assimilation, are imperfectly performed. The arterial changes give a feebleness to cell nutrition which shows itself in the visible signs of advancing age. "The bones, the cartilages, the membranes, the flesh, the skin, and every fibre of the body becomes more solid and dry." But long after the decay of corporeal vigor, the understanding and the higher powers of the mind preserve their energy and precision.

It has been said that no sooner does man arrive at his full maturity than he begins to decline. This may be true of his animal life, but not of his intellectual. It does not seem consistent with the design of the Creator that all growth in man should cease with the attainment of his maturity. It is evident that his intellectual powers do not attain their highest development with the completion of his body growth; for we often find that those qualities by which "he rules the world, as reason and judgment," are most active after his body decline has begun. Some of the most brilliant and powerful productions in literature, science, and art have been the work of old age. Disraeli claims that the age of three score and ten is a most powerful one for writing.

There have been many striking examples, which prove how often the mind resists the body decay, and that the age of the physical organism does not necessarily enfeeble the mental powers. We can but believe that an intelligent care of the body, after it has reached its period of maturity with healthful exercise of the mental faculties, would make old age, not a period of decline, but a period of mental power and vigor. One has said "that among men of genius there is no old age." I would, therefore, make as strong requisites in the conditions which shall prolong and render healthful old age, a climate and environment which shall favor and tend to stimulate the mental activities.

To one studying the physiology of old age, it becomes apparent that the gradual and progressive impairment of the functions of organic life and the anatomical changes which precede or accompany their failing activity, can only be retarded by furnishing "to each organ, or each system of organs, their appropriate and natural stimulus without undue excitement or depression." There is unquestionably a hygiene of old age, which, if carefully studied and intelligently observed, would prolong its physical vigor and mental power. I have the opportunity of daily watching and studying one who has reached the ninety-fifth year; all her physical and mental powers retain their activity, her pulse has the characteristics of youth, her skin is as fair and soft as that of a girl of eighteen; in fact, the changes of old age, as usually met with in persons from seventy to eighty, have not taken place in her. This case, as well as others of great age that have come under my observation, have taught me that the absence of senile changes is the chief reason of their attaining their age, and have convinced me that if the hygienic laws of age were more carefully studied and observed, not only would greater age be reached but they would be far more vigorous and useful.

I believe that the progressive degenerative changes in structure and failure in functional activities may so adapt themselves to each other as to produce an old age which may be as healthy as mature life. One of the most important of these hygienic laws is that the brain shall be stimulated by a pleasurable employment of its faculties, care being taken that it shall not be enfeebled by prolonged and continuous labor, this, together with healthful exercise, has a salutary influence on the entire system, while idleness and listlessness lead to senile atrophy of both mind and body. It is most essential also that the diet shall be simple and nutritious, as moderation in eating and drinking is indicated by the diminished capacity of the stomach, its reduced muscular power, and its declining nervous energy. So long as it can be accomplished without fatigue, exercise in the open air is another condition which promotes longevity, for it is evident that the perfect performance of respiration is stimulated by moderate exercise in a pure atmosphere and insures the highest state of oxidation, which is important to the healthful nutrition of the aged.

There is perhaps nothing that has a more prejudicial effect upon the aged than cold; their greatly diminished power of generating heat and of preserving it, renders it necessary for their greater activity that they should live in a more equable climate, in localities that are sheltered from the north and east winds. Dr. Farr, in the *Third Annual Report of the Registrar-General of England*, states "that the rate of mortality rises in the aged, as the mean temperature falls. When the mean temperature of day and night falls a degree or two below 32° F., the rate of mortality immediately rises, and the effects of the low temperature go on accumulating and continue to be felt for thirty or forty days after the extremes of cold have been passed. I have noticed that the extremes of heat seem to be as hurtful to the aged as extremes of cold, and should be equally avoided."

Another essential to healthy old age is personal cleanliness. The skin which becomes unfitted for carrying off effete matters from the system, should have its activities stimulated by frequent warm alkaline baths followed by frictions to the surface.

The ancients showed great familiarity with the principles of hygiene of old age. Cicero in his "Senectute" says that we must make a stand against old age and its faults must be atoned for by activity. We must fight against disease, and in like manner against old age. Regard must be paid to everything healthful. Moderate exercise must be adopted, so much of meat and drink must be taken, that the strength may be recruited and not oppressed. Nor, indeed, must the body alone be supported, but the mind and soul much more, for unless we drop oil on them as a lamp they are extinguished by old age. Our bodies, indeed, by weariness and exercise, become oppressed, but our minds are rendered buoyant by exercise.

With these thoughts before us in seeking climates and environments suited to the development and prolongation of old age, we naturally reach the following conclusions:

First. That healthy old age thrives best and is most vigorous when it can be passed in moderately warm climates. To accomplish this, a change of residence once or twice a year becomes a necessity. For some reason which I am sure is not based on experience or observation, it has come to be a common belief that old people should pass their last days in one locality, that they are so wedded to their homes and surroundings that any change affects them unfavorably; so prevalent is this opinion, even among medical men, that the usual professional advice is, that it is better that the aged should be made comfortable in their own homes however anti-hygienic they may be, than that they should change their residences as the seasons change. This, I am confident, is a very great mistake. I have found that old people not only bear changes well, but if such changes are judiciously made, they are not only invigorated by them, but that change of air and scene stimulates them to greater mental vigor and physical power. It is an established fact that change gives fresh impulse to mature life, and my experience teaches me that the same holds good with the aged.

Second. The localities best suited to the development of healthy old age are those which invite to an out-of-door life with surroundings and associations such as shall stimulate to mental and physical activity free from excitement, for it is to be remembered that the aged live more within themselves and are consequently annoyed and fatigued by excitement.

An old man that has the spirit of a Walton within him, who can spend most of his hours from sunrise to sunset with his rod in a pure air, grows strong and young, he hardly knows how or why. Paint to yourself the picture of such a one by some quiet stream angling for the

wary trout, there is nothing to disturb his mental poise, and the pleasurable excitement of the educated and enthusiastic fisherman is a stimulus to his mental and physical vigor, such as cannot be found elsewhere in the wide world. The botanist may find his new life in the flowers and plants that are not familiar to him in his old haunts. Or an Agassiz may find his inspiration as he revels in a new world of marine life.

Third. The localities suited to healthful development of age must furnish an abundance and variety of well-cooked food, the comforts and, if possible, the luxuries of life must be within easy reach, for if there is any one period of life more than another in which comforts and luxuries are essential to its healthfulness, it is that of old age. For what ought men in their activities to strive for more than comfortable sunset? As I have already stated, the food of the aged must be simple and nutritious, and, above all, well cooked. If you send a toothless old man to a second-rate hotel, even in the garden of Eden, his muscles will grow more flabby, his step more tottering; his mind will fail to be stimulated by the glories of nature which surround him, and he will languish and die for the good table and comfortable bed which he has left in his own home.

These, gentlemen, are a few of the conditions of environments which are necessary to the development of a healthy and vigorous old age, and it seems to me in this period of progress, it is not unworthy of scientific workers in our profession to study and make themselves familiar with those conditions and requests which shall tend to give us more vigorous and useful aged ones, and the few that astonish us by their mental power and ability to do good work long after the period of maturity has been passed, shall become the many.

As maturity passes almost insensibly into the period of decline, so the diseases of the early period of old age resemble very closely those of maturity. Dyspepsia, arthritic affections, and renal diseases, are then frequent. Later, obstruction to the venous circulation and the rigidity of the arteries, lead to local hyperæmia and extravasation, which cause all inflammatory diseases to assume a subacute or chronic type, so that in estimating the therapeutic value of climate and environment in senile diseases, we are led to consider them from two standpoints:

First. Those diseases which may occur during other periods of life, but when they occur during the period of senility present special characteristics.

Second. Those diseases which arise partially or entirely from changes in the economy which has taken place as the result of age.

In the last class may be included those structural changes which sooner or later reach such a point of development that the physiological and pathological states become blinded by an imperceptible transition, and can no longer be sharply distinguished. It is simply a process of atrophy, the cellular elements of the parenchyma, the muscular and, perhaps, the nervous elements, progressively diminish in volume, but without presenting any essential modifications in structure. The connective tissue, however, does not participate in the same degree in this mode of slow destruction. It often predominates over the other tissue elements. During the period in which these changes are taking place, the body is especially susceptible to influences which lead to the development of diseases which are characteristic of this period of life, and which largely depend on the defective nutrition of the tissue elements.

That all chronic pulmonary diseases in the aged are greatly influenced by atmospheric conditions is taught by every day's experience. There are, however, certain anatomical and physiological differences in the respiratory organs of the aged which must be considered in determining the locality to which we will send the old man with bronchitis, emphysema, or phthisis. The rarefied condition of their lungs, the dilatation and diminished elasticity of their air-cells, and the obstruction of a large number of their pulmonary capillary vessels, accompanied, as it is, with the diffusion of the carbonaceous matter throughout their substance, modify very greatly the pathological changes which occur in them; besides, as years multiply, the volume of the vital capacity diminishes at the rate of one and a half cubic inches with each year, and the frequency, as well as depth and force, of the respiratory acts much less than in middle life, causing a greater preponderance of venous blood in the lungs than at any other period. It is evident that, on account of these changes, the climatic conditions and environment which would act therapeutically in pulmonary disease in the young, would not be suited to the aged—certainly, from a physiological standpoint, the rarefied atmosphere of high altitudes is not suited to the aged suffering with pulmonary diseases; too dense an atmosphere is equally injurious, nor do their cardiac and vascular conditions allow such changes to be safely made.

It is never safe for an aged person with chronic bronchial catarrh to pass quickly from a very dry to a very moist atmosphere. My clinical experience has given me many examples of the injurious effects of such changes in this class of cases, as well as the ill effects of high altitudes on the vascular system of the aged. The localities which I have found best suited to old persons suffering with chronic bronchial catarrh and pulmonary emphysema, from December to April, is Nassau, the Bermudas, and Monterey. In July and August they do well at Shelter Island, and at Newport or Cape May; all of this class of cases that I have sent to the mountains have done badly, except a few that were complicated by hereditary asthma of long standing.

The phthisis of *old age* is generally of the fibroid variety, slow in its development, and never entirely recovered from; but its progress may be delayed and its distressing symptoms very much alleviated by an out-of-door life in a warm, moderately dry atmosphere. The locality of all others in which this class has been the most benefited during the winter months is on the Gulf coast of Florida. During the early spring, Thomasville, Ga., and Aiken, S. C., are places at which they can spend two or three months with benefit on their way north for the summer. During the summer months I have found that the seacoast off Cape Cod and Narragansett furnishes atmospheric and hygienic conditions which are especially adapted to a large class of old persons suffering with phthisis. I have frequently found that, after a summer spent in these regions, the activity of the phthisical processes was arrested, and that often those in whom the disease was quite far advanced make a remarkable gain in flesh and strength.

I have one patient, a gentleman now seventy-six, who

has been under my observation for nine years with advanced phthisis, who had three homes—one in Orange County, Florida, one in Columbus, South Carolina, and one in Newport, Rhode Island; he divides the year between them spending his winters in Florida, his springs in Columbus, and his summers in Newport, and maintains a fair degree of strength and vigor; but for these changes, and the great care which he exercises in diet and an out-of-door life he long since must have succumbed to his disease.

In connection with the climatic treatment of the pulmonary diseases of the aged, I wish to say a word in regard to change of climate as a prophylaxis against their development. Physicians, as well as patients, are too apt to think only of the diseases that already exist, and lose sight of those which may threaten. While we are usually consulted for the relief of present difficulties, and not as to how possible ills may be averted, still in our capacity, as guardians of health, it seems to me that the time has come when we should impress upon the public mind the importance of prophylaxis, and teach those under our immediate supervision that after sixty a failure to recognize the changed condition of their vital powers, and a continuance in the business habits of earlier life, after this period, are often no better than suicide.

Not a winter passes that I do not see cases exemplifying this point. When one who in early life has suffered from repeated attacks of severe bronchitis, or, it may be, has passed safely through a pneumonia or pleurisy or barely escaped a phthisis, finds himself in sight of three score and ten, he should be taught that, from a business as well as a physiological standpoint, he should so arrange his affairs as to avoid those months in our northern climate in which pneumonia and other acute pulmonary affections have their harvest among the aged.

During the past winter one of the most important and influential men in the business circles of New York, who barely escaped phthisis as a young man, was warned by his physician that at sixty-five he could not safely risk the vigor of a northern winter, and was urged to spend it on an island in the South where he owned a beautiful residence, but he plead the importance of a new business venture, which one of forty ought not to have undertaken single handed, and laughed at the warning. In February after a hard day's work, he became chilled on his way home, and in three days added another to the list of business suicides.

In a country like ours, which offers so many delightful winter homes which are closely connected with our great business centres, there is no excuse for men of means neglecting these provisions of common prudence.

Physicians who have passed sixty years, especially if their previous history indicates a strong liability to pulmonary disease, ought also to remember that a doctor above ground can accomplish more in nine months of the year than he can below in twelve.

Very few old persons escape arthritic disease in one or other of its many forms. Charcot says that "rheumatism and gout are 'par excellence' the diseases of old age, and that the pain and inconveniences which they occasion interfere very greatly with their activities, and thus tend to shorten the duration of life." There is, perhaps, no class of diseases which are more markedly influenced by atmospheric conditions. It is by his gouty twinges that the old man so accurately predicts the coming storm, and the question is constantly coming to us from the aged sufferers, Where shall I go to escape my rheumatism? Certainly they must avoid cold, damp sea-places, as well as the mountains. I would advise that they should spend the winter months below the frost line in Florida, or in Southern California. I have yet to send an old person with gout or rheumatism to either of these localities to spend the winter who has not been benefited by the change. So soon as the comforts and luxuries of life can be obtained by invalids in these regions, I am quite sure they will become the winter homes of the old who are the subjects of arthritic diseases; chronic vesical catarrhs, independent or connected with prostatic enlargement, so common in the aged, is as much influenced by atmospheric conditions as are bronchial catarrhs, and occurring as they do in gouty or rheumatic subjects, usually obtain benefit in the same localities that are suited to arthritic subjects.

This class of cases, however, are exceedingly obstinate; if there is anything that shows more clearly than another their intractable nature, it is the long list of remedies which have been employed in their treatment.

I have long since abandoned the local measures usually resorted to in their management and have relied almost exclusively upon diet and climate. My experience has shown that they are always aggravated in damp, cold localities, especially those that are subject to sudden and extreme atmospheric changes, while they are greatly improved and sometimes entirely relieved by a residence in a warm sea climate.

I have found the Bermudas and Nassau best suited to this class of cases. I recall a very obstinate case of a gentleman seventy-two years of age, who had suffered constantly for four years with an aggravated form of chronic cystitis, and had been subjected to various plans of treatment, both local and constitutional, without relief, who entirely recovered after he had taken up his residence in Monterey.

The localities which I have named as best suited to the aged in health and disease, are those with which I am personally familiar; I have not referred to those outside the boundaries of our own country, for my experience has convinced me that it is seldom wise for an old person to take the risks of a long sea-voyage. There are undoubtedly many other localities equally as desirable as those which I have named, but my personal experience is not sufficient for me to recommend them.

If the few suggestions which I have made shall have so interested the members of this Association, that a more careful and extended study of the hygiene, and a more intelligent care of the aged in health and disease, shall gain a more prominent place in the work of our profession, I shall be satisfied and feel that I have added my mite to the relief and prolongation of the most interesting period of human life.

ORIGINAL ARTICLES.

"AINHUM,"

With Case and Remarks.

By R. H. DAY, M.D.,

OF BATON ROUGE, LA., EX-PRESIDENT OF THE LOUISIANA STATE MEDICAL SOCIETY.

IT is a somewhat remarkable coincidence, that Dr. Shepherd and I should have operated for the

relief of this rare disease in the same year and the same month; he, in Montreal, on the 14th of May, 1886, and I, in Baton Rouge, Louisiana, on the 8th of May, 1886.

I infer from Dr. Shepherd's report of his case (*American Journal of the Medical Sciences*, January, 1887, p. 137), that it was the first he had seen. Mine was the first I had seen; and, in truth, I was perfectly at sea as to its name or nature, for in all my experience or reading I could not recall any affection bearing the slightest resemblance to it, or affording any light upon the subject.

Dr. Shepherd has given us a very interesting and full account of all that is known of this singular disease. The name "ainhum" is a most unfortunate and inappropriate one, from the fact that it expresses no one feature of the affection According to Dr. Shepherd, it is simply the "negro name" for this disease; but whether of any linguistic origin or a negro vulgarism we are not informed.

My case first came under my notice in the early part of 1885. The subject, a colored woman (Sylva J.), was born in August, 1824, in the Parish of East Baton Rouge, Louisiana. Has always been healthy and well nourished; and of healthy parentage, so far as can be learned from her statements. I was first called to see her on account of the excruciating pain she was suffering, which I found to be located in the little toe of the right foot. The appearance of the toe was peculiar and striking. The extremity of the toe was much larger than normal, and of a blunt, ovoid, or club shape, with a deep fissure in the second phalangeal space, immediately behind the first articulation, with considerable enlargement of the toe behind the stricture, involving the metatarso-phalangeal joint and the dorsum of the foot. On the upper and outer aspect, near the first joint, there was a dry eschar, like a condensed corn. There was no open ulcer or abrasion of the skin on any portion of the toe; and the deep fissure looked exactly as though it had been purposely brought about by the continuous constriction of a tightly drawn elastic cord; so much so, that I questioned and cross-questioned the patient closely in that direction, before my mind could be disabused of the strong suspicion that such had been the cause of the trouble. The strictured pedicle was small and felt destitute of bone, as if composed of tendons and condensed tissue only, as the toe could be rotated and deflected at any angle without trouble, but with excruciating pain.

The patient states that in 1881, early one morning, after a short walk, she experienced an itching, burning sensation in her right foot, and that upon inspection she noticed upon the little toe a small point or vesicle, as of the bite or sting of some insect. Her foot and leg became inflamed and swollen, which she relieved by bathing and poulticing; but the toe from that time on, she says, was a source of trouble and very painful, at times much more intense and aggravated.

She tells me (for I have recently questioned her) that previous to my first visit to her, a negro doctor had been called to see her, and that he clipped off the end of her toe, which, no doubt, accounts for its club-like extremity.

The history of this case is given as derived from the patient, and although a woman of the average intelligence of her race, such is the superstitious nature of the negro, and his proneness to magnify his ailments and sufferings, that it is almost a matter of impossibility to obtain a clear and intelligent history. Hence in this case, the origin of the disease, its progress and history, are all more or less obscure and unsatisfactory, and but little light is shed upon its origin.

That the disease is obscure in origin and slow in its progress, seem to be pretty well established by the few cases that have been reported; and also it is demonstrated to be peculiar to the African or dark raced people. That it is also a disease of rare occurrence seems to be fairly well made out; and yet it is a question if this characteristic feature may not be owing, in a great measure, to its limitation to the negro race, and to its slow and non-fatal tendency. Although I had been in regular practice fifty-two years before I saw my first case, I have since seen one other.

Dr. J. L. Deslattes, of St. James Parish, La., has seen four cases. He writes me as follows:

"While I was practising in St. Johns I saw two cases occurring in old negroes.

"About ten years ago there was an old negro in the Longview settlement, who gave a pretty clear history of his case. The toe, when seen by me, seemed to have suffered from a slow molecular necrosis. This necrosis had begun on the inside of the toe and had gradually reached the bone. The bone itself had become denuded of periosteum, was somewhat loose and perfectly detached. The probe introduced into this cavity went way beyond the bone to the skin on the opposite side. A very slight discharge came from this cavity. There seemed to be very little or no pain. The disease was slow in its progress. This old man begged me to cut off his toe. Some two or three months afterward, on inquiring about him, I was told that he had amputated his toe himself with a hatchet a few days after he had seen me.

"There is now in that neighborhood, a man who, I am told, has amputated his toe himself for the relief of the same trouble."

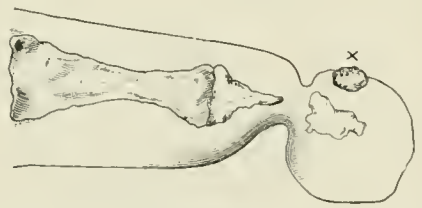
There appears to be no heredity in connection with this affection; and, as far as we can judge, it is strictly local in character, the general system, in the subjects affected, remaining well nourished, robust and unimpaired in health, during the protracted and painful progress of the local disease. Its real pathological and essential lesion seems to be necrosis of the phalanges of the toe, with limited circumscribed stricture of the superimposed tissues. What

causes, specific or general, can so alter or modify the nutrition of the parts, as to produce this decay and death of the phalanges and circular constriction of the soft tissues, must be a matter of mere speculation, and so remain until more extended observation and research shall develop facts sufficient to disperse the darkness that now enshrouds the subject.

The theory of Dr. Shepherd, that the disease is of "nervous origin," and is due to some "trophic disturbance of the nerve centres," is very probable.

As already stated, I operated on my case on the 8th of May, 1886, amputating the toe at its metatarso-phalangeal articulation. The patient made a good recovery, and is still living and in good health, with no tendency, that can be discerned, to any further toe trouble.

In order to give a fair representation of the disease, and to make the description of it more intelligible, I have endeavored to present in the accompanying drawing the exact appearance of the toe, and also



Appearance of the toe. The shaded border on the inferior aspect shows an injected and purplish condition of the tissues in that locality, indicating a previous congested state of the tissues and capillaries. × indicates the position of the little eschar.

a *fac-simile* of the abnormal changes wrought in the phalangeal bones. It will be observed that there is a notable difference in the appearance of the toe and its phalanges in my case from that of Dr. Shepherd. This, however, is merely one variety in the form of the disease, or stage of development, and evidently evinces the essential morbid lesion in the two cases to be identically the same.

THE CONNECTION BETWEEN MASTURBATION AND STRICTURE OF THE URETHRA.[1]

By SAMUEL W. GROSS, M.D., LL.D.,
PROFESSOR OF THE PRINCIPLES OF SURGERY AND CLINICAL SURGERY IN THE JEFFERSON MEDICAL COLLEGE.

Although masturbation had previously been recognized by several writers as a cause of organic stricture of the urethra, I was, if I do not mistake, the first to call prominent attention to that fact in the *Medical and Surgical Reporter*, May 5, 1877, and subsequently in the three editions of my brochure on *The Diseases of the Male Sexual Organs*. It is my present purpose, through the medium of this body, in a very few words, to direct the attention of the general practitioner to the very common occurrence of stricture in masturbators, in order that he may search for a factor in maintaining the disorders, both local and general, to which these persons are subject.

In the second edition of my brochure the statement will be found that, of 173 masturbators, one or more strictures were detected in 151, or 87 per cent. Since the appearance of that edition, I have had 157 additional cases, and find that, out of a total of 331, strictures were present in 291, or 88 per cent. The last 157 cases were carefully examined as to the calibre, number, and seat of the coarctations, and my remarks will be confined to these cases alone. In order that there may be no doubt as to the accuracy of the observations, it should be stated, first, that the examinations were conducted with the soft acorn-headed bougie upon patients who had never suffered from gonorrhœa and many of whom had never had sexual intercourse; and, secondly, that when, in addition to a stricture at or near the meatus, other coarctations were discovered, the final diagnosis of the more deeply seated ones was made only after the division of the stricture at the orifice.

Of the 157 cases, one or more strictures were present in 140, or 89.18 per cent., and absent in 17, or 10.82 per cent. In 19.3 per cent. the calibre was below 21 of the French scale—the smallest having measured fourteen millimetres in circumference; 22.6 per cent. ranged between 21 and 24; 51.5 per cent. between 25 and 27; and 6.5 per cent. between 28 and 31 millimetres.

Of the 140 examples of stricture, there was one in 82, or 58.57 per cent.; two were found in 41, or 29.29 per cent., and from three to six were present in 17, or 12.14 per cent. Of the 82 solitary strictures, 65 were seated at or near the meatus; 4 in the spongy portion of the urethra; and 13 in the bulbous division. Of the 41 examples of two coarctations, 31 were found at the meatus and bulb; 4 at the meatus and spongy urethra; and 6 in the spongy and bulbous portions. Of the 7 cases of three strictures, in 5 they were located at the meatus, in the spongy, and in the bulbous divisions, and in 2 there was a single coarctation at the meatus, and two in the pendulous urethra. Of the 7 instances of four strictures, there were one at the orifice, two in the pendulous portion, and one in the bulb in 2; one at the meatus and three in the pendulous portion in 2; and three in the pendulous urethra and one in the bulb in 3. Of the two examples of five coarctations, there were one at the meatus, two in the pendulous urethra, and two in the bulb in 1; and one at the orifice, three in the pendulous portion, and one in the bulb in 1. In the single case of six strictures, five were found in the spongy urethra and one in the bulb.

An interesting fact, deducible from a study of the preceding measurements, is that in not less than 113,

[1] Read at the meeting of the American Association of Genito-Urinary Surgeons, Washington, September 18, 1888.

or 80.71 per cent., of the 140 cases, was a stricture found within one-third of an inch of the orifice. It, moreover, appears that when there was only one coarctation it was seated near the orifice in 79.26 per cent. of all cases; while, when there was more than a single stricture, one was present near the meatus in 82.75 per cent. of all examples.

In conclusion, it may be affirmed that, as a result of my personal observations, urethral stricture may be looked for in nearly nine-tenths of all masturbators who have never had gonorrhœa, and that, as a rule, the stricture will be found to be of large calibre, single, and seated near the meatus.

MEDICAL PROGRESS.

Ether in Heart Failure.—Two years ago Bamberger (*Wiener klinische Wochenschrift*) had under his care a man, aged sixty, who was suffering from severe insufficiency of the heart depending on fatty degeneration, and most probably also from sclerosis of the coronary arteries, but without cardiac failure. The other symptoms present were considerable dropsy, albuminuria, swelling of the liver, severe dyspnœa and continual sleeplessness. The patient had enjoyed perfectly good health until recently, but owing to overwork and irregularity of life the action of his heart became impaired. As the ordinary remedies were of no use or were only temporarily beneficial, the patient was directed to undergo the Oertel "cure" in the mountains. The symptoms, however, and particularly the dyspnœa, increased to such a degree before the treatment commenced that the attending physician, becoming anxious about the case, had recourse to injections of ether with a Pravaz's syringe. This had a really surprising effect, as immediately after the injections the secretion of urine, which could not be augmented by any means before, increased to several thousands of cubic centimetres a day, and continued to be so for some time longer without any other remedy being used; the dropsy and the dyspnœa also simultaneously decreased. In this ameliorated condition the patient was able to undergo the Oertel treatment, at Reichenau, where his health made further progress. In the spring of the following year, the patient was seized with an apopletic attack—probably of embolic origin—with hemiplegia of the left side; contracture of the left arm remained behind. Later on symptoms of dropsy again showed themselves, for this the treatment with calomel proved very useful, as the excretion of urine rose to 6000 cubic centimetres a day; the vital powers of the patient, however, decreased more and more, and death supervened. With regard to the surprising effect of the ether, Professor v. Bamberger says that two possibilities had to be taken into account, namely, either the effect on the heart itself, which stimulated the weakened organ to a last successful effort, and thus overcame the congestion in the renal bloodvessels, or there was a direct influence on the excretory apparatus of the kidneys. From the fact that calomel had a similar effect, which could only be explained on the latter of these two hypotheses, Professor v. Bamberger considered that the direct influence on the secreting apparatus was, in all probability, the correct explanation.—*British Medical Journal*, September 1, 1888.

Convulsions in Children Caused by Opium.—Roth (*Bulletin Médicale*) has confirmed the fact that opium, even in small doses, causes, in infants, convulsions, which may be fatal. The dose may even induce convulsions in the fœtus, of which Roth cites a case. A pregnant woman who had taken large doses of opium observed, shortly after ingestion, violent, almost unendurable fœtal movements. The author therefore considers irrational the use of opium to prevent abortion.—*Deutsche medizin. Wochenschr.*, August 2.

Experimental Sinus Thrombosis.—Ferrari thus summarizes the results of fourteen experiments upon dogs with artificial plugging of the venous sinuses of the dura mater:

1. Thrombosis of a sinus of the dura mater occasions no obstruction of the circulation in the related cerebral area and gives rise to no more profound anatomical changes.

2. A large portion of the sinus passages may become impervious, *e.g.*, all the sinuses of the vertex, without disturbance of the cerebral function. Simple, though extensive, sinus thrombosis in dogs occasions no symptoms whatsoever.

3. Obstruction of all the sources of exit of blood from the cranium is rapidly fatal, death being usually preceded by an epileptic attack.

That the results attained in dogs are applicable to man cannot be determined. The analogy of the cranial venous symptoms makes such a view plausible. Clinical observation does not contradict it. Repeatedly at autopsies have thromboses been accidentally found which gave rise to no symptoms. Such conditions may often arise and be overlooked, because of the recovery of the patient. The severe symptoms of thrombosis are the result rather of the complications than of the constriction of the sinus.—*Medizin. Jahrbücher*, Heft 3, 1888.

Kidney-bean in Renal Troubles.—It is stated that a wineglassful of an infusion made from the dried leaves of the kidney-bean, has remarkable effects in quieting the pains of nephritic colic. M. Bouloumis has used it with favorable results in several cases; in one of which, renal calculi accompanied the spasm; in another case, of urethral pains, the patient was afflicted with chronic cystitis and enlarged prostate.—*Revue de Thérapeutique*, September, 1888.

Oxyuris Vermicularis.—The following mixture is said to be highly efficient:

R.—Tinct. rhei	. . . . .	gtt. iij.
Tinct. zingiberis	. . .	gtt. ij.
Magnesii carbonatis	. . .	ʒ iv.
Aquæ	. . . . .	ʒ iij.—M.

This amount to be given three or four times daily, according to the effect produced.

The rhubarb may act as a vermicide or as an agent which simply detaches the worms. In either event it causes the expulsion of great numbers of them and induces regular bowel movement.

Sterilized Milk in the Digestive Disorders of Children.—Penzoldt, before the local medical society of Erlangen, stated that the excellent results from the nourishment of

healthy children, during the first months of life, exclusively with milk sterilized according to the method of Soxhlet, induced him to introduce the method into the institution for nursing children. As sterilized milk was not the exclusive source of nourishment, but was given only by day, some other and less appropriate form of nourishment being given during the evening and morning, the result from the outset naturally seemed uncertain. Nevertheless, it really proved surprisingly successful. The number of cases of diarrhœa, from careful records of the matron, was extraordinarily diminished after the innovation. This result encouraged him to use sterilized milk in the dietetic treatment of existing gastric disorders. It is well known that when such conditions arise it is useful to withdraw the milk, particularly ordinary cow's milk for a time, and replace it by demulcent fluids. The latter, however, are not sufficiently nutritious for long periods of time. The possibility of continuing the use of milk during the course of dyspepsias would be most desirable from a nutritive point of view. For more than a year, all cases of chronic dyspepsia in infants at the polyclinic were treated with milk sterilized by the Soxhlet method, partly without and partly with simultaneous medicinal therapeutics. The milk was prepared by the matron. The doctor ordered the quantity to be given by the parents. That the necessary care in administration was not always observed, and that other nourishment was given in addition, were unfortunately unavoidable evils, resulting from the ignorance of the parents. The practical outcome, however, may be better understood from the studies of the assistants at the polyclinic, Drs. Haas and Grätz, of a large variety of cases, with modifications of the treatment. They have come to these conclusions: In the chronic dyspepsias of infants the exclusive use of sterilized milk affords none or but slow improvement; if, however, the treatment is begun with an efficient calomel purge, milk entirely withdrawn for a few days, and then milk sterilized by Soxhlet's method given, the result is frequently favorable and relapses occur less readily. The explanation is evident. If, in the course of a dyspepsia, milk, sterilized, but still capable of fermentation, is introduced into the intestinal canal, the contents of which are in a state of abnormal fermentation, the fermentative processes will continue. If the fermenting mass is diminished and disinfected by means of calomel, renewed abnormal fermentation may then be avoided by the ingestion of sterilized milk. Thus the Soxhlet process becomes an important prophylactic measure in the case of dyspeptic children as well as in the nourishment of healthy children.—*Münchener medicin. Wochenschr.*, August 21, 1888.

Erythrophlœin in Cardiac Trouble.—The action of erythrophlœin has been carefully studied in the clinic of Drasche, in Vienna (*Wiener klinische Wochenschrift*). It was used in cases of compensated and non-compensated failures of the heart, as well as in cases of fatty heart with slight disturbances of circulation. The drug was used in a solution of 0.002 gramme of erythrophlœin in 10 grammes of cherry laurel water, ten drops of this solution being given every hour. In general, the drug was well tolerated, and only in a case of insufficiency of the aorta depending on acute articular rheumatism did the sensation of disgust and great irritation supervene. Retardation of the pulse after the administration of erythrophlœin came on in several cases, and this was particularly true of the case of insufficiency of the aorta after 150 drops of the solution had been given for eight days. The number of the pulse-beats was reduced from 100 to 84 a minute, and in another case of insufficiency and stenosis of the mitral valve, the pulsations decreased from 100 to 68 a minute after the administration of 50 drops of the solution, and during an interval of time of from midday till 5 P. M. This, however, was not constant, as in the last-mentioned case the number of the pulsations reached 108 a minute three hours later, although the administration of the solution was continued.

In another case of insufficiency of the mitral valve with severe palpitations, the drug was administered for twelve days, and it was not until some days later that the frequency of the pulsations sank from 120 to 96 in a minute, and at the conclusion of the experiment it decreased to about 84 beats. As to the effect of the erythrophlœin on the renal function no particular influence could be observed in some cases, whereas in another series of cases the effect was quite striking. In a patient affected with incompetence of the mitral valve the daily quantity of urine, during an interval of twelve days, increased from 800 to about 1500 cubic centimetres. In another case of slight fatty heart, in which, before the use of erythrophlœin, the number of the pulsations was from 68 to 60 a minute, and the quantity of urine reached 700 cubic centimetres, the latter increased to 2150 cubic centimetres, while the pulse remained unchanged. The disturbance of respiration had also diminished. Erythrophlœin had also a marked effect on the pupil. In a patient with incompetence of the mitral valve, persistent dilatation of the right pupil ensued on the sixth day after administration. In another case with insufficiency of the aortic valve, distinct dilatation of both pupils came on on the fifth day; this disappeared some days later when the administration of the drug was discontinued. Kaposi had also observed dilatation of both pupils in a case of poisoning from the subcutaneous injection of two centigrammes of erythrophlœin.

For the sake of comparison, experiments were made with strophanthus. In cases in which erythrophlœin exerted no particular influence on the frequency of the pulsations, the arhythmia and the congestive symptoms, from 60 to 70 drops of the tincture of strophanthus with equal parts of laurel water were administered in the day. The difference was very striking, and the slight effect of the erythrophlœin could not be compared with that of strophanthus. In one case, for instance, the frequency of the pulsations after the use of strophanthus soon fell from 112 to 72 a minute, and remained nearly at this rate. The arhythmia had almost entirely disappeared, and the excretion of urine was augmented to a much higher degree than after the use of erythrophlœin. Symptoms of poisoning with erythrophlœin were observed on only two occasions. The results of the experiments with erythrophlœin may be summarized as follows: The drug had a marked retarding influence on the pulse, but the effect was not lasting. This was also true of its diuretic influence. The drug was well borne, and might be tried in cases in which digitalis, strophanthus, and similar medicaments, were either not well tolerated or were contraindicated. Erythrophlœin did not appear to have any cumulative effect.—*British Med. Journ.*, Sept. 1, 1888.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, SEPTEMBER 29, 1888.

WHAT SHOULD BE DONE TO ARREST THE YELLOW FEVER EPIDEMIC.

IN our issue of last week we insisted that when an epidemic of yellow fever occurs in the United States, some one is responsible, inasmuch as the disease is nowhere endemic in this country, and, when introduced, its extension may be prevented by the efficient application of known sanitary measures.

We cannot at present discuss the question as to where this responsibility rests. Evidently not upon any single individual, but upon our imperfect system or want of system of sanitary defence, for which the responsibility rests with the Congress of the United States, and not with the leading sanitarians of the country, who have repeatedly asked for the enactment of legislation establishing a Central Health Bureau, with full powers and ample means to cope with this and other epidemic diseases, which do not respect State boundary lines; and upon the absence of well-organized and vigilant State and local health boards in the State first invaded.

Leaving, then, this question of responsibility, we ask, What can and should be done, in this emergency, to arrest the progress of the epidemic? The principles which should govern the action of those upon whom this task devolves do not differ from those which we indicated last week as essential for arresting the disease at the outset in one or more isolated foci; but the difficulty of the undertaking is enormously increased by the wide extension of the disease and the panic of the population in invaded or threatened towns. Theoretically, the main reliance of these towns should be upon general sanitary police, by which the nidus in which the exotic germ is known to thrive is removed. But it is Utopian to expect that this condition of defence can be established upon short notice in towns without an efficient sanitary service, and in which, too often, the rudiments of sanitary science are unknown, or, if known, are utterly neglected. Clean up by all means, but do not imagine that street-sweeping and removal of garbage from back doors and vacant lots will prove a sufficient defence against this enemy, which domiciles itself in insanitary dwellings and appears to thrive luxuriantly in a filth-polluted soil. Our main reliance, then, must be upon isolation of the sick, disinfection, and depopulation of infected areas.

As a rule, it will be best in the interest of the community and of the sick, to care for the sick in the infected locality. Those, however, who fall sick at a distance from the point where they contracted the disease should at once be removed to a place where isolation and disinfection of excreta can be enforced, for they are likely to establish new centres of infection—not by communicating the disease directly to those in contact with them, but by sowing germs which, under favorable circumstances, multiply external to the human body, as is the case in cholera and typhoid fever.

But when an infected centre is developed in any locality, as shown by the occurrence of cases of local origin, the rule should be to remove all unprotected persons from the infected area unless their presence is absolutely required for the care of the sick. Remaining within this area does not seem to add to the danger of an attack, while removal after the first forty-eight hours of sickness is often fatal, and, on the score of humanity, should only be tolerated under very exceptional circumstances. The removal of the sick from an infected area with the idea that in this way the disease may be gotten rid of is a fatal error which has repeatedly been made, and invariably with the same result. The locality is none the less infected because the sick have been removed, and the danger to unprotected persons remaining in it is not diminished by such removal.

All experience shows that the opposite procedure is the only sure method of checking the progress of an epidemic. Remove the well from infected areas, disinfect their clothing and personal effects, and keep them under observation for a sufficient time to

insure the safety of other communities; while the sick are cared for as far as practicable by nurses and physicians who are protected by a previous attack of the disease or by acclimatization in a place where it is endemic.

Depopulation of infected areas, with the exception of those persons required to take care of the sick, should be compulsory, and, therefore, at the expense of the general government—for if in the interest of the public health we force people to leave their homes, it is evident that we are under an obligation to take care of them during this enforced absence.

What we have said relates to the depopulation of infected localities only. The general depopulation of a city in which one or more infected localities have been developed is another matter. We would not attempt to depopulate Baltimore or Philadelphia because one or more foci of infection had been established, but we would attempt to isolate each focus. This is the place for a sanitary cordon, not to keep well people shut up in a death trap to protect others, but to keep foolhardy persons from entering the dangerous area. To attempt to shut in the whole population of the town is preposterous. On the other hand, they should be encouraged and assisted in removing to a place of safety, while this can be done without endangering other communities—*i. e.*, while the infected area is still restricted to one or more localities of limited extent; and this without any unnecessary restrictions or detention. The barbarous and unreasoning shotgun quarantine of their neighbors should not stand in the way of their exodus; they have as much right to make a sortie with shotguns in their hands to save their lives as the others have to protect themselves from infection.

Evidently here the strong arm of a superior authority is required, not only to prevent the extension of an epidemic, and to secure the rights of individuals under all circumstances, but to save us from disgrace in the eyes of enlightened people in other parts of the world.

LABORATORIES FOR INSTRUCTION IN PRACTICAL HYGIENE.

THERE are not less than six European institutes for the practical teaching of sanitation, that of Pettenkoffer, of Munich, being the earliest; Berlin, Leipzig, Göttingen, Amsterdam, and Buda-Pesth following. London has its College of State Medicine, with a museum, under the direction of Sir Joseph Fayrer, begun this year. Wurzberg, as we recently announced, has the promise of an institute of hygiene under Prof. Lehmann. Prof. Proust, of the Paris Faculty of Medicine, is at present engaged upon a laboratory and museum specifically designed and devoted to practical sanitary instruction.

The first American university to take this department of tuition seriously in hand will, without doubt, be Columbia College, New York, where steps have been taken to locate in its School of Mines this added study. It is true that a sanitary museum has been begun at Washington, in the Department of the Navy, but it has not yet been made available for teaching purposes.

AN Intercolonial Medical Congress will assemble in Melbourne, in January next, under the presidency of Mr. T. N. Fitzgerald. About 500 medical men will meet in conference, including the presidents of the various medical associations throughout Australasia, the medical advisers of the different Governments, the inspectors of asylums in all the colonies, the professors and lecturers in the several medical schools, and a large number of the leading members of the profession. After the inaugural meeting, to be held on January 7th, the Congress will meet in nine or more different sections. Prof. H. B. Allen, of the University of Melbourne, is Secretary of the General Committee.

THE meeting of the Southern Surgical and Gynecological Association was not held in Birmingham on the 11th, 12th, and 13th of September, as announced, but has been postponed till the first Tuesday in December, owing to the quarantine against yellow fever.

ACTS of heroism in medical life are so frequent and appear to be so natural a part of it that they are not chronicled as often as they should be. One such deed, however, recently found its way into the *British Medical Journal*, where it is mentioned as an illustration of the self-sacrifice of medical men in behalf of suffering humanity. It is the case of a surgeon in the British army named Landon. Mortally wounded himself, and with the grasp of death rapidly closing down on him, he heard a wounded soldier crying out from the sharp pain of his hurt. Forgetful of self, he crept with difficulty to where the man lay and gave him a hypodermatic injection of morphia to lessen his suffering and, having given it, lay down and died by the side of the soldier.

REVIEWS.

The Physician's Bedside Record. By Gideon C. Segur, M.D. Hartford, Conn.: The Plimpton Manufacturing Co., 1888.

This record is designed for use in a single case. It contains a page for preliminary history; twenty-eight pages for the record of as many days' observations, ruled with spaces for pulse, temperature, respiration, medicine, notes of the nurse, and the physician's orders and directions; pages for the personal notes of the physician, the whole concluding with a chart for pulse, temperature, and respiration. It is of convenient size for the pocket, bound neatly and cheaply, with spaces on the cover for the data of value for future reference.

The peculiarity of the record is that it includes the observations of the physician and nurse upon a given case, in convenient shape for filing and reference. It seems, to us, of practical value, and likely to prove a welcome addition to the physician as a handy method for making and preserving notes of his private cases.

The Disorders of Menstruation. By Edward W. Jenks, M.D. 12mo. pp. 120. Detroit: Geo. S. Davis, 1888.

This is one of "The Physicians' Leisure Library," a series of short, practical treatises addressed to practitioners. In the present volume Dr. Jenks has given a fair *résumé* of the modern treatment of disordered menstruation. The limits of his book forbade discussions of doubtful points, and the introduction of a thorough survey of the pathology of the affections described. Nor can the book claim original methods of treatment The practice of the average American gynecologist is, however, fairly described; formulæ and illustrations sufficient to bring clearly before the mind the instruments and drugs used are inserted; and the book may be read in the scattered moments of a physician's leisure with profit and interest.

SOCIETY PROCEEDINGS.

AMERICAN SURGICAL ASSOCIATION.

Annual Meeting,

Held in Washington, September 18, 19, and 20, 1888.

(Concluded from page 338.)

Wednesday, September 19th.

Morning Session.

Dr. Hunter McGuire, of Richmond, read a paper on

THE FORMATION OF AN ARTIFICIAL URETHRA FOR PROSTATIC OBSTRUCTION.

It has been his lot to meet with a number of cases of hypertrophy of the prostate gland, which produced more or less obstruction to the passage of urine. These are conveniently divided into three classes.

1. Cases in which the obstruction was due to temporary congestion of an already enlarged gland, which yielded to the ordinary treatment, and did not return.

2. A class of cases in which the obstruction to the passage of urine was permanent but not great. Attention to the general health, the occasional introduction of the catheter, and washing out the bladder, were all that the cases required. These cases are, however, never free from danger from exposure, etc., and gradual enlargement may go on, and bring about the condition met with in the third class.

3. In these cases the obstruction is great and fixed, micturition is frequent and difficult, perhaps impossible without the aid of the catheter. The introduction of the instrument grows more and more difficult, offensive resident urine is always present, and the general health suffers greatly. Cystitis, localized or general, is a painful and pronounced symptom. Violent tenesmus of the bladder, provoked by the obstruction, injures the vesical ends of the ureter, possibly a reflux of stale urine is driven into these canals, and ureteritis follows, then pyelitis, and pyelonephrosis, from which the patient dies.

The paper was devoted to a consideration of surgical interference in the third class of cases. He was led to resort to the measures described from the following circumstances: During the past eight months, four cases of stone in the male required the suprapubic operation. Two because of organic stricture; one because of the large size and hardness of the two the bladder contained; the fourth, because the stone was large and hard, and the patient too anæmic to bear the shock and loss of blood which often accompany section through the rectum.

In one of the cases of stricture, in a man sixty-five years of age, the patient had, two years before coming under observation, a second cause of obstruction. A well-organized stricture was found in the membranous portion of the urethra. Prostate was enlarged, more marked on the left side. Urine showed no evidence of renal disease. An oxalate calculus, three-fourths of an inch in diameter, was also recognized. The high operation for stone was performed. The bladder walls were found thick and unyielding, and contracted. The left side of the gland jutted into the bladder one and one-half inches further than on the right side. The middle lobe was of the size of the thumb, and almost completely closed the urethra. It was decided to retain a fistulous opening, through which urination could take place. This tract was two and half inches long, and extended upward and forward. In its passive state it was closed by the pressure of the parts through which it passed. When the bladder became full and contracted, the urine was forced through the fistulous tract. The patient can now retain water for two or three hours, and has voluntary power both to retain and expel urine.

Case 2 was a man sixty-nine years of age, who had been cut for stone in 1881. In 1883 Dr. McGuire found the prostate enlarged and cystitis present. The patient was given a gum catheter, and shown how to use it. In 1886 electrolysis was employed, without success, in trying to reduce the size of the prostate. July 4, 1888, an operation similar to that performed in the first case was done, with equally good results. At times he is able to retain urine for six hours. He never has any desire to empty the bladder, no matter how full the organ is.

Mode of operation.—The night before the operation the bowels are opened. On the day of operation fifteen to twenty grains of quinine are administered. Antiseptic precautions are adopted throughout. The bladder is washed out with a weak solution of carbolic acid in hot water. An empty gum bag, capable of holding twelve ounces, is passed into the rectum. About twelve ounces of water are then injected into it, which pushes the bladder over

the pubes. The bladder is next filled with a hot solution of carbolic acid. The use of force should be avoided. The penis is tied with a piece of rubber tube to prevent escape of fluid. A vertical incision is next made, beginning three or four inches above the pubes, and extending to the symphysis; this extends to the linea alba. The incision in the latter structure should be from three-fourths to one inch shorter than through the skin. When the transversalis fascia is reached, it should be divided, but not for more than two inches, but should reach to the pubic bone. The fat and cellular tissues between the transversalis fascia and bladder are separated with the handle of the knife. This tissue should be disturbed no more than is necessary. The bladder is now drawn forward with a tenaculum, and opened as low down as possible. The anterior portion of the organ should be carefully explored with the finger.

Sutures should now be applied, extending down to, but not including the recti muscles. The opening left in the skin should be at the upper extremity of the wound, so that the fistula will be oblique, and from two and a half to three and a half inches in length. A catheter is passed through this opening. If the catheter causes annoyance, it may be at once removed; otherwise it is better to allow it to remain a few hours. The dressing consists of a pledget of absorbent cotton, changed as often as necessary. In none of his operations has he met with the peritoneum.

In the after-treatment it is important to keep the urine acid, for acid urine is aseptic. In operations in these cases and in the high operation for stone the amount of blood lost has not exceeded two drachms.

Dr. J. H. Packard, of Philadelphia, read a paper on

SUPRA-PUBIC CYSTOTOMY,

supplementary to one on the same subject read by him at the last meeting, and was intended to correct an accidental omission of the views of Sir Henry Thompson. These were now considered, extensive quotations from the works of this author being given. Two cases were reported, in one of which the operation was performed for the removal of a portion of silver catheter broken off in the bladder; and in the other for the removal of a piece of rubber catheter, said to have been broken off several months previously. In this case a stone weighing 571 grains was removed, in the interior of which was found the foreign body.

Dr. S. W. Gross, of Philadelphia, thought that Dr. McGuire was to be congratulated on having introduced a new operation based upon the mechanism of the bladder and the physiology of micturition; the formation of an artificial urethra in a new position. The various operations which had been performed for the relief of prostatic obstructions were next referred to; the operations of Harrison, Mercier, Bartinini, and McGill were considered.

Dr. William T. Briggs, of Nashville, thought that perhaps in the cases reported by Dr. McGuire a better result might have been obtained by the lateral lithotomy, provided the stone was not too large to be removed by that route, for he had noted that after incision into the prostate the gland diminished in size, and after the wound had healed a catheter could be passed in cases in which its use was before impossible. The perineal operation allows of freer drainage. Under some circumstances the supra-pubic operation is a valuable one. This is especially the case when the stone is so large that its removal through the perineum is liable to produce serious injury of the soft parts. It is, however, often possible, through an incision in the perineum, so to break the stone as to prevent its removal. Every case should be studied by itself; in some, one operation is the best; in others, another is most suitable. All the circumstances of the case must be taken into consideration.

Mr. Reginald Harrison, of Liverpool, said that there are two general methods of relieving obstructions due to enlarged prostate, one by attacking the gland through the bladder; and the other through the perineum. In his operation he makes a median or a lateral incision through the perineum, according to circumstances. The obstructing prostate is next divided with considerable freedom, and a drainage tube of considerable size introduced. From this operation he gets good results. Perineal lithotomy is preferable to the supra-pubic operation, because the lateral incision gives sufficient room for all manipulations. It gives an ample opening for the removal of a stone of considerable dimensions. It also permits of the more or less permanent drainage which these cases require. He had, also, through a perineal opening, used the perineal lithotrite with success. All methods of operation should be remembered, and each employed in those cases in which it seems indicated.

Prof. Annandale, of Edinburgh, had come to the conclusion that if an operation is to be performed for the relief of prostatic obstructions, the perineal operation is the best. This allows of examination of the bladder, permits drainage, and probably causes a diminution of the hypertrophy. It enables one to remove occasionally a portion of the enlarged prostate, when this assumes a pedunculated form. The speaker exhibited a rubber tube which he had found useful in cases of Harrison's operation, when a permanent cure is required.

Dr. A. Vander Veer, of Albany, said that the testimony presented in his paper last year was in favor of the perineal opening so far as drainage was concerned. He had employed Harrison's operation in a number of cases, and the results had impressed him favorably.

Mr. Arthur E. Durham, of London, emphatically endorsed what had been said in regard to operations for stone that no one operation is applicable to all cases. It is a great mistake to be sure of one method, especially in surgery. When we hear a man say that he treats all his cases of fracture in such a way, all his cases of stone in such a way, and all his cases of prostatic disease in such a way, we may be sure that such a man has a very small practice and experience, or else he is a very great fool. In cases in which stone in the bladder is complicated with enlarged prostate, the perineal incision seemed to him to be better than the supra-pubic. He described a method of performing perineal lithotomy which is performed with satisfaction at Guy's Hospital. This consists in the use of a straight staff, the groove extending to within one-third of an inch of its extremity. A knife with a straight back is passed through the perineum until it reaches the groove, then carried along the groove to its extremity, and the point of the knife being held in close contact with the staff, the two are carried forward into the bladder, thus avoiding many of the risks of the operation as ordinarily performed. In concluding, he

referred to the great improvement of the Bigelow operation over the old method of crushing for stone. He had no doubt that this method renders both lateral and suprapubic operations much more rare than they have been in the past.

DR. HINGSTON, of Montreal, believed that the suprapubic operation was one to be performed only in exceptional cases. These he classified as follows: 1. In those cases of stricture in which obstruction cannot be overcome in time to relieve the patient of great suffering. 2. In cases of prostatic obstruction. 3. In cases of tumors of the bladder which would interfere with the lateral operation. 4. In cases in which the stone is too hard or too large to be removed either by lithotrity or by lateral lithotomy. He had removed, without injury to the soft parts, a stone weighing five ounces and five drachms.

SIR WILLIAM MACCORMAC, of London, had performed the operation of supra-cystotomy occasionally. He had never seen any untoward consequences, and the operation seems to be devoid of all risk. He did not consider that drainage was necessary after this operation. The bladder empties itself freely and the drainage tube is a source of irritation.

DR. HUNTER MCGUIRE said that the only object of his paper was to describe the two cases in which he had made an artificial urethra to relieve prostatic obstruction. The various operations referred to were not applicable to all cases, while the formation of an artificial urethra could be done in all cases. He was surprised to hear that supra-pubic cystotomy was considered dangerous. It had the advantage of avoiding some of the unpleasant consequences of the lateral operation, such as dribbling of urine and impotence.

DR. J. H. PACKARD did not want to be considered as an advocate of supra-pubic cystotomy. It had, however, been shown that the danger attributed to this operation did not exist. He considered that the operation was a valuable resource in certain cases. After this operation he had noted diminution in the size of the enlarged prostate. This he attributed to the rest afforded the bladder. It will take place in whatever way the rest may be obtained.

THE PRESIDENT, DR. D. HAYES AGNEW, being called upon, said the ground had been so thoroughly covered that there was little to be added. He agreed with those who held that no single operation was applicable to all cases. The supra-pubic operation may be appropriate in certain cases, while in others the perineal operation is the proper one. In order to avoid the unpleasant consequences which occasionally follow the perineal operation in children where the prostate is small, he avoids the introduction of the finger into the bladder and removes the stone with forceps not much larger than the staff.

While there may be no damage done in the supra-pubic operation in skilled hands, yet with the inexperienced operator there will be risk of opening the peritoneal cavity. He thought that a number of cases had been reported of rupture of the bladder following injection of the organ after dilatation of the rectum with the rubber bag.

The following were elected

OFFICERS FOR THE ENSUING YEAR:

President.—Dr. D. W. Cheever, of Boston.

Vice-Presidents.—Dr. T. G. Richardson, of New Orleans, and Dr. John B. Roberts, of Philadelphia.

Secretary.—Dr. J. R. Weist, of Richmond, Ind.

Treasurer.—Dr. P. S. Conner, of Cincinnati.

Recorder.—Dr. J. Ewing Mears, of Philadelphia.

Members of Council.—Dr. W. F. Peck, of Davenport, and Dr. S. W. Gross, of Philadelphia.

The *next meeting* to be held beginning the second Tuesday of May, 1889, in Washington.

Chairman of Committee of Arrangements.—Dr. J. S. Billings.

AFTERNOON SESSION.

DR. W. T. BULL, of New York, read a paper on

THE SURGICAL MANAGEMENT OF TYPHLITIS AND PERITYPHLITIS.

He reported seventeen cases operated on by himself. These he divided into three groups: the first, including ten cases in which abscess was opened by incision without opening the general peritoneal cavity at periods varying from seven days up to six weeks from the beginning of the attack. All of these cases recovered.

The second group included six cases in which laparotomy was performed seven times for supposed perforation (one patient being operated on twice). The earliest operation was at the expiration of thirty-six hours, the latest on the fifth day. Death occurred in two of these cases, one from incomplete operation and the other from imperfect technique.

The third group contained but one case, but the author hoped that in the future more would be reported. In this case laparotomy was performed in the presence of threatening symptoms on the twelfth day of an attack of perityphlitis. No pus was found and no signs of recent peritonitis. The appendix was surrounded by old adhesions. The diagnosis of this class of affections was then referred to.

The operations described were laparotomy and simple incision of the abscess. Antiseptic precautions should be adopted in both. The incision for laparotomy should begin a finger-breadth above the right Poupart's ligament and extend upward four inches. The peritoneum should be divided at the lower angle of the wound. Adhesions are then separated, and any pus found, evacuated. The intestines should not be allowed to escape through the wound; the region behind the cæcum must be carefully examined. If there is perforation or gangrene of the appendix, it should be removed at its junction with the cæcum. After thorough washing out of the cavity a drainage tube should be introduced, passing to the bottom of the iliac fossa.

For opening an abscess, the incision should start from the point before mentioned and continue either parallel with the ligament or more vertical according to the position of the abscess. Incision may be required above and parallel with the crest of the ileum, if the maximum of tumefaction is found there.

A brief report of the cases operated upon was then given and the following conclusions presented:

Our present knowledge justifies the statement that both the cæcum and appendix may be the starting-point of an inflammation spreading to the peritoneum or to the peritoneum and cellular tissue of the iliac fossa constituting a complicated lesion which for convenience' sake we may call "perityphlitis." This may be in its clinical course

resolving or suppurative; each marked by definite symptoms in some cases, in others difficult to recognize.

Needle exploration is a justifiable and desirable method of diagnosis, though attended by some risks. These may be reduced to a minimum if care be taken to reserve the practice for cases in which the symptoms have lasted several days and in which a distinct indication, "tumor," can be made out.

Suppurative perityphlitis may be a spreading or limited (circumscribed) perityphlitis. Both begin with the same set of symptoms, and it is important to discriminate between them in the first twenty-four or forty-eight hours, or even on the third day.

The presence of any of the local or constitutional signs of general peritonitis justifies the diagnosis of a spreading or generalization, and calls for the performance of laparotomy and the repair of the lesions found.

The absence of these signs or their strict localization warrants delay of a varying length. Any time after a week the abscess may be opened by an incision which must reach the pus whether it be extraperitoneal or intraperitoneal.

In doubtful cases the risk of the operation is less than the risk of the disease.

The propriety of exploring and removing the appendix in recurring cases must still remain *sub judice*.

Dr. J. Ewing Mears, of Philadelphia, then read a paper on

THE PROPRIETY OF SURGICAL INTERFERENCE IN PERFORATING TYPHOID ULCER.

The present state of our knowledge and our largely accumulated experience have enabled us to define with a degree of exactness the limits of surgical interference in certain affections of the abdominal organs. The researches of Senn have shown that complete extirpation of the pancreas is invariably followed by death, while partial excision is a feasible operation. We are also able to define the limits of operation in affections of the spleen and kidneys. We may venture to approach the discussion of operative interference in perforating typhoid ulcer with the feeling that here we may be compelled to define a limit to the employment of surgical measures, not without regret at our inability to overcome the barriers which oppose success, but with a desire to maintain always the good repute of surgical science and art.

A clear distinction must be made between the widely different conditions which precede and follow perforation in typhoid ulcer and in ulcerations of the intestinal canal due to other causes. In typhoid fever, in addition to the intestinal lesions, there is a general degenerative process involving all the important organs. In traumatism the general condition of the patient may be good. In inflammatory conditions, while the general system may be profoundly impressed, the lesion may be regarded as local in its nature. In diseases of a chronic character, the system has accommodated itself to the impression made by the morbid affection, and the degenerative changes which may occur are not usually general in character.

The symptoms are usually quite distinctive. Death, as a rule, occurs on the second or third day; rarely the fatal result may be postponed two or three weeks, and instances are recorded in which recovery has taken place, adhesion having occurred between the edges of the perforation and adjacent parts.

A careful search of current medical literature reveals but four cases of surgical interference in perforating typhoid ulcer, in all of which a fatal result occurred. The reports of these four cases were given in detail. These cases were operated on by the following surgeons, Prof. Kussmaul, of Strasburg, Mr. T. H. Bartlett, of Birmingham, Dr. R. B. Bontecou, of Troy, N. Y., and Dr. T. G. Morton, of Philadelphia. In Prof. Kussmaul's case the disease was severe and perforation occurred early when the infective process was at its greatest height and the vital forces at the lowest point. In Dr. Morton's case the disease was mild, "a walking case." In both of these cases the shock consequent upon the perforation was prompt and profound. In the first case operation was performed within a few hours, but death without reaction from shock occurred in eleven hours. In Dr. Morton's case operation was resorted to twenty hours after the accident. Six hours after operation, the patient sank into a collapsed condition and died. The operations in these cases were performed by surgeons of experience, under strict antiseptic precautions and within a reasonably short time after the accident. We must, therefore, look for the cause of failure in the systemic condition; the degenerated and devitalized condition of the organs and tissues caused by the infectious process in active progress, utterly deprived of the power to resist the shock of operation; or in the condition of the structures beginning to recover from the effect of the poison in milder form, extremely sensitive to any rude impressions and wanting in tone and power of resistance. It is in the latter conditions alone that the surgeons may hope to achieve success by surgical interference, and then only when such methods are adopted as will reduce to the lowest point shock of operation.

The following propositions and suggestions were offered:

1. Surgical interference is not justifiable and should not be instituted in cases of typhoid fever in which perforation occurs when the infective process is at its height.

2. In mild cases of the disease in which the pyrexia has not been of high grade, and in which perforation occurs at the end of the third week, or later when the stage of convalescence is fully pronounced, laparotomy may be performed. Surgical interference in cases of this character is advocated with the hope that if the method of operation suggested by Lücke,—laparotomy with the creation of an artificial anus—be adhered to, success may be attained.

3. Rapidity of operation will be an essential factor in the achievement of success, through which prolonged exposure of the cavity will be avoided and shock greatly lessened.

Dr. B. A. Watson, of Jersey City, said that in cases in which perforation occurred the sooner operation is performed the better. He considered that it is safer to make an exploratory incision than to use the needle.

In regard to the paper of Dr. Mears, it covered the ground completely. In those severe cases of typhoid fever in which perforation occurs and life is about ebbing away, it would be folly to resort to operation; but in mild cases in which perforation occurs the operation should be done early.

DR. R. B. BONTECOU, of Troy, N. Y., had performed the operation in one case of perforation in the third week of typhoid fever; the patient, however, died. He thought that it would succeed in some cases, as in those in which perforation follows imprudence during convalescence.

DR. C. B. NANCREDE though that the proper place for incision was two inches to the right of the anterior superior iliac spine. He had operated in two cases; in the first there was no pus, but three or four perforations were found. This patient recovered. The second case was that of a child operated on four days ago. The patient had done well since the operation.

DR. GORDON, of Portland, referred to the absence of symptoms met with in these cases, and cited a case in which the symptoms were not distinct, but in which a pint of pus was found, with general peritonitis and perforation of the appendix. In this case an incision on the right side would not have reached the pus.

DR. D. W. CHEEVER, of Boston, reported a case in which strangulation of an old hernia occurred in the third week of typhoid fever, the patient not being seriously ill. A simple incision through the sac was made and the bowel replaced, but the patient did not rally from the shock.

DR. W. H. CARMALT, of New Haven, referred to a case which had come under his observation with symptoms of intestinal obstruction. Operation was suggested but refused. The patient died and the autopsy showed perforation of the appendix and extravasation of fecal matter. The appendix was attached deep down in the pelvis, where there was a small collection of pus. This was reached only with the greatest difficulty and after turning the intestines out of the abdominal cavity. This abscess was inaccessible to any of the ordinary methods of operation. The careful exploration of the rectum in this case failed to reveal any sign of disease.

DR. JOSEPH RANSOHOFF, of Cincinnati, thought that the general impression that perityphlitis is necessarily associated with perforation, was an error. There are two classes of cases. In one there is a distinct tumor and in these early operation is by no means indicated. In these cases adhesions have formed, and there is a natural tendency to cure. In these cases the abscess finally perforates the abdominal wall or is relieved by incision. The second class is that in which the symptoms of perforation develop suddenly. In these cases the incision should be median.

DR. T. F. PREWITT, of St. Louis, thought that there must be many cases of inflammation in the region of the cæcum that never suppurate. He recalled a number of these cases, two of which had died, one from perforation, and the other, an old man, from exhaustion incident to an intestinal affection. In almost all of these cases the patients had had three or four previous attacks.

DR. REGINALD H. FITZ, of Boston, held that the appendix was the seat of disease in the great majority of cases. The symptoms usually enable the physician to make a correct diagnosis. The use of the exploring needle was not considered advisable. The cæcum can always be readily found by remembering that it is attached to the colon.

DR. GEORGE W. GAY, of Boston, remarked that in the cases in which he had operated, recovery had followed in those cases in which offensive pus had been evacuated, while in those in which he had found only serum and flakes of lymph, a fatal result followed operation.

THURSDAY, SEPTEMBER 20TH.—MORNING SESSION.

DR. GEORGE W. GAY, of Boston, read a paper on

THE COMPARATIVE MERITS OF TRACHEOTOMY AND INTUBATION IN THE TREATMENT OF CROUP.

Dr. O'Dwyer's method of intubing the larynx, he said, has now been before the profession in a prominent manner about three years, and it is surely gaining favor, as its merits and its limitations are being more clearly understood. The operation has its advantages and its disadvantages. It gives relief to the dyspnœa and it saves lives. The statistics of recovery vary much, as in tracheotomy. Twenty-six per cent. is a fair average after intubation. The recovery rate in 327 tracheotomies performed at the Boston City Hospital was twenty-nine per cent. In about 100 cases of intubation performed at the same institution, the rate of recovery was twenty-six per cent., showing a slightly smaller percentage than the old operation. It is not claimed that these figures and facts are conclusive. The number of intubations is, as yet, too small to settle the question. The recovery of patients under three years of age was in the same proportion after each operation, namely, twelve per cent. O'Dwyer, Brown, and Waxham save about one in four after intubation; Huber and Montgomery save one in two; Northrup and Denhard save one in five; Jenning, one in ten; Chatham, one in fifteen; and A. B. Strong, one in thirty-one. This variation of results in the experience of different operators, proves conclusively that the type of the disease determines the result to a great extent—far more, in fact, than any mode of treatment. The conclusion on this point is that the new operation saves nearly or quite as many patients as did the old.

In regard to the facility of doing intubation, it may, like tracheotomy, be easy or difficult, according to the age of the child, the conditions of the larynx, and the strength of the patient. Both operations are difficult in children under three or four years of age, and both are attended with some danger. In tracheotomy the risk lies principally in hemorrhage and collapse. In intubation, it lies in pushing membrane, etc., down in front of the tube, producing more or less complete obstruction. In very weak children, collapse may result from prolonged efforts at placing the laryngeal tubes. Under these circumstances the surgeon should choose the operation with which he is most familiar. The old operation can be done with one good assistant. Intubation requires at least two fairly good ones. Unless great care be taken, the operator's finger may be severely bitten, which, in at least one case, has resulted in death.

It is desirable to have a physician close at hand for three or four days after both operations. If the tube must be allowed to take care of itself, intubation is preferable. If ordinary care, such as a good nurse or other clever person can give, is available in cases located at a great distance from a physician who can place O'Dwyer's tube, then the old operation is better, there being less danger of fatal obstruction and the question of feeding giving less anxiety.

The weight of testimony goes to prove that it is less work to take care of intubated than of tracheotomized patients. The time occupied in caring for the tube in

the latter class is largely taken up in feeding the former class of patients.

Northrup's statistics of 107 autopsies performed at the New York Foundling Hospital, go to prove that there is no such thing as "food pneumonia," as in no instance were signs of food found in the smaller bronchi. Dr. O'Dwyer advances the opinion that the secondary lung affections, especially pneumonia, are due to retained secretions, which, owing to the presence of the tube in either operation, cannot be ejected by coughing. Others hold that this complication is due to the fact that the air enters the lungs without first being warmed and moistened by passing through the nasal chambers. The author ascribes these affections to the natural tendency of exudative processes to extend in all directions, basing the opinion upon the fact that pulmonary complications are as frequent in cases not receiving surgical treatment, run the same course, and are as fatal as in those in which operation is resorted to.

While a wound in the skin is objectionable on general principles, yet the wound of tracheotomy gives little trouble and does little harm. The diphtheritic poison gains admission to the system before the wound exists, and the course of the disease, as regards sepsis, is the same after as before the operation. In only 6 of the 327 operations at the City Hospital of Boston was diphtheria in the wound noted; 3 of these cases recovered. Both tubes may produce ulcerations in the trachea, but the result is seldom serious.

Conclusions.—1. Intubation may be tried in all cases of croup.

2. It is preferable in young children and in cases in which the tube must be left entirely to itself.

3. It may be resorted to for euthanasia, provided the operator is reasonably expert and can do it without producing collapse.

4. Tracheotomy is called for in those cases in which intubation cannot be done or in which it fails to give relief; or in which the laryngeal tube is repeatedly ejected or requires frequent removal for cleansing. It may also be required in those cases in which sufficient food cannot be given while the O'Dwyer tube is in position. It is also preferable in cases situated at a distance from a surgeon capable of introducing the laryngeal tube.

5. The tracheotomy instruments should always be at hand in intubation in cases of emergency.

DR. H. H. MUDD, of St. Louis, said that intubation had been done as a precautionary measure in many cases in which tracheotomy would not have been thought of. Some of the good results of intubation are to be attributed to this fact. In most of his cases of intubation, in which the patient survived, he had found it necessary to resort to tracheotomy, patients have recovered after tracheotomy in whom intubation had proved unsuccessful.

PROF. THOMAS ANNANDALE, of Edinburgh, called attention to the value of the introduction of a tube through the glottis in cases of operations about the throat in which there was risk of suffocation or of hemorrhage into the trachea.

DR. HUBER, of New York, said that he had performed intubation in 94 cases, with recovery in 37. He does not operate early. He considers the internal use of bichloride of mercury as of equal importance as the intubation. There is an occasional advantage in using a small tube, with the expectation that it will be coughed out, and with it a portion of the membrane, and affording an opportunity for feeding while the tube is out.

DR. T. F. PREWITT, of St. Louis, said that in one case of diphtheritic paralysis he had, in order to avoid passage of fluid into the larynx, passed a catheter through the glottis and plugged the larynx with a sponge. This permitted the fluid to go into the œsophagus without risk of entering the trachea. After feeding, the sponge and tube were removed.

DR. D. W. CHEEVER, of Boston, advocated the disuse of anæsthetics in cases of tracheotomy, provided proper assistants can be secured. The operation is not accompanied by much pain. By avoiding the anæsthetic many of the risks of the operation are avoided.

DR. L. MCLANE TIFFANY, of Baltimore, then read a paper on

PREGNANCY AND OPERATIVE SURGERY: THEIR MUTUAL RELATIONS

The following conclusions were presented: 1. Pregnancy is a physiological condition and does not contraindicate a surgical operation. 2. During pregnancy temporary strain may be exerted on some organ—*e. g.*, kidney, inducing impairment of function. 3. A surgical operation upon a pregnant woman is to be conducted so as to avoid inducing abortion, in itself a serious accident. 4. The main cause of abortion after operation is sepsis. 5. The probability of sepsis after operation is increased if the patient is suffering from disease, either temporary or chronic. 6. Abortion may result from operation—shock perhaps. 7. Hemorrhage does not seem to produce abortion. 8. Union of fracture may be retarded by pregnancy. 9. Recorded cases show that the unborn child receives no evil impress when the mother is subjected to operation. 10. When a surgical operation upon a pregnant woman is under consideration, the function of all the patient's organs must be carefully investigated and regulated. An operation then conducted antiseptically may be expected to result as though pregnancy were not present.

DR. J. EWING MEARS, of Philadelphia, thought that while pregnancy was to be regarded as a physiological process in the native woman, it would not be considered in this light in the society woman. Another important point to be considered was whether the operation required was one of expediency or of necessity. In the latter case the surgeon must do his duty let the result be what it may; but whether or not operations of expediency were to be performed on the pregnant woman was a question only to be decided by further experience.

DR. P. S. CONNER, of Cincinnati, reported a case of subcutaneous operation for ankylosis of the knee in a woman who, it was subsequently learned, was six weeks pregnant. The operation was followed by severe septic infection, but this did not interfere with the normal course of the pregnancy.

DR. WILLIAM HUNT, of Philadelphia, raised the question whether or not in the case of inevitably fatal injury to a pregnant woman, as from burns, it was justifiable to run the risk of sacrificing the mother a few days sooner, when by so doing the life of the child might be saved, or must we wait until the last breath has left the body before making the incision?

DR. R. B. BONTECOU, of Troy, reported the case of a

rupture of an umbilical hernia in a woman seven months pregnant. The intestines were out four hours. They were then cleaned and replaced. The woman recovered and a healthy child was born one month later.

DR. L. MCLANE TIFFANY thought that, in the case suggested by Dr. Hunt, there could be no question as to the propriety of operation. By so doing one life may be saved.

DR. N. P. DANDRIDGE, of Cincinnati, read a paper on

NERVE-STRETCHING.

The following conclusions were presented: 1. That nerve-stretching should be condemned in all forms of central disease, such as tabes, myelitis, etc. 2. That it offers little prospect of relief in tetanus. 3. That it should be regarded as a reliable method in cases of persistent neuralgia and peripheral paralysis of sensation in the extremities. 4. That stretching the facial is indicated in tic convulsif. 5. That further trial is justified in reflex epilepsy. 6. That stretching the lingual should be tried in painful affections of the tongue. 7. That resection should always be preferred to stretching in the spinal accessory and in the branches of the fifth nerve, except the lingual.

AFTERNOON SESSION.

DR. DE FOREST WILLARD, of Philadelphia, read a paper on

NEPHRECTOMY.

Case 1. Gunshot wound of kidney.—Male, mulatto, aged seventeen, was shot July 10, 1887, at such close range as to burn the clothing and skin. He was able to walk one-fourth of a mile to the hospital, and the shock was but moderate. Symptoms of internal hemorrhage steadily increased, and when seen by Dr. Willard, four hours after the injury, the signs of collapse were imminent. The ball entered just above the eleventh rib, three and one-half inches from the spinous process. There was no wound of exit. Almost pure blood was voided from the bladder, and continued to flow freely. The entire left side of the abdomen was dull on percussion, and there was every evidence that there had been an escape of intestinal contents, as well as urine and blood, into the peritoneal cavity. Abdominal incision was, therefore, chosen as best suited to arrest hemorrhage, repair injured organ, and remove clots. The bladder was found full of blood, but uninjured. Ureters, the same. The huge hæmatocele was found to be retro-peritoneal, filling all the tissues in the loin, and downward into the pelvis. The left kidney was traversed by the ball from the centre of the rim to the infundibulum, and the renal artery and vein cut. Aseptic silk ligatures were applied, and the organ removed. The ball had passed behind the peritoneum without injuring other organs, and could not be found. No blood or feces were found in the peritoneal cavity. The site of the extirpation was thoroughly mopped with sublimate solution, 1 : 10,000, made with boiling distilled water, and the abdomen irrigated with hot distilled water. The utmost precautions were taken to prevent infection, and all the dressings were thoroughly antiseptic. The temperature during the next four days varied from 99.4° to 101.4°. About twenty ounces of slightly albuminous urine were secreted daily. The skin was kept active, and no signs of uræmia at any time made their appearance. The patient, however, died of loss of blood, shock, and exhaustion, eighty-six hours after the injury. At the post-mortem no blood or pus was found in the peritoneal cavity, and the adhesions between the serous surfaces were very slight. There was no pus at the site of nephrectomy, and the hæmatocele was perfectly aseptic. The ball had grazed the eleventh rib, passed just below the pleura without entering it, had perforated the diaphragm, left kidney, the renal artery, and vein and sheath of the aorta just at the origin of the renal artery, being found lying directly upon the aorta. The right kidney was healthy.

In his remarks he dwelt upon the advantages of abdominal incision, in which the probabilities of other organs having been injured were so great; as hemorrhage could be arrested, perforations repaired, and escaped fluid removed. Drainage through the loin or abdomen was not advisable, provided urine had not escaped into the peritoneal cavity before the operation. The hæmatocele, if large and retro-peritoneal, could not be thoroughly removed, and should, therefore, be allowed to remain undisturbed. All fluids in the abdominal cavity should be removed.

The three primary nephrectomies for gunshot wound thus far reported, have all been done by Philadelphia surgeons. Keen (*Trans. Amer. Surg. Asso.*, vol. v. p. 193) removed the left kidney of a girl of eighteen, in whom the ball had perforated the stomach, liver, spleen, and kidney. This patient died on the fifteenth day. Price (*Trans. Penna. State Med. Society*, 1888) removed the right kidney in a girl of fourteen, in whom the liver was also perforated. His patient recovered after multiple abscess of the liver. Dr. Willard's case died on the fourth day. In none of these cases was there anuria.

Case 2. Nephrectomy for tubercular kidney.—Female, aged thirty-two, married eight years, but never pregnant, Tubercular history of ancestry uncertain. Failing in health for ten months. Seven weeks ago first noticed tumor in right side of abdomen. Has had increasing pain in this region; this is now very severe at times. Has emaciated rapidly. Temperature varying from 99° to 101° in the evening. Diarrhœa quite constant. Passes large amounts of pus in the urine. Urine, one-sixth albuminous, but contains no casts, and no distinctive cell elements. Tumor rounded in form, occupies the space from the right renal region forward to linea semilunaris, and vertically from lower margin of liver to line of anterior superior spinous process. Indistinct dulness extending into pelvis. Resonance between liver and tumor. Tumor movable.

Diagnosis uncertain as to purulent kidney or sarcoma of kidney. The size of the tumor, and its projection forward, determined the selection of the abdominal median incision. The right side of abdomen was found filled with thick sacs, giving indistinct sense of fluctuation. From it extended downward two elongated masses, one evidently a pus-filled ureter, and the other a mass extending down from the external iliac muscle, and passing under Poupart's ligament. Puncture evacuated only a few drachms of pus, and did not diminish its size. Tearing open the sac, the kidney was found riddled with multiple abscesses. The vessels and the ureter lower down were tied with silk ligatures, and the kidney removed. The abdominal cavity was irrigated with distilled water, drainage tubes inserted behind the uterus and into the site of the nephrectomy, and the wound closed with one set of

sutures. The woman was exceedingly low during the operation, but rallied, so that the temperature rose to 99°, and she became perfectly conscious. Two hours after operation she suddenly sank and died.

Post mortem showed that behind the suppurating kidney, and in a separate sac, divided from it by a wall two lines in thickness, was another pus sac; this sac was three inches wide, and the pus had worked its way down the aortic, common iliac, and iliac arteries to Poupart's ligament. If nephrectomy had been attempted, this sac might have been drained and the kidney never reached at all. No hemorrhage after operation. Death from shock; the other kidney was enlarged, but not diseased.

DR. W. W. KEEN, of Philadelphia, believed that blood exuded between the folds of the peritoneum was not a source of danger, and that it might be left without interference. If we could make out that the kidney alone was injured, the lumbar incision would be the proper one. Where there is a probability of injury of other structures, the abdominal incision is the best.

DR. JAMES MCCANN, of Pittsburg, reported a case of nephrectomy for multiple abscess, in which the patient died suddenly six hours after operation.

DR. L. MCLANE TIFFANY, of Baltimore, held that in simple gunshot wound of the kidney the proper plan was to drain the kidney through the lumbar region and not to perform nephrectomy.

DR. CHARLES T. PARKES, of Chicago, reported a case of gunshot injury of the abdomen, in which, in addition to a number of perforations in the bowel, the ball entered the kidney. The intestinal wounds were closed. No operation was performed on the kidney. The patient died from hemorrhage from the kidney twenty-four hours later.

DR. KEEN thought that in the condition referred to by Dr. Tiffany the proper plan was to drain, but when there is much injury of other parts, the patient will stand a better chance if the wounded kidney is removed.

DR. ROBERT F. WEIR, of New York, said: If there is simply a gunshot wound of the kidneys, the organ should be thoroughly exposed in order to ascertain the extent of the injury. Their thorough drainage should be employed, and to guard against hemorrhage the wound should be tamponed with iodoform gauze.

DR. H. H. MUDD, of St. Louis, reported a case of lacerated wound of the kidney, in which drainage was adopted. Irregular fever and loss of strength supervened, and fifty-one days after the injury the kidney was removed. The whole organ was in a state of parenchymatous nephritis.

DR. C. B. NANCREDE, of Philadelphia, had, in his paper last year, recommended that in gunshot wounds of the abdomen, involving the kidney, an attempt should be made to save the organ, when that was possible. He had also suggested packing of the kidney to prevent hemorrhage.

DR. R. N. ISHAM, of Chicago, considered hæmaturia a pathognomonic sign of injury of the kidneys. There are two forms of laceration of the kidney, those in which the capsule is involved in the injury, and those in which it is not. In the first, operation will probably be required. In the second, no operative procedure may be required.

DR. DAVID W. CHEEVER, of Boston, then read a paper on

SHOCK.

The operative surgery of our time has annulled pain, arrested hemorrhage, and averted septic absorption, but it has not prevented shock. The object of the paper was to inquire whether or not modern surgical procedure had diminished shock, wherein it fails to do so, and to suggest improvements of its defects. A simple description of the degrees of shock is, apprehension, fluttering, sweating, chilliness, pain, vertigo, nausea, faintness, convulsions, unconsciousness, and collapse. Moderate shock terminates in reaction. Severe shock is more lasting, and is a condition in which a feather turns the scale against the patient. An operation at this period causes renewed and prolonged shock. The effect of modern surgery has been to diminish primary shock, and to increase secondary shock. The time of an operation since the introduction of anæsthetics has been much prolonged. Do we realize what this prolonged cutting, pinching, and dissection mean to the nervous system? It is unphilosophical and fatal to operate in cases of primary shock before reaction has come on. The golden moment of fairly established reaction must be seized before traumatic fever sets in. This moment comes in from six to eighteen hours after the injury, or it never comes. Anæsthesia does not diminish the existing shock, but only annuls the additional shock from pain produced by cutting. If prolonged, it adds to the secondary shock. There is lowering of bodily temperature after operation under anæsthesia, even to 97° or 96°. This is due to the anæsthesia, which, if prolonged, ends in dripping sweat, to careless exposure of the patient, and largely to antiseptic irrigation, and to the application of cloths wet with antiseptic solutions around the seat of injury. Nausea frequently follows anæsthesia. This is one of the marked symptoms of severe shock. It is a most dangerous factor in preventing reaction.

In order to diminish shock: 1, wait for reaction; 2, never neglect to calm the mental shock by a cheerful word and personal presence; 3, give alcohol a quarter of an hour before anæsthesia; 4, make the anæsthesia short; 5, operate as rapidly as possible; 6, as short dressing as possible; 7, avoid chilling of the patient.

To promote reaction after operation: 1, persistently and carefully applied dry heat; 2, liquid nourishment combined with a stimulant, and a little laudanum by enema; 3, subcutaneous injection of brandy; 4, aromatic spirits of ammonia by the mouth; 5, black coffee and brandy—the stimulant *par excellence*, when it can be retained by the stomach; 6, quiet, a more than horizontal position, sleep, assurance that all is over and doing well.

Modern surgery has won three great triumphs: 1. It substitutes sleep for pain. 2. It averts secondary hemorrhage by animal ligature. 3. It prevents fermentation by germicidal applications. Can we add a fourth, by stilling the nervous system and averting secondary shock?

DR. W. W. GAY, of Boston dwelt upon the importance of preserving animal heat. He is in the habit of using a small dose of morphia hypodermatically ($\frac{1}{20}$ to $\frac{1}{12}$), before beginning a capital operation. If the operation is a severe one, the patient is not removed from his bed, and is given only a few whiffs of ether to obtund the pain of the first incision.

DR. C. B. NANCREDE is in the habit in cases in which it is doubtful whether or not the patient has recovered sufficiently to bear an operation, of employing the "ether

test." If after the administration of an anæsthetic is commenced, the pulse and the general condition improve, the patient will stand the shock of the operation.

If, however, the respirations increase in rapidity, and the pulse becomes frequent and weak, the ether is removed. These patients never react. Shock is often kept up by a crushed limb. In these cases the condition often rapidly improves when the limb is removed. In order to favor the flow of blood to the head, and to overcome the consequence of its collection in the abdominal vessels, he had employed elevation of the limb and the application of the Esmarch bandage.

DR. LANGE, of New York, thought that the influence of loss of blood in the production of shock, was underrated. He could not recall an instance of prolonged operation in which shock followed, provided extreme loss of blood was prevented. In operations in which loss of blood was apprehended, he employs large rectal injections of hot water.

DR. B. A. WATSON, of Jersey City, referred to the experiments which he had made showing the influence of ether and chloroform on temperature.

DR. DAVID PRINCE, of Jacksonville, recommended the use of small doses of morphia with tincture of digitalis hypodermatically to guard against reflection and depression. He considered reflection an important cause of shock. He also advised that the temperature of the part operated upon should be maintained.

DR. B. A. WATSON moved that a vote of thanks be extended Dr. C. H. Mastin, of Mobile for his efforts in introducing and perfecting the plan of organization of the

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

This motion, seconded by Dr. E. M. Moore, of Rochester, and by Dr. William H. Pancoast, of Philadelphia, was unanimously adopted.

After extending to the retiring officers a vote of thanks, the Association adjourned to meet in Washington, the second Tuesday of May, 1889.

AMERICAN GYNECOLOGICAL SOCIETY.

Thirteenth Annual Meeting,
Held in Washington, September 18, 19, and 20, 1888.

(Specially reported for THE MEDICAL NEWS.)

(Concluded from page 343)

SEPTEMBER 18TH.—AFTERNOON SESSION.

SIR SPENCER WELLS, of London, read a paper entitled

CASES OF OVARIOTOMY PERFORMED TWICE UPON THE SAME PATIENT.

During the past three months he had twice performed ovariotomy upon subjects who had previously submitted to the same operation at his hands, one twenty-four years previously, and the other eight years previously. His entire experience with the secondary operation includes sixteen patients. The causes were various, trouble from the stump, neuroses, tumor in the other ovary, etc. Olshausen reports a case in which he had performed laparotomy five times upon the same person, the patient dying one year after the fifth operation; all of these operations were done in the course of six years. The speaker believed that if a patient recovered from an ovariotomy in which only one ovary had been diseased, the chances that the other ovary would also become diseased were relatively few, perhaps not more than one in fifty.

DR. T. GAILLARD THOMAS, of New York, could recall six cases in which he had performed ovariotomy twice upon the same patient. In none of these had any trouble respecting the first operation been the cause for performing the second. In none of the cases did he discover any traces of a ligature upon the stump of the first operation. He differed with Sir Spencer in regard to the removal of the second ovary, and made it a rule to take it away if there were any good excuse for doing so, as it did not materially enhance the danger of the operation and effectually prevented the recurrence of ovarian disease.

DR. GOODELL, of Philadelphia, had performed the secondary operation in two cases. He agreed with Dr. Thomas as to the desirability of removing both ovaries at one operation, and especially if the patient is near or has passed the menopause.

DR. JAMES B. HUNTER, of New York, had performed the secondary operation in three cases. Unless the second ovary was decidedly diseased at the time of the first operation he did not usually remove it.

DR. HOWARD A. KELLY, of Philadelphia, referred to certain statistics in Sir Spencer Wells's book in which he had shown that of two hundred and twenty-three women upon whom ovariotomy had been performed one hundred and seventeen children had been born, only two of whom had died at birth. This might be considered an argument in favor of retaining the second ovary.

SIR SPENCER WELLS, in closing, observed that he did not consider the presence of a few enlarged follicles in an ovary sufficient evidence of disease to warrant its removal. He did not question the propriety of removing the second ovary in old women, nor in young women in whom the second ovary was diseased to any considerable extent.

DR. WILLIAM T. LUSK, of New York, read a paper upon

THE NEW CÆSAREAN SECTION.

Careful study of the questions involved in connection with the Cæsarean operation led him to the conclusion, years ago, that changes must be made in order to put the operation upon a proper basis. Such changes had been formulated by Sänger, and the speaker gave him all praise for the work which he had done. The rules of Sänger had been put to the test by obstetric surgeons and with the exception of his recommendation to exsect portions of the muscular structure of the uterus these rules were generally followed. Those who belittle Sänger simply follow historic precedent in such matters; witness the experience of Sims in his efforts concerning vesico-vaginal fistula. During the past year the speaker had performed three Cæsarean sections, all resulting favorably to both mothers and children. The first case was operated upon to avoid craniotomy and had been reported at length. The second case was in a woman with advanced carcinomatous disease, and in very bad general condition, and who died sixty-two days after the operation from the cancerous disease. In the third case the patient was weak and anæmic, labor pains having begun six and a half days before her entrance into the

hospital. She was rachitic, and craniotomy would certainly have been fatal to her. On the ninth day from the operation she was taken with catarrhal bronchitis, and this was followed by double pneumonia. The child died thirty-six hours after birth from trismus. A plea was made that the Society should undertake a series of investigations having for their object the proper regulation of operations for Cæsarean section.

In justo-minor pelves with a conjugate of not less than three and a third inches, normal delivery can usually be accomplished. Cæsarean section is indicated in cases in which craniotomy has been required in previous labors, in cases of flat pelvis with a two and a half inch conjugate, and in justo-minor pelves with less than three and a third inches conjugate. In deciding between craniotomy and Cæsarean section it should always be considered that the mother's life is of the greater value, hence in some cases craniotomy must be the operation of election. Dohen's table of statistics giving a mortality of twenty-seven per cent. for this operation was out of date, having been prepared before the days of antiseptic surgery. The most recent statistics show a percentage in favor of craniotomy, and Leopold and others have clearly set this forth to check too great enthusiasm for Cæsarean section. The question as to the choice of operations should always be left to the patient and her friends. In cases in which the natural passages are obstructed by tumors or malignant disease it is useless to try and deliver by those avenues. In America the Cæsarean operation had thus far had only forty per cent. of recoveries. The conditions of obstruction to labor should be recognized early, and the relative chances in both operations should be carefully weighed. Thorough cleanliness and disinfection of everything which is to be concerned in the operation are cardinal points, there should be plenty of assistance at each step, it had better be done by daylight, and can generally be done more satisfactorily in a hospital than in a private dwelling. The uterus should be secured by an elastic ligature before it is incised; the suture may be of silk or silver; Leopold uses catgut. One must be certain, by auscultation before the operation, that the fœtus is alive, otherwise the operation is not indicated. The incision should extend from the umbilicus to the pubes, half a dozen long ligatures should then be passed through the edges of the wound, after which the uterus is to be turned out of the abdomen at right angles to the body, and enveloped in hot towels. The uterine incision should be four to five inches long, and the placenta should be quickly detached with the fingers. The elastic ligature will effectually control all hemorrhage. Then the uterus is to be irrigated, the water being allowed to pass out through the vagina. Through the muscular tissue of the uterus eight to twelve sutures should be passed, half an inch from the edges of the wound, the peritoneum being subsequently closed with fine silk or catgut. After the abdominal wound has been closed a full dose of ergot should be given. Fluid food should be given almost as soon as the patient recovers consciousness, and there need not be much fear of vomiting. The more constant and faithful the watching during the subsequent weeks the better will be the chances of recovery. The sutures should be removed in the course of eight to fourteen days. Without the greatest care and all necessary precautions such patients are not likely to get well.

DR. HOWARD A. KELLY reported two cases of Cæsarean section, performed during the past year, one on absolute, the other on relative indication. The first patient was a dwarf, with justo-minor pelvis and two and a half inches conjugate; mother and child saved. The second was a suitable case for craniotomy, but the mother wished a living child, and elected the operation. She recovered, but the child survived only a short time.

DR. H. J. GARRIGUES, of New York, also reported two cases of Cæsarean section, the first being fatal, in a woman with kyphotic pelvis. The second was in a woman with justo-minor pelvis, and was favorable to mother and child. The speaker agreed with Dr. Lusk in the advantages of a hospital for this operation, as compared with a private dwelling, and also in the necessity for many assistants. For ligatures, he believed that silk offered many advantages over catgut, the latter being more difficult to tie, and more liable to slip. Turning out the uterus before extraction of the child, after Müller's method, was to be commended. He was unwilling to accord so great praise to Sänger's labor as did the reader of the paper. He had merely formulated what others had written, and his only original suggestion—namely, to exsect portions of the muscular tissue of the uterus—was now not considered advisable. The speaker's first operation was performed before he knew of the existence of Sänger, and yet it had been recorded by the latter as a Sänger operation. Those who are entitled to most praise and gratitude in this connection are the ones who have introduced antiseptic measures, and who have given us a good method of suturing.

DR. GEORGE J. ENGELMANN, of St. Louis, thought that the results from craniotomy in Europe would be better but for the fact that patients requiring this operation are usually in very bad condition when received at the hospitals. Cæsarean section cases are usually prepared for the operation beforehand.

DR. WILLIAM M. POLK, of New York, had had two fatal cases of Cæsarean section during the past year. In the first case the woman was far advanced in extensive cancerous disease, and lived only fourteen hours after the operation. In the second case the patient had a kyphotic pelvis, with a three-inch conjugate, the operation being performed with all possible precautions, six hours after labor had begun. The only possible neglect was that the uterus was not washed out after it had been emptied of its contents. The patient died in forty-eight hours, from septic peritonitis.

DR. LUSK remarked, in conclusion, that Cæsarean section must never be considered as anything but an operation of last resort.

DR. T. GAILLARD THOMAS, of New York, read a paper entitled

THE ETIOLOGY, PATHOLOGY, AND TREATMENT OF ANTEFLEXION OF THE UTERUS.

He thought there was too great a tendency at the present time to devote excessive attention to things which were new, while conditions which had heretofore been well recognized were being overlooked. There are things still to be learned concerning these well-recognized conditions, among them being that of anteflexion, which is ignored by some teachers and writers. Four varieties were proposed in the treatment of the subject: 1st, that form in which the body alone is

bent; 2d, that in which the cervix alone is bent; 3d, that in which both body and cervix are bent and irreducible; 4th, that in which both are bent and reducible. Each form requires separate and distinct treatment. The term *congenital deformity* of the uterus was considered a bad one, and was not included in the author's classification. Deformity of the uterus did not exist at birth, but was the result of faulty development. The irreducible uterus began to be deformed about the age of ten years, as puberty approached, from various causes, and was intensified by such causes as tight-lacing and constipation, these being potent causes in bending the body or the neck, or both. Flexion may also be produced gradually as the result of poor nutrition; as Graily Hewitt has shown, it may be caused by the pressure influence of tumors, by uterine catarrh, peritonitis, etc. He could not agree with those who considered anteflexion an insignificant condition; between the ages of fourteen and fifty years it might prove of very great significance, some of its effects being vesical irritation, gastric disorder, and various nervous troubles. The prognosis of anteflexion as regards a cure is often bad, but many cases may be greatly relieved by suitable means. Good results should not be expected if cases are treated as though the condition were not of great importance, and even cases which have been well treated frequently suffer relapse, even though the misplacement may have been corrected for months. After serious tissue changes in the organ have once taken place repair is either difficult or impossible. The method which is too commonly adopted of treating this condition with medicated tampons and ill-adjusted pessaries is very apt to prove a failure; each case is a study by itself. An attempt should first be made to replace the organ with the finger and the sound, and then, if the case is a suitable one, a pessary of proper shape and size may be adjusted. Either the Thomas, Hewitt, or Cutler pessary will be appropriate in certain cases, and it may be necessary to substitute one for another of different form from time to time. After the flexion has been overcome the speaker uses a glass intra-uterine stem with a vaginal support of hard rubber, and additional means of treatment are to be had in tonics, electricity, and an abundance of nutritious food. The pessary is usually retained six months. In severe cases of flexion of either the neck or the body dilatation should first be performed; the speaker suggested the instrument of Goodell, before the glass stem is introduced. The patient should be taught to remove the instrument herself if it causes pain. Severe cases of cervico-corporeal anteflexion should be submitted to Sims's operation of posterior section, or, if this be unavailing, the cervical portion should be amputated. The direction of the canal would thereby be much improved, dysmenorrhœa would be relieved, and, in some cases, sterility would be overcome.

DR. GRAILY HEWITT, of London, opened the discussion. We should remember, he said, that anteflexion was often a long time in coming on; it developed gradually, perhaps during years, and when it was accomplished the tissues of the uterus had lost their normal power of resistance. The classification of the reader of the paper seemed to him a satisfactory one. Curability of this condition must often be very difficult if we remember the changes in density, in structure, in relations to which the tissues in question have been subjected. He agreed with the reader that this condition had been too slightingly regarded in certain quarters, especially as to its influence in producing stenosis, abortion, and other serious conditions or accidents, which may often be avoided if this cause is recognized and treated. In place of amputating the cervix, as suggested by the reader, he had found it useful to excise a portion of mucous membrane in the posterior vaginal wall between the posterior aspect of the cervix and the posterior fornix, draw the cervix backward, and secure it by sutures to the posterior wall, thus straightening the uterine canal.

DR. W. O. PRIESTLEY, of London, thought the diagnosis of anterior displacements was not always easy or clear. He remembered that Churchill had once said that in all his experience he had never seen a case of anteflexion. It was desirable that more complete statistics should be published concerning the frequency of certain symptoms which were believed to be common with anteflexion, and also as to the extent to which treatment of them had been effective. He believed that too much attention had been given to this subject, perhaps owing to a miscomprehension of the teachings of Graily Hewitt. Discrimination should be made between those forms of this condition which give rise to symptoms and those which do not; and statistics would also be useful which should show the extent to which anteflexion alone caused appreciable symptoms requiring treatment.

DR. E. VAN DE WARKER, of Syracuse, N. Y., recalled the paper upon anteflexion and its treatment, which had been presented by him to the Society ten years ago, and in which he presented views identical with those in the reader's paper. The reader at that time showed a lack of sympathy with his propositions, and he was very glad that his conversion was evidenced by the paper which he had presented. The speaker had never seen a case of anteflexion with which there were no symptoms, but symptoms varied greatly in degree and intensity. Symptoms might not appear until the complete functional life of the organ began—that is, after marriage. They might also be associated with hysteria and other nervous symptoms. With the conversion of Dr. Thomas it only remained for Dr. Emmet to withdraw statements in his book concerning the iniquitous stem-pessary.

DR. H. P. C. WILSON, of Baltimore, agreed with the statement that anteflexion seldom occurred suddenly; in other words, it was a progressive condition. The most frequent of all causes was constipation, the frequency of which in women is well known. He believed that the present system of educating girls was largely at fault for many cases of this condition. This system was a forcing system, too much being crowded into too few years. Pessaries were undoubtedly of use in some cases, but the speaker had never seen any benefit derived from their use, and he had experimented with all kinds. In cases of anteversion he had seen useful results follow the use of the pessary. He was in the habit of treating anteflexion by Sims's operation of posterior section, dilating the canal after the wound had cicatrized. In nineteen out of every twenty cases of antetlexion there are associated sterility, constipation, and more or fewer nervous symptoms.

DR. BACHE MCE. EMMET, of New York, agreed with the teachings of Dr. Thomas Addis Emmet that anteflexions which gave rise to no symptoms required no treatment. The cause was usually in some preëxisting inflammation

and this, not the displacement, usually called for the treatment. He thought the evidence of this was seen in the fact that if the uterus were raised in the pelvis the symptoms which had been attributed to the displacement disappeared. An ordinary retroflexion pessary accomplished this end without the necessity of resorting to those which were designed for adjustment in the anterior vaginal fornix.

Dr. W. Goodell, of Philadelphia, believed that anteflexion *per se* had no symptoms except such as arose from dysmenorrhœa and sterility. He agreed with the reader in the propriety of using the intra-uterine stem in treating this condition if symptoms seemed to indicate it, but did not think such indications frequently existed. Sterile women and virgins were most likely to present symptoms in connection with anteflexion; it was also of frequent occurrence among the hysterical. For all classes of cases tonic treatment would be beneficial. The speaker never treated this condition by posterior section, his limited experience with the operation having been most unsatisfactory. He frequently practised dilatation for anteflexion and seldom used pessaries.

Dr. W. Gill Wylie, of New York, differed with his teachers, Drs. Thomas and Hewitt, regarding the mechanical theory of displacements. He regarded cases of anteflexion as illustrations of imperfect development, and treated them in accordance with that view. The means which he used were stimulating general and local treatment, dilatation, and drainage. The benefit to be derived from an intra-uterine stem was from its dilating and stimulating influence and the improvement to nutrition which it caused. Flexions might exist without symptoms in his opinion. Sims's operation was indicated for some cases, but he believed it well to omit the incision in the anterior uterine wall, cutting the posterior alone. Ball's method of dilatation combined with section of the posterior lip of the vaginal portion was the best plan of treatment of which he knew.

Dr. Thomas, in closing, admitted with Dr. Wilson that pessaries were not useful in cases in which the womb was irreducible; he had made such a statement in his paper. He was not yet convinced that Sims's operation was not good for certain cases. The object of the intra-uterine stem as a means of treating anteflexion was to produce changes in the innervation and circulation, not merely to cause distention.

Wednesday, September 19th.

Morning Session.

Dr. Thaddeus A. Reamy, of Cincinnati, read a paper on

Amputation of the Cervix in Fifty-five Cases of Cancer.

These were all selected cases, and were operated upon between the years 1876 and 1886. Certain points in regard to this disease were accepted, among them, that its predisposing cause was not known, and that medical treatment of it was unavailing. The accumulating results of surgical treatment tended to show that, in some cases, life could be saved if they were seen sufficiently early in the history of the disease. There was nothing peculiar in the method by which these operations were performed. In some cases the peritoneal cavity was accidentally opened, but without serious result. In those in which this accident did not occur the wound was touched with bromine. No rule was followed as to the quantity of tissue to be removed; the speaker was governed by the extent of the disease in each case, so that in some the section was made at the vaginal junction, in others it was carried to the os internum. The aim in all cases had been to cut widely, rather than deeply, with reference to the diseased tissues. In the greater number of cases it was found that the disease began in the pavement epithelium of the vaginal portion, and spread thence to the vagina with a tendency subsequently to invade the parametrium, and infect the general system, instead of working inward to the cylindrical epithelium of the uterine canal, and thence into the deeper structures. This furnished a hint to the advisability of cutting widely, rather than deeply, as was his plan. The idea of the reader's operations has been conservatism; that is, that no unnecessary tissue should be removed. For this reason the supra-vaginal amputation is preferred to vaginal hysterectomy in cases in which the disease began in the vaginal portion. It was also probable that by the former operation more of the readily infiltrated vaginal tissue would be removed than by the latter. Of the 55 tabulated cases, death had resulted from the operation in 2. During the ten years which were covered by the table there had been recurrence in 29, at periods ranging from a few months to several years from the operation. The rest had apparently been cured. To this table two other cases could be added in which operations had been done respectively nine and fifteen years ago, and in which there had been no recurrence. The diagnosis of cancer was established in most of the cases by the microscope, in the others the clinical evidences were deemed sufficient.

Dr. W. H. Baker, of Boston, opened the discussion. He referred to the useful work which was being done at the Woman's Hospital during his residence there, in connection with this disease, by Sims, with knife, scissors, and chemical cautery, and Thomas, with the actual cautery, and expressed great regret that that work should have been cut short by the decision of the governing authorities at that hospital, that cancer must not be treated there. The operation which had been described by him was a modification of Sims's as well as of Schroeder's supra-vaginal excision, and consisted in amputating the vaginal portion, and then cutting out a cone of tissue from the body of the uterus with a knife, the apex of the cone being the fundus. Of the ten cases which had been reported by him as thus treated, five were still living in six to ten years from the time of the operation, another had died within a year, with no return of the disease. In the speaker's opinion this operation was preferable to total extirpation, which should be limited to cases in which the body was diseased, and in which the infiltration extended upward, rather than laterally.

Dr. John Byrne, of Brooklyn, N. Y., had operated for cancer of the cervix with the galvano-cautery, many hundreds of times. His tables were not yet ready, but he could state that a large percentage of his cases had lived five, ten, or fifteen years after the operation, with no recurrence. In no case upon which he had operated had the disease ever recurred in the stump, though it might have appeared elsewhere.

Dr. E. Van de Warker, of Syracuse, N. Y., referred to the work which he had been doing with the chemical cautery, for cancer of the cervix. It was a method which

was available after nothing more could be done by knife or scissors. In recurrent cases, he first used the sharp curette, and then applied the chloride of zinc to the wound. He recalled a case in which seven such operations had been performed during the past six years.

Dr. Reamy, in closing, said that he had been in the habit of using the chemical cautery as Dr. Van de Warker had described, and could testify to its value. The reason why many of the profession were wont to look upon cancer as always incurable, and always refused to operate for its relief, was because the cases were usually seen when a radical cure was impossible. Many could be cured if they were seen sufficiently early. The value of the supra-vaginal amputation over complete removal of the uterus, was recently recognized by John Williams in his Harveian lectures, and was recommended as sufficiently radical if an operation were indicated.

Dr. Robert Battey, of Georgia, then read his

PRESIDENTIAL ADDRESS.

He referred to the formation of the Congress and the meeting in Washington which had led to a change in the place for holding their annual meeting the latter having been appointed for Boston. He had taken the responsibility of directing the change only after having obtained almost unanimous consent from the Fellows. The Society had been organized and was continued not in the interests of medical politics, but solely for the advancement of science. The plea which he made was that the Society should increase its membership. Though their number was limited to 100, they had never exceeded 58, with an average number of 51 and an average attendance of 29. Statistics were given showing various features of their work at the different meetings which had been held.

The theme for the remainder of the discourse was the basis upon which merit in discovery should rest, the view which obtained upon this subject at common law and under certain statutory restrictions, also the equitable view which should obtain upon the subject among honorable medical men, the necessity of asserting proofs, and the reasonable alternative that if proofs were not presented within a reasonable time the claim should lapse.

Dr. E. C. Dudley, of Chicago, read a paper on

THE TECHNIQUE OF VAGINAL HYSTERECTOMY.

The most recent statistics of Leopold, Klatz, Standi, and others were read, showing the comparatively small mortality of the operation at the present time, and this was advantageously contrasted with the results which were obtained soon after the operation may be said to have had its revival. One of the most important features of the operation is a perfect hæmostasis, and this is now more readily secured by means of forcipressure forceps after the method of Péan or Richelot than by any other. His own method of separating the uterus from the surrounding structures was described, nothing unique being claimed for this portion of the operation. The broad ligaments were then clamped with a sufficient number of forceps, the uterus was cut away and small bleeding points were secured with catch forceps. He thought it was well to follow Leopold, who does not turn the uterus either backward or forward, but drags it directly out. The only advantage in closing the peritoneal wound was to prevent infection from the vagina. As the pressure forceps drag the stumps of the broad ligaments into the vagina, there is no fear of infection from them. The forceps also serve every purpose for drainage. They should be allowed to remain in position from forty-eight to seventy-two hours. Those which secure the smaller vessels could be removed in twenty-four hours. It was not thought necessary that one should be particular to remove the ovaries and tubes. A vulvar pad might be used to the exclusion of any other dressing. It seemed possible to the speaker that a combination might be made in laparotomy and vaginal incision in the removal of large carcinomatous uteri, and large myomata of the uterus, the pressure forceps securing the stumps in the vagina as in ordinary vaginal hysterectomy, the tumor itself being removed through the abdominal opening. So far as the speaker was aware, this plan had not been suggested by anyone previous to himself. He also read a personal letter from Péan in which he demonstrated his priority of use of pressure forceps for securing the stumps of the broad ligaments in the vagina.

Dr. J. B. Hunter, of New York, had operated in four cases with the broad ligament forceps, three of them being successful. He objected to the forceps devised by the reader of the paper as too weak in their grip. He preferred Richelot's instrument as modified by Polk.

Dr. H. T. Byford, of Chicago, Ill., had used the method in question in four cases; he had not given up the use of the ligature, however, and believed it was sometimes the more appropriate.

Dr. Thaddeus A. Reamy, of Cincinnati, thought that no more shock was, as a rule, experienced by a patient after vaginal hysterectomy than after ovariotomy. The forceps shown by the reader seemed weak, but if they were strong enough to prevent hemorrhage, they would also serve the useful purpose of hastening the sloughing process. The forceps were better than the ligature in the latter respect.

Dr. Lane, of San Francisco, stated that he was the first one in America who performed vaginal hysterectomy. He reached his conclusions as to the feasibility of the operation after a series of dissections upon this portion of the body. He had operated fourteen times since 1877. He considered this one of the safest of the capital operations, and had found very little difficulty in controlling hemorrhage. If the broad ligaments were out of reach for the ligatures, the case might usually be considered inappropriate for operation. He had always used ligatures upon the broad igaments, never forceps. The operation was much easier in thin than in fat women; his second operation was done in twenty minutes. His principal care was to avoid the uterus and the rectum. Of his fourteen cases, three have been permanently cured.

Dr. Dudley, in closing, simply said that he had referred to certain steps in the operation as *easy* because they seemed easy to him while operating.

Afternoon Session.

Dr. C. M. Green, of Boston, reported a case of

RUPTURE OF THE UTERUS IN LABOR AT TERM,

the child born alive, the mother subsequently having a full-term child in normal labor.

The patient in this case had a flat rachitic pelvis with

a three inch conjugate. The cause of rupture was unknown. The point was made that if a patient survived rupture of the uterus a few hours she had a fair chance of recovery. Subsequent progress would depend upon the presence or absence of hemorrhage; in the former case laparotomy should be performed. The rupture in question occurred during the patient's third labor, the occiput presenting anteriorly. After a period of three years a fourth labor took place, an eight pound child being normally delivered.

DR. T. PARVIN, of Philadelphia, thought that the great question in such cases was always that of drainage. A posterior rupture is favorable to drainage, an anterior one is not, and usually indicates laparotomy.

DR. GRAILY HEWITT, of London, read a paper on the

SEVERE VOMITING OF PREGNANCY.

As this symptom was occasionally the cause of death, the old saying that "a sick pregnancy is a safe one," could not be literally true. Whether this condition led to a fatal issue or simply be very annoying it may arise from a variety of causes, as shown by Anketan in his work published in 1865. Duncan has considered the condition as showing the common reflex form of vomiting with various grades of symptoms even proving fatal occasionally, and pernicious vomiting which may be associated with disease of the liver or other glandular organs. Lower has also made interesting contributions to the subject. Other possible causes would be emotion, alcoholism, and various displacements and disorders of the uterus, to the latter of which attention and investigation have been directed by the efforts of the reader. Of all the causes which were tabulated by the author it appeared that anteflexion most frequently stood in this position toward vomiting of pregnancy. The severer degrees, with impaction, incarceration, and induration, were, of course, much more mischievous in their effect, but in all of them the condition was usually influenced favorably by treatment. In some cases it was merely necessary to restore the organ to its proper position, in others dilatation was effective. Applications of cocaine to the cervix were occasionally helpful. In addition to the distressing symptom of vomiting there were sometimes associated pain in one side of the pelvis, sensitiveness of the vagina and uterus to the touch, frequency of micturition, etc.

DR. FORDYCE BARKER, of New York, had observed that the vomiting of pregnancy was largely a matter of temperament, a peculiarity analogous to other peculiarities which individuals show. The changes in the vascular and nervous apparatuses of women during pregnancy were so decided that it was not difficult to understand why such phenomena did appear. Though anteflexion was frequently associated with this condition, the speaker could recall instances of anteflexion in which they did not coexist. The condition was frequently a neurosis.

DR. A. J. C. SKENE, of Brooklyn, agreed with Dr. Barker that the condition in question most frequently occurred with women of delicate organization. It was quite likely to coexist with endometritis especially of the corporeal variety.

DR. W. GILL WYLIE, of New York, favored treating the vomiting of pregnancy by Copeman's method of dilatation of the uterine canal, which was referred to by the reader. He would modify that method, however, by limiting the dilatation to the cervical canal. This method had cured three-quarters of the speaker's cases.

DR. GRAILY HEWITT, in closing, thought too much stress was generally laid upon neurosis as a cause of vomiting; the term was too vague. In the treatment of simple cases rest in the horizontal position was frequently all that was necessary. The diagnosis and cause of the condition were the most essential features; the treatment became easy subsequently.

DR. WILLIAM M. POLK, of New York, read a paper on

THE TREATMENT OF CHRONIC ENDOMETRITIS BY DRAINAGE WITH IODOFORM GAUZE.

The disease in question might be divided into two forms: the purulent and the hemorrhagic. It is a prominent symptom in such diseased conditions as salpingitis, retention of the secundines, stenosis of the cervical canal, etc. The hemorrhagic form may simulate, or may be the prelude to malignant disease of the uterus. In such cases as indicate the method of treatment which is recommended the uterus is large, the mucous membrane is thick, and the os internum may be patulous. The principle of the treatment is that which applies to inflamed cavities in general drainage. The essential requirement is to keep the os internum widely open, but this is not best accomplished by either hard or soft tubes. Vulliet's method is to be preferred, and in accomplishing this the uterus is first cleansed and dilated, and then packed with small strips of iodoform gauze. This is removed in twenty-four hours, and new applications are made, the treatment being continued until the mucous membrane has assumed a healthy appearance, and its secretion is normal again. This method of treatment is also efficient as a substitute for curettement, as it renders that operation unnecessary.

DR. VAN DE WARKER then read a paper on

THE DANGERS OF GALVANO-PUNCTURE IN PELVIC TUMORS.

He based his conclusions on three cases:

Case I.—M., aged twenty-three years, married. A large tumor filling the pelvis. Bipolar puncture was made, followed by chronic febrile movement, and subsequent rupture of an abscess that had developed in an abdominal extension of the tumor.

Case II.—H., aged forty-three years, married. Large irregular pelvic tumor. Galvano-puncture with negative pole, large abdominal electrode. Rapid cystiform degeneration of the tumor. Great increase of pus and discomfort.

Case III.—H., aged thirty-seven years. Solid tumor filling the pelvis. Negative galvano-puncture, shot abdominal electrode. Cystiform degeneration of the tumor without pus, with fifty-seven days of low fever, and death from exhaustion.

The author offered the following conclusions: That galvano-puncture of pelvic tumors must follow careful discrimination of the character of the mass. That in certain forms cystiform degeneration is promoted to the discomfort of the patient, if not the jeopardy of life. Tumors that appear to be solid may not be so, but have alveolar spaces of various and irregular size with intervening trabeculæ of varying thickness. This condition has been regarded as either the degeneration of a pure fibroid, a fibroid cyst *de novo*, or a fibroid with disseminated lymph-spaces. Whatever may be the pathological

condition involved, the author believes that the group of tumors enumerated may prove hostile to electrolysis. We have in such instances the elements of cystiform degeneration, which is quickly intensified by the electrolytic current. The trabeculæ separating the lymph-spaces become thinned by the pressure of the accumulating fluid, and as a consequence the general mass becomes greatly enlarged, and, owing to the structure of the tumor, impossible to drain.

Second. The fluid so accumulating may become purulent, and, owing to the same peculiarity of structure, be impossible to evacuate, and thus render laparotomy imperative, no matter what its difficulties.

Third. Peculiar changes may be induced in the fluid from the passage of the current, either septicæmic or ptomainic, that result in a chronic form of blood poisoning with fatal exhaustion.

Fourth. In order to render galvano-puncture of pelvic tumors safe, special diagnostic precautions must be taken. To this end he recommends exploratory puncture with careful antisepsis. If cystiform changes are already taking place, the tumor is not a suitable one for galvano-puncture.

Fifth. The absence of pus in cases following this operation with low persistent febrile reaction (Case III.) points to the exemption of bacterial infection, and the development of some other form of poison, possibly a ptomaine due to the reducing action of electrolysis upon the fluids.

DR. F. H. MARTIN, of Chicago, thought that the dangerous elements of electro-puncture might be avoided. They were usually due to improper currents, improper selection of cases, improper location for applying the current, improper antiseptic precautions, and bungling operators. It would also be desirable to use a graduated rheostat and a milliampèremeter which registers not more than 100 milliampères to each 4 square centimetres of tissue exposure. Vaginal puncture should be used, instead of abdominal, if possible, or the electrode should be passed into the cervical canal. The electrodes should be insulated, clean, and aseptic. Great care should be used in every operation. In answer to a question, he replied that he had cured 5 cases of small fibroid tumor, 5 others were symptomatically cured, and 5 more were still under observation and treatment. In an experience of 70 cases with 3000 applications of electricity he had had no deaths, and but 1 pelvic abscess, which occurred in a woman who had previously had 3 of them.

DR. T. PARVIN, of Philadelphia, thought we should ever be on our guard in the use of this means of treatment. Danger always accompanied it, and death had occurred in some cases.

THURSDAY, SEPTEMBER 20TH.

MORNING SESSION.

The following were elected

OFFICERS FOR THE ENSUING YEAR:

President.—Dr. H. P. C. Wilson, of Baltimore.

Vice-Presidents.—Drs. W. T. Lusk, of New York, and E. W. Jenks, of Detroit.

Secretary.—Dr. Joseph Tabor Johnson, of Washington.

Treasurer.—Dr. M. D. Mann, of Buffalo.

Council.—Drs. J. E. Janvrin, of New York, W. H. Baker, of Boston, C. R. Drysdale, of Philadelphia, and Ely Van de Warker, of Syracuse.

The papers of Drs. Campbell, Sims (In Memoriam of Dr. J. Scott), Chadwick, J. Tabor Johnson, and Busey were read by title, also a paper by Dr. Alexander R. Simpson, of Edinburgh, Scotland, on *The Use of Chlorate of Potash in Obstetrics and Gynecology.*

DR. H. MARION SIMS read a paper on

THE IMPORTANCE OF THE MICROSCOPE IN THE TREATMENT OF STERILITY IN WOMEN.

Sterility, according to Sir James Simpson, occurred in every eighth marriage. The term implied that the ovum in the female was unfruitful, and was analogous to impotence with reference to the male. If a woman required treatment for sterility, the conditions pertaining to the sexual apparatus of both herself and her husband must be carefully ascertained. The examination would not be complete until the spermatozoa had been examined at various intervals after copulation, also the vaginal and cervical secretions, and the influence of each upon the other had been noted. It is not certainly known whether the ovum is fructified in the vagina, the uterus, or the tube. Analogy from certain of the lower animals would suggest that it took place in the vagina. Mechanical obstructions to impregnations in the form of displacements and diseases of the uterus and its appendages must usually be cured, or the sterility will continue. In the course of treatment for this condition, which may require months, the microscope would give valuable information, for it is not until the vaginal and uterine secretions are restored to normal conditions that the desired end could be attained.

DR. FORDYCE BARKER, of New York, referred to the question of age at which childbearing should terminate, and had never seen a woman who gave birth later than her fifty-fifth year. Late parturitions, as late as the fortieth year for the first time, had not proven, in his experience, either particularly difficult or dangerous.

DR. J. B. HUNTER, of New York, had found dilatation of the cervix with suitable local applications efficient in relieving sterility.

DR. H. P. C. WILSON, of Baltimore, had found the operation of posterior section useful in curing sterility. The cure of sterility was essentially the cure of a diseased mucous membrane.

DR. JOHNSTON, of Danville, Ky., stated that in the infantile uterus with an undeveloped mucous membrane there was absolute sterility, necessarily due to an abnormal condition of the sympathetic. Such individuals might menstruate irregularly. An examination of their secretions would not be sufficient to determine absolutely as to sterility.

DR. H. C. COE, of New York, thought that a slight constriction at the end of a Fallopian tube might suffice to produce absolute sterility, but would give rise to no symptoms.

DR. A. J. C. SKENE, of Brooklyn, inquired whether Dr. Johnston had found in the senile atrophic uterus the same histological condition which existed in the uterus of arrested development; and whether premature atrophy did not correspond anatomically with arrest of development. He had observed a changed appearance of the secretions from the uterus in arrest of

development—it looked like the sputa of pneumonia. He had always observed sterility in such cases.

Dr. Johnston replied that the condition of the uterus in infantile development was not the same as in senile atrophy. In the latter there is much fibrous tissue and a deficiency in the corpuscular elements; it resembled scar tissue. In the infantile uterus there was an abundance of the epithelial elements, and it was these facts that caused the difference in the secretions.

Dr. Robert Battey, of Rome, Ga., observed that the time for the climacteric, which was designated as the forty-fifth year by the text-books, was not the same for all localities. In the locality in which he lived it was nearer the fiftieth than the forty-fifth year, and he had not infrequently seen it occur as late as the fifty-fifth. In his own family there had been childbirth as late as the fifty-sixth year. Sterility was due in certain cases to mechanical difficulties, which could be overcome by suitable precautions on the part of the individuals concerned.

Dr. Collett, of South Carolina, remembered a case in which a woman gave birth to a child at the age of sixty-two years eight months.

Dr. Sims, in closing, expressed gratification that some of the gentlemen present had not yet abandoned the posterior section of the cervix for sterility. He believed that the operation was a useful one.

Dr. James B. Hunter, of New York, presented a paper on

PREGNANCY AS A COMPLICATION IN PELVIC DISEASES.

Though all writers did not share the reader's opinion, he believed that pregnancy had a marked influence upon existing pelvic disease. All diseases of the external genital organs were aggravated by it, whether they were of inflammatory or neoplastic origin. The same was true of diseases of the vagina; vaginal cysts ruptured during parturition, and after parturition the posterior vaginal wall always tended to prolapse. The pressure of the gravid womb might cause injury to the bladder. A vaginal enterocele might become strangulated, as the womb enlarged. Diseased conditions of the cervix became worse during the first three months of pregnancy, and subsequently became better, though indurated tissue in the angles of a fissured os uteri was perceptible during the entire period of gestation. Malignant disease of the cervix was wont to get rapidly worse under the influence of pregnancy, and frequent pregnancies seemed to predispose to the development of malignant disease. If pregnancy occurred coincidently with a displacement, the latter would be relieved in some cases, especially if the displacement were anterior, in others an abortion would result. Inflammation of the utero-sacral ligaments sometimes followed labor. Small fibroid tumors of the uterus might undergo fatty degeneration and absorption during pregnancy, those of the intra-mural variety might give rise to hemorrhages, and soft or cystic growths might enlarge rapidly. During this period also endometritis might be aggravated and lead to tubal disease, ovaries might prolapse, cysts rupture, and benign tumors become malignant. Though all these conditions might occur, one should never advise a woman not to marry on account of pelvic disease unless the latter were quite severe, or there was good reason for believing that it would be.

Dr. A. J. C. Skene, of Brooklyn, had often observed that pregnancy had a decided influence on nutrition, weak and delicate women often becoming more robust and menstruating more freely. Chronic inflammatory conditions were sometimes benefited and sometimes made worse, and the benefit obtained more than counterbalanced the risks which pregnancy entailed. Abortion need not occur in connection with displacements if the latter were properly managed, and retroflexions would usually be found cured when labor was over and involution had taken place. Retroversions were not usually cured by this process, especially if subinvolution existed.

Dr. Bache McE. Emmet, of New York, called attention to the fact there were certain forms of pelvic disease which were mild in their symptoms but might prove serious in their results. The quiet of pregnancy in itself was often a relief to a woman. In general it seemed to him that pelvic disease should be cured before pregnancy took place. In cases in which displacement was due to the weight of the uterus pregnancy would probably be beneficial.

Dr. Cameron, of Montreal, narrated a case in which the condition of a fibroid tumor of the uterus was decidedly modified by pregnancy, and another in which chronic inflammation of the pelvic tissue preceded pregnancy, the latter being followed by rupture of the uterus and death.

Dr. George J. Engelmann, of St. Louis, read a paper upon the

NEW METHODS OF ELECTRO-THERAPY IN THEIR BEARING UPON GYNECOLOGICAL SURGERY.

Electricity, it was observed, had had many enthusiastic advocates, but had often been indiscriminately applied and with improper apparatus. It had been a means of relief in many cases of fibroid tumor, but the results had not always been as good as could be desired. Only the galvanic current was referred to in the author's remarks, and only in those cases in which surgery would otherwise be resorted to. It was not to be considered a substitute for surgery, except when surgery was inappropriate or was refused. The advantages of electricity were its safety, the possibility of receiving it without being confined to bed, etc. It was useful in the treatment of neoplasms and inflammations, which admitted of a healthy retrograde metamorphosis, and it did not prevent a final resort to the knife if this was deemed advisable. Such conditions as indurated exudates, chronic stenosis, intramural fibroids, caruncle, chronic metritis, etc., were indications for its use. It should be used in nervous disorders before resorting to oöphorectomy. One could judge after a few applications whether it would be of any benefit. It would be better to progress slowly, avoiding electro-puncture if possible, and act with perfect safety. In tumors in which cystic degeneration had taken place, or for large collections of fluid in general, electricity was harmful, in tumors in which fatty degeneration was in progress it was beneficial.

Sub-serous tumors with long pedicles were less affected by the current than those which were closely adherent to the uterus. The reader had had no serious nor fatal results from his use of electricity; he never used abdominal puncture for the treatment of fibroids, but vaginal puncture if the tumor were penetrated at all. Care

should be used in the selection of cases which were to be treated, and those should never be treated which were beginning to disintegrate.

DR. H. P. C. WILSON, of Baltimore, thought that cases for treatment by electricity should be selected as carefully as for laparotomy. Keith and Apostoli had stated that if a patient were to be benefited at all it would be in the course of thirty sittings. Apostoli did not puncture a tumor if he could pass an electrode into the uterine canal. Accidents could happen with this as with any other means of treatment if it were improperly used.

DR. GRAILY HEWITT, of London, stated that he was still a student upon this subject, and he believed that electricity was destined to relieve much suffering. The prevailing tendency to rush into surgical operations should be restrained and safer methods like electricity employed.

DR. W. H. PARISH, of Philadelphia, thought that the best results which he had seen from the use of electricity had been in the treatment of pelvic exudates. No suppuration followed such treatment. He would like to know the extent to which electricity was useful in the treatment of pelvic abscess and whether it was of more advantage when the pus was in the cellular tissue, or when it was in the tubes.

DR. ENGELMANN, in closing, observed that Keith had said that a surgeon was almost criminal who cut a fibroid before he had tried electricity upon it. Electrical treatment heretofore had been of too crude a character, and without instruments of precision. In answer to the question concerning the value of electricity in the treatment of pelvic abscess, he would say, that if the quantity of pus were small it would be useful, and would favor absorption. If the quantity of pus were large, it would do no good, whether the pus were located in the tubes or in the cellular tissue.

AFTERNOON SESSION.

DR. MATTHEW D. MANN, of Buffalo, presented a specimen of a large and degenerated ovary, which contained a small, but well-developed placenta. This was an illustration that

OVARIAN PREGNANCY,

which had been declared impossible by some writers, did take place.

DR. JOSEPH E. JANVRIN, of New York, read a paper on

THE TREATMENT OF EXTRA-UTERINE PREGNANCY.

He took the same stand that he had already taken on several occasions during the past two or three years, that the existence of an extrauterine pregnancy is in itself an indication for laparotomy. The author's case in which fatal hemorrhage occurred, though electricity had been several times administered by competent hands, was cited as proof that electricity was not devoid of danger, and that it was not absolutely certain to stop development. Notwithstanding the statements of some high authorities, the diagnosis of ectopic gestation in the early months could frequently be made, and the prominent symptoms were given which usually attended that condition. If the condition were one of danger, it seemed rational to him that laparotomy should be performed and the sac extirpated, the same as in any other serious tubal disease, or, in fact, any condition for which opening of the abdomen was now deemed perfectly justifiable. While he believed that the electricity would in most cases do no harm, it was not so reliable nor so radical a measure as laparotomy, and he was, therefore, in favor of that procedure as soon as possible after the diagnosis was made.

DR. H. T. HANKS, of New York, read a paper on

THE EARLY DIAGNOSIS OF TUBAL PREGNANCY AND ITS TREATMENT BY ELECTRICITY,

with a report of two successful cases. It was thought that no general law could be laid down concerning the treatment of tubal pregnancy during the early months. Some cases could be best treated by electricity, others by laparotomy, especially if there were any suspicions that rupture had occurred. Two cases of undoubted tubal pregnancy were narrated, which were treated with the galvanic current by the reader. Both resulted favorably, and the tumor in both cases rapidly grew smaller. This method of treatment was the one which was favored by most American gynecologists, if the diagnosis were made prior to the fourth month of pregnancy. Of twenty cases which had been reported during the past two years as treated by electricity, only two had been fatal, and it was not clear that electricity had been the cause of death in those cases. For those who were inexperienced in laparotomy it was much more prudent to use electricity, which required comparatively little skill, than to cut; besides, should electricity fail, laparotomy could still be resorted to. The diagnosis of tubal pregnancy must always be a matter of more or less difficulty; the differentiation between this and other small tumors of the pelvis was seldom easy. In cases in which it was clear that the fœtus had died, one must be governed by circumstances in electing to do laparotomy, or to do nothing. Should a pregnancy pass the fifth month without mishap, and the mother express great desire for a living child, one must consider the propriety of allowing the pregnancy to continue until the child is viable. In general, the reader thought the following rules upon this subject could be followed:

1. If the diagnosis is made during the first four months, electricity should be used.
2. If the diagnosis is made after the fourth month, laparotomy is indicated.
3. Should serious symptoms arise at any period, immediate laparotomy is indicated.
4. If the diagnosis is not made until the fifth month, and the symptoms are not severe, it is well to wait until severe symptoms arise.
5. If the pregnancy has extended beyond the ninth month, and the fœtus is dead, laparotomy should be performed for its removal.

DR. HARVEY, of Calcutta, stated that laparotomy was not yet in favor in India, for any condition, though it was done occasionally. He did not believe that laparotomy should be resorted to in extra-uterine pregnancy by inexperienced operators, and yet one was sometimes called upon to do it without much preparation, as the urgency of the case would not admit of sufficient delay to send for an experienced operator.

DR. J. C. REEVE, of Dayton, Ohio, recalled the paper which he had read before the Society five years previously, in which he reported the fourth recorded case treated in this country by electricity. Much progress in connection with this subject had been made during that

period. One point to which he called attention in regard to diagnosis, was the vascular activity which was perceptible in the tubal cyst as it was projected against the vagina. It had impressed him as a most important diagnostic symptom. He admitted that he did not feel quite satisfied that the contents of ectopic gestation would always be readily disposed of after the use of electricity, but this was only a theoretical consideration; he had no facts to support. In general, he was in favor of electricity during the first three months of gestation, but he was not prepared to say that he thought its use unattended with danger, that danger being the rupture of the cyst.

DR. GORDON, of Portland, Me., thought the records of treatment of tubal pregnancy, as given by Dr. Hanks, were quite as favorable for laparotomy as for electricity. By the former method, there had been two deaths in sixteen cases; by the latter, two in fourteen cases. If one waited for hemorrhage, or other serious symptoms, before operating, the delay might be fatal, as had occurred in a case to which a colleague had recently been called—too late to render any servive. If ninety-five per cent. of cases of extra-uterine pregnancy could be diagnosticated, certainly many of them should be saved by laparotomy, without exposing them to the danger of death from sudden hemorrhage on the one hand, nor to septicæmia from absorption after the fœtus had been killed by electricity.

DR. JOHNSTON, of Danville, Ky., stated that ninety-nine out of every one hundred cases of tubal pregnancy had already ruptured one or more times before the attention of the physician was called to them. When pain and collapse occurred, it was evidence of rupture, and a clot or scar would be found upon the cyst, indicating the place at which this had occurred. The danger of rupture of the cyst from electricity is great. There is also great danger of subsequent sloughing and suppuration. Electricity was wrong in principle, and dangerous in practice for this condition. Even if lithopædion were formed, the patient was not safe, for sloughing might occur even in that condition. The safest method was the radical one—namely, the removal of the cyst and its contents.

DR. COLLETT, of South Carolina, narrated two cases which corroborated Dr. Johnston's statement concerning the record which each rupture made for itself upon the cyst.

DR. G. J. ENGLEMANN, of St. Louis, thought that in cases in which the diagnosis of extrauterine pregnancy was doubtful, electricity might be used, and no harm would result if there were no pregnancy. If pregnancy did exist, electricity might kill the fœtus in the early stages of its development. If this agent were to be used at all, there should be greater precision than has heretofore been employed, and directions should be carefully formulated for use in the treatment of extrauterine pregnancy.

DR. H. C. COE, of New York, remarked that the diagnosis of extra-uterine pregnancy was easy in typical cases, in others it was difficult.

DR. KINLOCH, of South Carolina, thought that the superiority of electricity, or of laparotomy, as a measure of treatment, would depend upon the circumstances connected with each case. From a surgical standpoint, a radical operation was always preferable, and with reasonable skill and favorable surroundings laparotomy would seem to him the better method of treatment.

DR. A. P. DUDLEY, of New York, thought that sufficient information was not at hand to assist one in making an early diagnosis in extra-uterine pregnancy, especially a differential diagnosis. The treatment was not difficult after a diagnosis had been made. In almost all cases there was little danger in an exploratory incision, and it would be very helpful in making a diagnosis.

DR. MANN objected to the criticism of Dr. Johnston, that the specimen which he had presented as a specimen of ovarian pregnancy was a dermoid cyst. His logic, that because dermoid cysts might contain almost anything, therefore placental tissue; and that, hence, this was a dermoid cyst, was lacking in convincing power. The speaker had seen several cases in which electricity had been used for the treatment of extra-uterine pregnancy, all of them had done well, and in none of them had there been the suppuration which Dr. Johnston feared. He had also seen a patient with lithopædion who had had no bad symptoms at any time.

DR. JANVRIN referred to the cases of Drs. Price and Hawley (two) as the only three recorded cases in which primary laparotomy had been performed for extrauterine pregnancy. Of course, laparotomy was recommended only for those who were competent to perform it, others might use electricity until serious symptoms should demand skilled assistance. The case which was narrated by Dr. Harvey of ruptured tubal pregnancy operated upon by Mr. Tait was incomplete, as it did not appear that he had seen anything but blood clots and a cyst; and a tubal pregnancy was not complete without a fœtus. In so far as the narration was concerned, it was only a hæmatocele. Dr. Johnston's statements harmonized with the speaker's belief, that the sharp pains of extra-uterine pregnancy were indicative of rupture.

DR. HANKS said that he did not exclude skilful or experienced laparotomists from operating at any period of extra-uterine pregnancy when a diagnosis had been made; but electricity could be used by the general practitioner when, perhaps, the services of a laparotomist were not available. No serious trouble had ever been reported in cases in which the fœtus had been destroyed before the third month by electricity, excepting in the case of Dr. Janvrin.

ADJOURNMENT.

THE PRESIDENT then made his parting address to the Society, introducing his successor, Dr. H. P. C. Wilson, of Baltimore, who assumed the chair, and adjourned the Society until its next meeting, in Boston, on the second Tuesday in September, 1889.

AMERICAN DERMATOLOGICAL ASSOCIATION.

Twelfth Annual Meeting,
Held at Washington, September 18, 19, and 20, 1888.

WEDNESDAY, SEPTEMBER 19TH.

DR. J. E. GRAHAM, of Toronto, read a

REPORT OF FOUR CASES OF DERMATITIS HERPETIFORMIS.

Three of his cases were mild in character, exhibited the characteristics described by Duhring, and ended in recovery. The fourth was very severe in its manifestations, and ended fatally in spite of treatment; the case exhibited many of the lesions and symptoms of pemphigus.

DR. H. W. STELWAGON, of Philadelphia, reported

THREE CASES OF DERMATITIS HERPETIFORMIS, WITH NOTES.

Among about 5000 cases of skin diseases he had seen but three of dermatitis herpetiformis; all conformed to Duhring's description. *Case 1* did well under arsenic and salines. *Case 2* had suffered from scarlatina; the dermatitis herpetiformis which followed, was obstinate, recurring in severe exacerbations, and not amenable to treatment. Arsenious acid was pushed to one-eighth of a grain doses, three times daily, in this case, without benefit. This patient subsequently passed to the Skin and Cancer Hospital, New York. *Case 3*, a woman, exhibited a milder form of the disease, and was improved by arsenic.

Dr. Stelwagon endorsed Duhring's description of these cases, and confirmed his description of the affection by his own observation.

DR. HYDE, of Chicago, in discussing these papers, preferred to separate simple exfoliative lesions from graver disorders. He described the case of a male patient who presented an extremely aggravated disease, bearing some resemblance to dermatitis herpetiformis, but which he considered pemphigus. The patient had blebs, large denuded patches, and extensive denudation along the back. He was placed upon a splint with an iron frame and broad supporting surfaces of cloth, on which he was immersed in the constant water bath for long intervals; he was given tonics and arsenic freely, but a fatal result followed.

DR. L. DUNCAN BULKLEY, of New York, described a case of dermatitis herpetiformis which developed diffuse sarcoma; another case died from a cerebral lesion. He regarded such cases as pemphigus, not herpes.

DR. FOX, of New York, had Dr. Stelwagon's second case under his observation. The diagnosis is difficult, as the case presents features of pemphigus and herpes also. He is inclined to question the utility of large doses of arsenic in these cases.

DR. HEITZMANN, of New York, had described a case some twelve years previous, presenting the clinical features of dermatitis herpetiformis, which proved to be pemphigus. He has seen but one case of Duhring's dermatitis herpetiformis in his experience.

DRS. GRAHAM and STELWAGON, in closing the discussion, stated that they would include under dermatitis herpetiformis a class of cases not described under other names. They would not classify skin disease on the basis of etiology.

DR. A. VAN HARLINGEN, of Philadelphia, described a case of

FILARIA MEDINENSIS.

The patient was employed in handling invoices and goods imported from the tropics. The worm developed typically in the palm of the hand, and Dr. Van Harlingen endeavored to remove it by cutting down upon it. Failing in this, he followed Tilbury Fox's advice, and gave assafœtida in free doses, with a prompt and successful result. The worm died, and shrivelled *in situ*. This parasite is frequently found in the soles of the feet of the inhabitants of the tropics, but is rare in temperate climates.

DR. HYDE, of Chicago, followed with a paper on

VEGETATIVE LESIONS CAUSED BY IODIDES,

which will appear in full in an early number of THE MEDICAL NEWS.

The discussion of this paper elicited the clinical facts that potassium permanganate and bromide may cause lesions similar to those caused by iodides. A possible connection exists between diseases of the heart and kidneys and such eruptions.

THE AMERICAN CLIMATOLOGICAL ASSOCIATION.

Fifth Annual Meeting
Held at Washington, September 18, 19, and 20, 1888.

(Specially reported for THE MEDICAL NEWS.)

TUESDAY AFTERNOON, SEPTEMBER 18TH.

THE PRESIDENT, DR. A. L. LOOMIS, of New York, called the Association to order at 2.30 P.M., and delivered

THE PRESIDENT'S ADDRESS.

(See page 345.)

DR. S. A. FISK, of Denver, then read a paper on

THE CLIMATE OF COLORADO FOR PULMONARY DISEASE.

The drainage of Colorado, he said, is subterranean, which insures a dry climate; there are no bodies of water near to furnish moisture. The elevation and physical features of the country vary greatly. The soil is sandy, and the atmosphere of considerable rarity; the elevation of Colorado increases the circulation of the blood and the respiration, the cutaneous circulation being very active. The climate is especially dry, the hours of sunshine being very numerous. In the winter of 1884 and 1885 there were but 11 days out of 242 in which the sun did not shine at some time during the day. Denver has twice as much sunshine as European resorts, the sun rising at 7.30 during January. The climate is hot in summer, in the towns; in the mountains and parks it is comfortably cool. Great variations of temperature occasionally occur, as much as 80° having been observed. The winter climate is cold, but not sufficiently so to debilitate any but the very weak. Wind storms are infrequent; dust is very easily raised. The average precipitation is very little; fog is almost unknown.

He did not consider altitude a protection against germs; the crowding together of human beings gives rise to germs in any altitude. Putrefaction is, however, very slight. Colorado is fit for a permanent resort; it is a prosperous, and growing State, and patients should be encouraged to remain there.

DR. SOLLY, of Colorado Springs, then read a paper describing the

PATIENTS SUITED FOR TREATMENT IN COLORADO.

The most frequent and marked effect of the climate is improved circulation, especially cutaneous; the complexion becomes reddened, and acute skin diseases are improved. With some patients the hair often falls, but returns when the circulation has become adjusted. Cardiac contractions are stronger, and dilatation may occur in weak hearts; as the patient becomes acclimated compensation is established. Cases of dilated heart are best treated elsewhere; such patients cannot exercise at an altitude. Fatty heart and valvular lesions are improved by the climate. Functional congestions generally disappear; anæmia and chlorosis are improved. Chronic pulmonary diseases do well, but croupous pneumonia is

violent, and attended by bloody expectoration; pneumonia occurs with greater facility than elsewhere. Pleurisy is ordinarily without effusion. Acute catarrhs are frequent. The phlegmatic and chlorotic do well. The climate is especially efficacious in arresting early tuberculosis. Phthisis and pleurisy developing after pneumonia, improve. When a tendency to acute catarrhs exists, the climate is contraindicated; when a patient has lung avities, but can react to the stimulus of the climate, great benefit often follows. Chronic nasal catarrh is improved. Renal disease is made worse. Colorado is a gymnasium, and intelligent activity and coöperation on the part of the patient are needed.

DR. R. G. CURTIN, of Philadelphia, then read a paper entitled

IS CLIMATE AN ETIOLOGICAL FACTOR IN GRAVES'S DISEASE?

He reported forty cases, occurring in fifteen families, most of these patients being natives of Alsace or Lorraine, and having lived in a moderately high altitude. His investigations led him to believe that intermarriage is the primary cause of this condition, favored by the disturbance of the nervous system by high altitude. Any exciting disturbance of the nervous system is known to favor the disease. He would not send such patients to high altitudes. He had seen cases go on to sudden death from heart failure.

DR. P. H. KRETZSCHMAR, of Brooklyn, then read a paper on

HEALTH RESORTS VS. INSTITUTIONS FOR THE TREATMENT OF PULMONARY CONSUMPTION.

He credited Bremer, of Germany, with the first institution for the treatment of phthisis, and considered the natural advantages for such treatment afforded by the springs of America neglected by the American profession. As there is no specific treatment for phthisis, the comprehensive treatment required can be best given in institutions. At health resorts the habits of patients are not sufficiently controlled; they are led, by association with well persons, to overtax themselves in pleasures which are innocent for the healthy. This is well shown by the mortality from phthisis at Nice, one in ten, while at the European institutions for the phthisical the rate is one in fifty. The danger of contagion from the phthisical at resorts is less than their danger. Relapses are usually caused by congestions resulting from indiscretions.

Detweiler and Trudeau have emphasized the dangers of the reckless use of mountain air. It is most important that the minutiæ of life and treatment be personally regulated by the physician. Thus the cold douche, a most valuable agent, should be given under the physician's order only.

Regarding the value of alcohol in these cases, Bremer uses it sparingly, giving brandy and milk for night sweats. Detweiler uses alcohol freely, to the exclusion of antipyretics. Bremer takes the patient's temperature every two hours during the day; he employs rest in the open air for cases with fever. In marked fever an ice-bag over the heart is useful.

Dr. Kretzschmar prefers to give antifebrin grs. iij four times daily. The patients are not influenced badly by their surroundings while at sanitariums.

DR. LOOMIS agreed with the author that resorts are not liable for these cases. He has obtained his best results in the Adirondacks, because of the care given to the patients by physicians resident there. Dr. Trudeau had between 75 and 100 patients about him last winter; he has about 20 who have built cottages to remain under his care. This plan of treatment Dr. Loomis endorsed.

DR. SOLLY thought contagion and mental depression important objections to sanitariums; he thought well of cottages. Eastern physicians sometimes send patients to Colorado, telling them to abandon all medical treatment and rely on climate—a grave error. Patients need a physician's advice regarding their use of a climate as a medicinal agent.

DR. LEVICK, of Philadelphia, preferred cottages to a sanitarium, on account of the mental depression caused by the latter; he cited the great Ventnor Hospital of England as an example.

DR. KRETZSCHMAR, in conclusion, quoted the statistics of Bremer, showing 50 per cent. recoveries from the first stages of phthisis during the past year in his sanitarium. He considered contagion doubtful. Among those living in a town containing a sanitarium, at which 14,000 patients had been treated in 31 years, but 5 died of phthisis. There had been no authentic case of contagion at Davos.

WEDNESDAY, SEPTEMBER 19TH.

DR. E. L. TRUDEAU, of Saranac Lake, N. Y., reported

AN ENVIRONMENT EXPERIMENT REPEATED

which he had made upon animals inoculated with tubercle bacilli. His experiments demonstrated that the virulence of such inoculation depends largely upon the number of bacilli introduced, and the anatomical location of their introduction. Specimens exhibiting the conservative work of nature in encysting tuberculous foci were shown.

DR. COUNCILMAN, of Baltimore, remarked that bacilli may be aspirated into the lung from the bronchi; they may follow the lymphatics, or enter the bloodvessels directly, as in miliary tuberculosis. The resistance of the tissues to the invasion is shown by the formation of connective tissue around the focus; caseation occurs when this tissue breaks down; this tissue is well illustrated in the "pearly disease" of animals, bovine tuberculosis. The degrees of difference in the virulence of the tuberculous virus are not accurately known, nor the reasons for such differences.

THE REPORT OF THE COMMITTEE ON MINERAL SPRINGS

was then read by the Chairman, DR. C. C. RICE, of New York.

The committee had found about 800 springs, whose nomenclature, however, was in a very disordered state. The classification of springs now attempted is on the basis of therapeutic value, the springs most useful being those but slightly impregnated with salines. Accurate chemical analyses are needed; but one-tenth of the whole number have been analyzed, and the government is ready to analyze waters sent to its laboratory. America lacks thermal springs, and investigation is needed to ascertain whether waters artificially heated are valuable in cases treated at European thermal springs. The committee proposed a plan for the selection of reliable

physicians residing at various springs, who should report their results in treatment by the waters of the springs in a systematic manner to the committee.

It was moved and seconded that the committee be continued, with power to act.

A discussion on the

THERAPEUTIC VALUE OF MINERAL WATERS

was then opened.

DR. WILLIAM PEPPER, of Philadelphia, spoke of their employment in *Gastro-hepatic Diseases*. His previous investigations had led him to believe that America is the richest of all countries in mineral springs; we lack, however, authentic analyses, and his custom in practice is to select that American water most similar to a European water of known ingredients. Simple water he regarded as valuable for its effect upon the secretion of bile, and the formation of urea, with the promotion of tissue metamorphosis. The use of mineral waters is indicated in gastric atony, catarrh, dilatation, and ulcer; in hepatic catarrh, cirrhosis, congestion, gall-stones, and nervous stasis. In stomach disorders the water should be taken fasting; in hepatic disease after eating; waters should contain but a small proportion of salines. Cold water stimulates, increasing secretion and muscular action. Hot water cleanses mucous membrane, increasing secretion.

Dr. Pepper uses Carlsbad water most frequently in his practice, in varying dilution; he also employs the waters of Vichy, Wiesbaden, Aix-la-Chapelle, Schwalbach, and Apollinaris water. For the development of American springs we need analyses by the government. The diet and regimen of the patient are also important. Saline waters cannot be safely ordered without a careful adjustment of the patient's food, as when carelessly given the excretory organs may be injured. He had recently used whey as a substitute for mineral waters with good results. Dr. Marshall, of the University of Pennsylvania, had recently analyzed samples of whey for him, and found that whey contains caseine, lactic acid, milk sugar, and water, with a small amount of salines; a pint of whey contains a considerable quantity of salines. He described the case of a man aged fifty-eight, whose tissues had become extensively disorganized through excesses, who had been greatly improved by abandoning alcohol and the free use of whey with mineral waters. The slightest indiscretion in diet caused alarming symptoms. In many of these cases silver nitrate or bichloride of mercury can be given with advantage.

DR. A. H. SMITH, of New York, then read a paper on

MINERAL WATERS IN URINARY AND ARTHRITIC DISEASES.

He believes that water is never injurious to the kidney in nephritis, but pure water without salines should be used. So-called "hard" waters undoubtedly favor the formation of calculus. The great increase in nephritis of various forms during late years has resulted from the very common use of saline waters now prevalent. Statistics show that nephritis causes more deaths in New York than in London; and there is reason to believe that it is not the consumption of alcohol, as often asserted, which produces this result. In gouty contracted kidney mineral waters are especially valuable, provided they contain but little salines. Water containing a trace of iron is valuable in these cases: such are the waters of springs in Wisconsin and Virginia. In joint diseases, waters containing alkaline carbonates are valuable, their bases combining with animal acids in the organism. Vichy is valuable in this way. The utility of thermal springs, as the Hot Springs, depends as much upon the general treatment and regimen enforced as upon the water.

DR. W. C. VAN BIBBER, of Baltimore closed the discussion upon mineral waters with a paper upon their use in *Malarial Diseases*. He described the pathological changes produced by the disease, and spoke of the value of waters increasing excretion, and thereby promoting assimilation and the effect of anti-malarial medication.

CORRESPONDENCE.

ABSCESSES IN THE PELVIC AREOLAR TISSUE.

To the Editor of THE MEDICAL NEWS,

SIR: In THE MEDICAL NEWS of September 22d, in the generally accurate report of the proceedings of the American Gynecological Society, I am reported as stating that "abscesses in the pelvic areolar tissue . . . should *not* be operated upon early." In this your reporter has erred. I insisted that they should be operated upon early, for delay in operating in such cases is extremely hazardous.

I advocated, also, a method of operating in such cases, not generally resorted to, one that I have in a few instances resorted to, and that is of special value *early* in areolar pelvic abscess and where an opening *per vaginam* cannot be safely effected. In such cases I make, first, an exploratory incision in the median line to determine whether or not pyosalpinx or ovarian abscess coexists. If I find that neither of these conditions is present, I then, with two fingers within the peritoneal cavity acting as guides, make a second incision, usually above the median portion of Poupart's ligament. I carry this incision, it may be, deep into the pelvis, keeping external to the peritoneum, until the small pus cavity is reached, I empty this of its contents, wash it out with a corrosive sublimate solution and introduce a drainage tube—usually a large rubber one. The peritoneal cavity is carefully protected during the operation. The median incision is closed and covered with an adhesive impermeable dressing.

This method of procedure I reported in the Society as one well adapted to limited purulent collections in the areolar tissue. The cases I have thus operated on have made speedy recoveries.

PHILADELPHIA, Sept. 22, 1888.

OPERATION FOR INGROWING TOE-NAIL WITH HYPODERMATIC INJECTION OF COCAINE.

To the Editor of THE MEDICAL NEWS,

SIR: I have just read in your issue of August 25th, page 208, Dr. F. Johnson's experience with cocaine in operating for ingrowing toe-nail. As he makes no mention of confining the cocaine anæsthesia to the toe to be operated upon by a ligature, I infer that he did not take this precaution, and hence the alarming symptoms.

In my surgical clinic at the Boston Dispensary I have operated many times upon ingrowing toe-nail under cocaine anæsthesia, but have always applied a rubber tube ligature a minute or two after injecting the cocaine. I have never met with the slightest unpleasant effect, either general or local. My method is as follows: I inject deep into the tissues a two or four per cent. solution of cocaine in three places, at each side and in the centre, then, in a minute or two, apply tightly at the root of the toe my rubber ligature. After waiting until complete local anæsthesia is obtained, I take off a thick slice of the toe on the affected side—under antiseptic precautions. This is known with us as the Cotting method.[1] The slice must be thick enough to expose the edge of the nail. With this the Cotting method stops, but in addition I remove about half of the nail on the affected side, evulsing it, and thoroughly destroy the matrix. Before removing the ligature—for there is much troublesome hemorrhage—I apply my dressing, which consists first of powdered iodoform or salve, followed by many layers of bichloride gauze, tightly bound on. Much care and time must be used in applying this dressing. After removing the ligature I have the patient wait a half hour to see if the bleeding soaks through the dressing. I then send the patient home, and do not touch the dressing—unless for cause—for a week. At the end of that time, I find the wound nicely granulating.

Under this method I have never to my knowledge had an unsuccessful case, or any accident with the cocaine. It is always in cases in which the cocaine cannot, or is not, locally confined, that the alarming systemic symptoms occur, although even in these cases it has never happened to me to meet with any accident, although I have constantly used this anæsthetic in minor operations. Still, I always have a feeling that such symptoms may occur.

EDWARD O. OTIS, M.D.,
Surgeon to the Boston Dispensary.

93 MT. VERNON ST., BOSTON,

NEWS ITEMS.

A Matter of Diagnosis—A suit of great interest to medical men has been brought in the courts of Rhode Island by a Mr. Larkin, proprietor of one of the hotels at Watch Hill, R. I., against Dr. Samuel O. Vanderpoel, of New York, for alleged damage to the plaintiff's business by reason of a diagnosis of scarlet fever made by the defendant in the case of a child staying at his hotel. Dr. Vanderpoel was called to see the child, diagnosticated a mild case of scarlet fever, and advised that the child be removed to a cottage belonging to the proprietor, so as to be isolated from the guests. This recommendation was not complied with, and the child's nurse continued to go to the servants' dining-room. The diagnosis becoming known, a general exodus of guests took place, and the house, which contained a great many familes with children, was soon nearly deserted. The damage in the suit is laid at $12,000, though it is difficult to see on what grounds the case is to be urged. Dr. Vanderpoel's diagnosis, it is said, was confirmed by two other physicians, though it was disputed by one practitioner who saw the case in the interest of the landlord. The manner in which the notice was served upon the defendant was particularly aggravating, the sheriff declining, it is said, the bail that was offered, and expressing his intention to lock up the doctor.

The exceedingly delicate position in which a physician is placed who is called to a case of infectious disease in a summer hotel is well illustrated in this case, but if a man is to be subject to a suit every time he makes such a diagnosis, it is time the profession knew it and protected itself. It is reported that Dr. Vanderpoel will bring a counter-suit against the hotel man for damages.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM SEPTEMBER 18 TO SEPTEMBER 24, 1888.

By direction of the Acting Secretary of War, the leave of absence granted ALFRED A. WOODHULL, *Major and Surgeon*, in S. O. 148, June 27, 1888, from this office, is extended fifteen days —Par. 14, *S. O. 218, A. G. O.*, September 19, 1888.

By direction of the Acting Secretary of War, ROBERT J. GIBSON, *Captain and Assistant Surgeon*, is relieved from duty at Alcatraz Island, California, and will report in person to the President of the Army Medical Examining Board, New York City, on October 16, 1888, for examination for promotion; on completion of his examination, Captain Gibson will proceed to Fort Trumbull, Connecticut, and report for duty to the commanding officer of that post, reporting by letter to the Commanding General, Division of the Atlantic.—Par. 13, *S. O. 217, A. G. O.*, September 18, 1888.

By direction of the Acting Secretary of War, EDWARD R. MORRIS, *First Lieutenant and Assistant Surgeon*, is relieved from duty at Fort Thomas, Arizona, and will report in person to the commanding officer, Fort Shaw, Montana, for duty at that post, reporting by letter to the Commanding General, Department of Dakota —Par. 14, *S. O. 217, A. G. O.*, September 18, 1888.

By direction of the President, the Army Retiring Board at San Francisco, California, convened by War Department Order dated July 20, 1886, published in S. O. 168, July 22, 1886, from Headquarters of the Army, is dissolved.—Par. 1, *S. O. 217, A. G. O.*, September 18, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING SEPTEMBER 22, 1888.

CABELL, A. G., *Passed Assistant Surgeon.*—Ordered to the Naval Hospital, Chelsea, Mass.

BAKER, J. W., *Passed Assistant Surgeon.*—Detached from the Naval Hospital, Chelsea, Mass., and ordered to the "Palos."

LEACH, PHILIP, *Passed Assistant Surgeon.*—Detached from the "Palos," and granted six months' leave abroad.

SIMONS, M. A., *Surgeon.*—Detached from the Naval Academy, and wait orders.

HARMON, G. E. H., *Surgeon* —Ordered in charge of Naval Academy.

PICKRELL, GEORGE MCC., *Assistant Surgeon.*—Detached from the "New Hampshire," and ordered to the "Ossipee."

ARNOLD, W. F., *Assistant Surgeon.*—Ordered to the "New Hampshire."

HENRY, C. P., *Assistant Surgeon.*—Detached from the "Ossipee," and granted sick leave.

CORDEIRO, F. J. B., *Assistant Surgeon.*—Promoted to Passed Assistant Surgeon.

SPEAR, J. C., *Medical Inspector.*—Placed on the retired list, September 14th.

RHOADES, A. C., *Medical Inspector.*—Placed on the retired list, September 14th.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

CONDITIONS WHICH TEND TO RENDER THE ATMOSPHERE OF A LOCALITY ASEPTIC.[1]

BY J. T. WHITTAKER, M.D.,
PROFESSOR OF THEORY AND PRACTICE OF MEDICINE IN THE MEDICAL COLLEGE OF OHIO.

CONDITIONS which tend to free, or keep free, the air from pathogenic microörganisms, is the construction I put upon this subject that it may have medical, as well as surgical consideration.

In this consideration the subject is brought into proper limit by study of the question, What pathogenic microörganisms do or may exist in the air, first outside, second inside the walls of houses? The older writers derived the cause of most diseases, certainly of most infectious diseases, from the air. The vague term "telluric influence" constituted a kind of refuge for everything inexplicable, including syphilis. With the discovery of the infusoria by Leeuwenhoek, 1675, came the birth of the germ theory, to give rise to the wildest conceptions regarding the infection of the air. The air was supposed to swarm with germs of animal nature, something in the form of moths, armed often with beaks and claws, individual varieties of which produced individual diseases. It was seriously proposed in the seventeenth century to drive them away during an epidemic by the noise of trumpets and the thunder of cannon, just as the people of our day, as much as in the days of the Athenian plague, attempt to frighten them with cannon or burn them with bonfires in public squares. Less fantastic, though nearly as extravagant, was the view that the myriad motes of the sunbeam were germs or carriers of germs of disease.

The natural reaction which dissipated for a time all belief in a *contagium vivum* did not detract from the air as the chief element in the production of infectious diseases. For telluric influences and swarms of animals were substituted electric currents, ozone proportions, volatile emanations, vapors, gases, etc., views which are not without advocates in very recent times. Thus, Surgeon-General Hunter of the British Army is inclined to ascribe the cholera of India, in 1884, to the state of the air. "When the epidemic was at its height," he says in his second report, "on the 23d of July, a very peculiar condition of the atmosphere was observed; a yellowness of the air, somewhat of the nature of a fog; and it was quite calm. The sparrows, it was observed, had deserted the place and did not return until July 26th."

With the reintroduction of the germ theory upon the basis of a fact, to wit, the discovery of the spirilla of recurrent fever by Obermayer, 1873, and the general adoption of it which gradually followed the discovery of the tubercle bacillus by Koch, in 1882, the *rôle* of the air as a reservoir of microorganisms became more prominent than ever. Inasmuch as this disease could be imparted to animals by inhalation experiments; inasmuch as the germs of the disease from their principal localization are known to be inhaled; and inasmuch as the lungs constitute a vast absorbing surface exposed to the air at all times: it was not unnatural to believe that all the infections could be contained in and received from the air. The majority of teachers, writers, and clinicians believed and maintained that cholera, typhoid fever, and dysentery, for instance, entered the body through the avenue of the lungs.

So long as microscopy and chemistry constituted the sole means of examining the matter deposited from the air there could be obtained no precise knowledge, which became possible only with isolation of its particles and cultivation of them in various soils. These investigations, which are necessarily of recent date, have nevertheless already disclosed the fact that the air is, as a rule, when compared with the water, and the soil singularly free from pathogenic microörganisms. In fact, the only pathogenic microörganisms as yet definitely discovered and established by inoculation experiments are the ubiquitous[1] staphylococcus pyogenes aureus and the streptococcus of erysipelas.

We are forced, therefore, to reach by elimination the diseases whose causes may exist in the outside air. We may exclude thus, first most, if not all, the eminently contagious diseases whose infectious principle is given off from the body directly or indirectly. Thus, it is not probable that smallpox, scarlet fever, measles, typhus fever, relapsing fever, aside from accidental direct contact with cases, are ever contracted in the open air. Cholera, typhoid fever, and dysentery, since the demonstration of their cause in drinking water, positively in the case of cholera and typhoid fever, presumptively in the case of dysentery, have lost all connection with the

[1] Read before the American Climatological Association, September 20, 1888.

atmosphere outside or inside. Should the meningococcus prove to be the cause of cerebro-spinal meningitis this disease will take its place with croupous pneumonia as a house disease, which is certainly the case with tuberculosis—no case of which was ever contracted in the open air. The tendency of our day is to regard acute articular rheumatism as a mycosis whose cause lies inside and not outside the walls of houses. Erysipelas, if not directly inoculated, falls upon wounded surfaces from bedding, clothing, house furniture, or walls from which its microörganisms have been directly scraped.

Diphtheria and croup stand on debatable ground, with the probabilities, on account of demonstrated infectiousness, strongly in favor of inside transmission. Yet it is not impossible that the diphtheria of fowls may be a source of infection of man. Since Stöhr has shown that the epithelium of normal tonsils presents openings, stigmata, or holes through which white blood-corpuscles pass constantly into the mouth the way is opened directly to the blood for the passage of outside germs.

The non-contagious infections, the group characterized as miasmatic diseases, the number of which grows gradually less as the causes of the infections become accurately determined, remain as the sole affections whose cause exists in the outside air in quantity sufficient to produce infection. Pre-eminent among these is the variety called bad air, malaria; and with the malarias may be associated influenza, hay fever, possibly pertussis and yellow fever, the last of which differs markedly from the rest in the fact that it must be introduced by a case of the disease. Hence it is not improbable that the determination of the exact cause of this disease will remove it from the miasms altogether. The infective principle lives, apparently, in the discharges, and is largely localized in the liver, but seems to require some transformation in bilge-water, bedding, or other soil, before it becomes actively infectious.

The statement is here superfluous, that the miasmatic diseases proper originate not in the air but in the soil, whence the cause is lifted and disseminated by currents of air.

Thus it is evident that the cause of but few, and these by no means the fatal diseases, actually exists in the outside air.

Direct examination of the air by even the first means employed, revealed the fact that the quantity or number of microörganisms in it varied greatly in different places. The air of the country is more free than that of the city in the proportion, according to Miquel, of 1092 to 9750 to the cubic metre, at Montsouris and Paris; or, according to Freudenreich, of 300 to 2400, about and in the city of Berne; the air of the city parks, according to Frankland, containing more microörganisms than that of the country about London. Microörganisms of all kinds are heavier than air, and, consequently, sink in a tranquil atmosphere, to abound most on the surface of the earth. Thus, Miquel counted in the air at the top of the Pantheon but 364 germs to the metre, and Tyndall and Pasteur found the air "optically pure"—that is, entirely free from microorganisms, at the top of the Alps. As a sample of the microörganisms of the air may be mentioned the results of an examination by the two Franklands, who found ten varieties of micrococci, twelve bacilli (among which was the hay bacillus and the bacillus prodigiosus), two ferments (one of which was the rosa-hefe), one mould, and yellow and orange sarcinæ. Hesse demonstrated the rapid gravitation of all microörganisms in air which was comparatively still, and observed the much more rapid gravitation of bacteria than of moulds and ferments. Petri shows thus that entirely different results are obtained in aspiration studies, which take the air above or in circulation, and plate studies, which collect it from the surface or at rest. In aspiration observations moulds and ferments abound, while in plates bacteria predominate. Hence, to obtain reliable results, both methods should be employed at once.

Marked diminution in the number of all microorganisms follows a rainfall which washes them down, or a tornado which sweeps them away, or a fall of snow which prevents their dissipation by the wind.

Absolute outside air is met at the surface of the earth only upon the high seas, and repeated observations, most accurately by Fischer on the steamer "Moltke," have shown that at a distance of 70 to 120 sea miles from shore, except in the presence of land winds, the air is nearly or absolutely pure. Thus, all microörganisms reaching absolute outside air are diluted to the infinite and lost.

Very different, in this regard, is the constitution of the air within the walls of houses. The number of microörganisms in the outside air sinks to insignificance in comparison with the air inside the habitations of man. Thus, in Miquel's own house there were in summer, in each cubic metre, 49,800, five times as many as in the street outside, and in winter, owing to diminished ventilation, 84,500, nearly ten times as many as in the street. Dennis found that not a single germ developed upon sterilized glycerine slides exposed off the bow of a ship; but five or six in ten days upon two slides exposed on the promenade deck under free ventilation of air, whereas upon one in the stateroom exposed for but fifteen minutes, there formed in eighteen hours five hundred points, or beginning colonies.

Microörganisms multiply in houses in proportion directly to the number of inhabitants, and inversely to the number of rooms or amount of inhabited space. Cornelly, Haldane, and Anderson published

tables showing the impurity of houses of one room compared with those of four or more. Disease stood in exact relation with the number of inhabitants. The mortality of tuberculosis is greater in houses of one and two than in those of three or more rooms. Neumann observed of the air at the hospital Moabit, examined by Hesse's method, that germs of all kinds were most numerous in the morning after sweeping and after the patients got out of bed—80 to 140 in 10 litres of air, when they gradually reduced in number until evening, at which time they numbered but 10 in 60 litres of air, the average number present in empty rooms. The gradual reduction of microörganisms in the course of the day in a still but peopled room is due partly to the subsidence of the heavier germs, but chiefly to the gradual incorporation of them into the lungs. Numerous observations by Tyndall, Grancher, Charin and Karth, have shown that the expired air is free from all microorganisms, which, introduced into the lungs by the act of inspiration, are retained upon the moist surfaces of the bronchi and air-cells. Thus, the introduction of a number of animals or men into a closed room, while poisoning the air with irrespirable gases, gradually frees it from microörganisms. This fact does not invalidate the observation just made and long ago established by Pasteur and many others that the number of microörganisms in a room corresponds with the number of inhabitants. : for movements of the inhabitants detach or set free the numerous microörganisms deposited upon the clothing, floor, and walls. One circumstance, therefore, which would tend to render the atmosphere of a closed apartment aseptic would be the introduction into it of a number of human beings, an experiment which we see made every day, but which has its results ruined by the subsequent multiplication of microorganisms in and from infected individuals.

No attempt has been made hitherto in this study of the infection of the air to separate the microorganisms of disease from those essential to life, the pathogenic from what we might call the genetic germs. In a general way, it is known to be true that an atmosphere infected with a great number of microörganisms is, or is liable to be contaminated by the largest number of the microörganisms of disease. But direct disclosure of pathogenic microörganisms, even in the air or on the walls of closed compartments, is very difficult, and has been accomplished positively only in the case of erysipelas and septicæmia. Kümmel claims to have found all kinds of microörganisms on the walls of his operating room. Emmerich found on the walls of the pathological institute of Munich the microörganisms of erysipelas, a discovery which was verified by cultivation and inoculation. Eiselsberg found deposited on slides placed on and under the beds of Billroth's wards the staphylococcus aureus, and later, in the same way, Fehleisen's streptococcus. Uffelmann found Friedländer's pneumonia bacillus in the air of a cellar under the hygienic institute at Rostock, and Cornel without doubt inoculated tuberculosis with sponge scrapings from headboards of beds occupied by phthisical patients.

Concerning the presence of microörganisms in general the wall studies of Esmarch, published in the *Zeitschrift für Hygiene*, vol. ii., constitute models for future investigation. Esmarch rubbed down definite spaces of wall paper with thoroughly sterilized sponge and cultivated the germs thus removed in various soils, finding thus, on an average, from various rooms 51 germs in 25 square centimetres, from which he computed 20,400 to the square metre; and to a whole room 979,200 a metre he thinks too small rather than too large. Any pathogenic germs in the air of the room must certainly constitute a certain percentage of this number and these germs, with the rest adhering but loosely to the walls, are liable to be detached at any time. Hence the danger of tearing off the paper from walls, whereby all kinds of microörganisms are set free in the rooms in efforts at disinfection which should be effected by means which incorporates everything in itself, as by rubbing down with bread to be subsequently burned. Such a method is now enforced by legal enactment in the city of Berlin. As was to have been expected, papers showing rough surface, as of silk or felt, offered lodgement to the greatest number of microörganisms. Painted walls with smooth surfaces contained less than smooth, unpainted papers. Closets but rarely opened always contained much fewer microörganisms, evidently because of less infection of the air and speedier gravitation. In all cases the number was greater nearer the floor.

Regarding specific microörganisms, model studies were made with tuberculosis by Cornet. These observations of Cornet, which extended over a period of two years and were first published in abstract (*auto-referat*) in the *Wiener medizinische Wochenschrift*, June 2, 1888, constitute the most remarkable contribution to the etiology of tuberculosis since the disclosure of the tubercle bacillus by Koch in 1882. The fact that all experiments hitherto had failed to discover tubercle bacilli in the air or in the walls of houses led the author to adopt the inoculation test with sponge scrapings from walls and beds of rooms occupied by phthisical patients. The sponges were, of course, previously thoroughly disinfected, and the animals inoculated, freshly bought and free from infection, were, if not dead from other disease, killed after the lapse of forty days—a period in which the disease remains confined to the peritoneum into which the injections were made.

The walls and headboards of beds, posterior surface uncontaminated by sputum or hands, of 21

rooms in 7 hospitals of Berlin occupied by phthisical patients were scraped in this way and 94 animals were inoculated with the scrapings. 15—*i. e.*, two-thirds, of the rooms furnished tuberculous matter. Of the 94 animals, 53 died of other diseases; of the remaining 42, killed after forty days, 20 were tuberculous, 22 sound. The frequency of tuberculosis among the insane led the author to examine the walls of 3 asylums, all of which furnished a virulent tuberculous virus. Dust removed in 11 cases from different places in the near vicinity of tuberculous patients was introduced into 33 animals, of which 16 died of intercurrent disease, 3 were found to be tuberculous, the remaining 14 healthy. 61 dust tests from the walls of houses of 53 private patients affected with tuberculosis, were introduced into 168 animals, of which 90 died soon after the injection, 34 were found tuberculous, the rest sound.

Control experiments from houses not inhabited by tuberculous patients, from surgical wards, operating rooms, crowded streets in Berlin, various public buildings, gave negative results.

Of 311 animals, in all, inoculated with dust from rooms inhabited by phthisical patients 167 died soon after infection, 59—*i. e.*, one-fifth of the whole number, were found tuberculous, and 85 were healthy. A room in a hotel occupied for six weeks by a phthisical actress, and a workshop occupied by a tailor who had directly communicated the disease to a fellow worker, were found infectious. *But in no case was the dust of the walls infectious where sputum cups or handkerchiefs were used exclusively to receive the expectorated matter*, notwithstanding the fact that such sputum often abounded in bacilli.

These observations, which singularly confirm the first statements of Koch, that the disease is chiefly spread by dried sputum, furnish convincing proof of the possibility of preventing tuberculosis pulmonum altogether, a possibility which should be seized upon with all the more avidity, in that the same author shows the futility of all specific treatment with the most varied agents.

From this brief and superficial survey of the constitution of the air the inference is fair that the contagious diseases are contracted not outside but inside the walls of houses, from microörganisms liberated from previous cases of disease, and circulating in the air or lying latent upon the walls and floors of houses, until detached by currents of air and inhaled into the bodies of susceptible subjects.

The proper disinfection of a room would mean, therefore, the removal of all carpets, rugs, curtains, upholstery, to be shaken in the open air and ventilated by exposure in it for several days; the subjection to steam heat of all bedding and clothing in any kind of contact with the sick; the rubbing down of walls with bread or bread-stuffs, which compose the bulk of the patent compounds for this purpose, two or three times successively, and the scrubbing of floors with solutions of corrosive sublimate, one part to one thousand parts of water; withal, the ventilation of the room day and night for several days, at least, to remove as much as possible germs still floating in the air; *in short, to bring as far as is possible the inside into the condition of the outside air by dilution, which is, after all, in the absence of fire, the essence of disinfection.*

But inasmuch as the extinction of a spark is easier than the suppression of a conflagration, the true method of making the air of a locality aseptic is to stamp out the spark. There is, as yet, nowhere in our country, at least, from lack of authority, any systematic attempt at the destruction of the germs of disease as they are produced. The discharges of typhoid fever, cholera, dysentery, yellow fever, are turned into sewers or scattered over soils with the same indifference as in the days when bacteriology was unknown, and with total disregard of its discoveries. Smallpox, which needs it least, meets with more attention from health authorities than scarlet fever, which is more fatal than cholera. Let it be mentioned, in passing, that but a single soldier in the whole army of Prussia has died of smallpox in the last thirteen years. Tuberculosis, which is now believed to be always acquired, and which destroys two-sevenths of mankind, meets with no check at all. The fear of "taking cold," by shutting out all ventilation, is largely responsible for the concentration of pathogenic microörganisms in sick rooms and the consequent dissemination of contagious disease.

Conditions which tend to render the atmosphere of a locality aseptic. Let us consider the subject from the standpoint of a place selected for the habitation of man and erect a house which is to remain, as far as possible, aseptic. It will stand facing the sun on a dry soil in a wide, clean, amply sewered, substantially paved street, over a deep, thoroughly ventilated and lighted cellar. The floor of the cellar will be cemented, the walls and ceiling plastered and thickly whitewashed with lime every year, that the house may not act as a chimney to draw up into its chambers microörganisms from the earth. Doors and windows, some of which extend from floor to ceiling, will be as abundant as circumstances permit, and will be adjusted to secure, as much as may be, thorough currents of air. The outside walls, if of wood or brick, will be kept thickly painted, not to shut out penetrating air, but for the sake of dryness. All inside walls will be plastered smooth, painted, and, however unæsthetic, varnished. Mantels will be of marble, slate, iron, or, if of wood, plain, and whether natural, painted or stained, varnished. Interior woodwork, including floors, will all show plain surfaces and be likewise treated. Movable rugs, which can be shaken daily, in the open air, not at doors or out of windows, where dust

is blown back into rooms, will cover the floors. White linen shades, which will soon show the necessity of washing, will protect the windows. All furniture will be plain, with cane seats, perhaps, but without upholstery. Mattresses will be covered with oiled silk; blankets, sheets, and spreads, no comforts or quilts, will constitute the bedding. Of plumbing, there shall be as little as is necessary, and all there is shall be exposed, as is the practice now. The inhabited rooms shall be heated only with open fires, the cellar and halls by radiated heat, or, better, by a hot-air furnace, which shall take its fresh air from above the top of the house and not from the cellar itself, or the surface of the earth, where microörganisms most abound. There will be "house cleaning" twice a year. Put into this house industrious, intelligent, and informed men and women—absolutely essential conditions, and as much will be done as at present may be done to prevent the dissemination from it of contagious disease, when an inmate brings it home from a septic house, hospital, sleeping-car, school-room, theatre, church, etc. A city of this kind, with a city government by such people, conditions which at present exist only in Utopia, would, least of all, permit to be introduced into it cases of infections like cholera and yellow fever, which must be imported from a distance on each invasion.

A PECULIAR ABSCESS, PUS FROM WHICH CONTAINED THE MICROCOCCUS TETRAGENUS.[1]

BY ROSWELL PARK, A.M., M.D.,
PROFESSOR OF SURGERY, MEDICAL DEPARTMENT, UNIVERSITY OF BUFFALO.

A HEALTHY woman, eighteen years of age, entered the Buffalo General Hospital, October 18, 1887, with the left side of her face and lower jaw so much swollen that the mouth could not be opened. She gave the statement that she had had a very carious third lower, left molar tooth for some time; that she had consulted a dentist about it; that for some reason or other he had failed to remove it or relieve her, and that a week before she entered the hospital her face had begun to swell. On examination, a brawny, carbuncular phlegmon was found, extending from the left ear above to the mastoid muscle behind, the hyoid bone below and the middle of the chin in front. The induration was very firm, could scarcely be indented with the finger, and apparently gave but little pain, since even on questioning she made but little complaint of it. Her temperature was never above 100°, her pulse not materially disturbed, her bowels sluggish; except for the location of the swelling, which extended too high, I should have regarded it as an illustration of the infectious submaxillary angina of Ludwig. It had the same character of induration and much the same indolence of disposition.

I kept the part poulticed, and daily applied mercurial ointment, with the idea of hastening suppuration; but in this respect I was disappointed, since, after three weeks of diligent poulticing, only in three small points were any evidences of softening observed. All this time the front teeth could not be separated to exceed a quarter of an inch; her general condition remained about the same. After waiting until November 9th, I anæsthetized her in my clinic, forcibly pried apart her jaws, and, with great difficulty, succeeded in extracting, bit by bit, the offending tooth, which was a mere shell, its cavity being entirely carious and its substance quite fragile. After doing this, I made incisions into each of the points of softening, evacuated a small amount of pus and débris from each, and then, with a sharp spoon, scraped out as much of the surrounding tissue as seemed judicious. Her convalescence was slow; the induration about the parts persisted for a long time. It subsequently seemed advisable to open two or three small collections of pus, but she was not anæsthetized for this purpose again. She gradually recovered ability to open her mouth, and by the last of December the swelling and induration had subsided sufficiently to allow her to go home.

At the time of the operation I made several inoculations, on gelatine and agar jellies, of pus from the depots of softening. These were subsequently carefully cultivated and plated out, and were found to contain the two common forms of staphylococcus and the unusual micrococcus tetragenus. It is on account of the latter that I have reported this case. So far as I know, this has not been previously found to be pathogenic in man, although it is known that when mice or other small animals are inoculated with it experimentally, they die in three or four days. It is stated that this organism is occasionally found in human *saliva* and in sputum.

According to Koch, these germs are also found in tuberculous cavities, forming groups often surrounded with capsules. When an animal is inoculated with these, it dies in three or four days, with symptoms of septicæmia or pyæmia, and with metastatic abscesses in the spleen and kidneys. Large masses of the microbes are found, especially in the vessels and in the pulp of the spleen. Cornil and Babes have also found this germ in a syphilitic abscess, in groups and encapsulated, and in several metastatic (pyæmic) abscesses in the same case. It is not at all improbable that their occurrence in connection with syphilis was accidental. Aside from these instances, so far as I know, their presence has never been associated with any distinct pathological condition, and I am unaware that it has been considered in any sense, in man, a pyogenic organism. The path of infection in this case was undoubtedly through the diseased tooth. Whether the micrococcus tetragenus was the principal source of the infection, or even whether it is capable of so acting, I am unable to say; also, whether to it is due the fact that one may have induration and tardiness of resolution. Not having found any case in which

[1] Reported to the American Surgical Association, Sept. 18, 1888.

this organism had been supposed to have any pathogenic effect in man, I herewith report this one as of some pathological interest.

CANTATORY PARESIS.

By J. SOLIS COHEN, M.D.,
of Philadelphia.

Cantatory paresis is a variety of vocal disability experienced only in singing; the voice remaining good in all portions of the register utilized in ordinary conversation.

Clinical History.—After some unusual vocal effort or after some ordinary vocal effort during a period of debility, a singer's voice will begin to fail at some special note of the register. In some instances failure is limited to a single portion of the register. As determined by the researches of Langmaid (*The Medical Record*, May 26, 1883, p. 576) this will most likely occur at the ninth note in the scale in the key of C, for tenor and soprano voices; and at the seventh for base and contralto voices. In other instances all tones are uncertain above the one at which the break begins.

Pathology and Morbid Anatomy.—In some instances no pathological condition can be detected. In most cases there is a slight congestion of one or both vocal bands, which becomes more and more pronounced as the defective tone is approached in singing the scale from below upward. In marked instances there may be a lack of due longitudinal tension of the vocal bands, so that the glottic orifice remains elliptic in its entire extent and does not close posteriorly as the voice rises in pitch. This is due to failure in the proper contraction of the thyro-arytenoid, lateral crico-arytenoid, and crico-thyroid muscles.

It is possible that undue strain may stretch, or tear, or otherwise impair some of the delicate muscular fibrillæ of the thyro-arytenoid muscles, so as to interfere with the adjustment of the vocal bands necessary to produce the tones at which failure occurs. This failure throws undue effort upon other muscles in the endeavor to secure the tension necessary for cantation; and this effort fatigues the muscles and produces atony with irregularity in contraction, and consequently in phonal vibration of the vocal bands.

Symptomatology.—There is a lack in the precision of the tone as the point of failure in the scale is reached; and this is sometimes associated with an involuntary slide or a tremble. Prolonged effort, as in singing, is quite fatiguing and sometimes painful. The conversational voice remains unimpaired.

Etiology.—The most frequent cause is overfatigue of the intrinsic muscles of phonation, from undue exercise in forced efforts beyond those required in the ordinary adjustments of the vocal bands for the natural emission of the tones made. This may be due to prolonged effort under ordinary conditions of health, or to customary efforts made during impaired conditions, whether physical or mental, or both. Faulty respiration in singing (Mandl, Paris, 1855) is, perhaps, the next most frequent cause.

Diagnosis.—There is usually a lack of longitudinal tension of the vocal bands, and, in some instances, the bands are more or less undulatory in outline on their horizontal surfaces. The vocal bands are usually somewhat congested, in some instances with a pearlish translucence. In the absence of positive laryngoscopic evidence of atony, the character of the voice and the history of vocal fatigue remain the sole features in diagnosis.

Prognosis.—The prognosis is good, provided that the voice be given proper rest and that suitable therapeutic measures be instituted. Should these precautions be neglected and the voice be continued in use, permanent injury may be sustained and the voice, for many months or even for a year or longer, may be rendered useless for singing purposes.

Treatment.—The first element in treatment is absolute rest of the singing voice and comparative rest of the conversational voice; that is to say, avoidance of all unnecessary use of the voice. The next point is attention to any impairment of the general health. Strychnine, quinine, and cocaine are the special medicinal agents most likely to be directly beneficial to the impaired muscles. Finally, systematic vocal exercises, limited to the unimpaired portion of the register, and daily percutaneous applications of currents of induction from one side of the larynx to the other will assist materially in overcoming the muscular atony, and thus hasten restoration of the vocal powers. Great care should be exercised in resuming prolonged vocal efforts for a year or two after apparent cure has been effected, lest the condition recur in an aggravated form.

In cases of moderate disability it is possible so to arrange the music as to avoid using the tones in which the voice shows impairment (Langmaid).

A CASE OF MARKED ŒDEMA OF THE LABIA UTERI DURING PARTURITION.

By DANIEL B. D. BEAVER, M.D.,
surgeon and ophthalmologist to St. Joseph's Hospital,
Reading, Pa.

The following case occurred eleven years ago, and is now placed upon record because of the extreme rarity of the class to which it belongs, and to show the ease with which gross errors in diagnosis are sometimes made under strange but otherwise simple conditions. During these eleven years I have not met a similar case in a pretty wide acquaintance with our periodical literature, nor did I find

the subject in an examination of a dozen or more text-books.

Mrs. B. had been in her third labor three hours when her physician called me, believing that he was confronted by a placenta prævia, although there had been no hemorrhage. Upon digital examination these curious conditions were found: The finger met in the orifice of the vagina a mass of tissue, somewhat cone-shaped, with the apex downward and base above, attached to and continuous with the vagina, and forming with it a cul-de-sac. It presented the doughy feel of œdematous tissue, which is not unlike that of the placenta. Upon sweeping the finger around the mass carefully a fissure was discovered, which divided the whole length of it into two very nearly equal parts, of which the inner surfaces were continuous with the cavity of the uterus. It was then clear that the mass was a growth from the os uteri or represented the labia of the os enormously thickened and elongated. Each of the lips was about two and a half inches long, three inches wide, and nearly half an inch thick at the base, from which they tapered both in thickness and width to a blunt point or edge, the whole shape bringing to mind strongly the figures and descriptions given of the elongated nymphæ of some of the South African tribes.

The external genitals were normal, and there was no œdema in any other part, but the case was further complicated by more common irregularities above the os uteri. The os was fully dilated, and the superior strait of the pelvis was engaged by a small fœtal head in the first position of the vertex, one arm and the funis. The patient was put in the knee-elbow position, the arm and cord pushed above the brim, and held there until the accession of the next contraction of the womb, when the head descended to the floor of the pelvis. Two more pains completed the delivery of the child without difficulty, and the woman recovered in the usual time.

There was no ascertainable cause for this anomalous appearance of the lips of the uterus. A bilateral rupture of the os and cervix in a preceding labor might suggest itself, but such a theory lacks the necessary support which a history of the symptoms of rupture would give it. She said she was in good health before this pregnancy, and has not shown any signs of uterine disorder since. It would be useless then to speculate further upon the causation.

MEDICAL PROGRESS.

The Sterilization of Milk at the Time of Milking.—Raudnitz, before the Central Organization of German Physicians in Bohemia, on July 15, stated that milk obtained from a cow three weeks before, and kept at the ordinary temperature of a room, remained as alkaline as immediately after milking, and was not to be distinguished by taste, odor, or appearance from freshly drawn milk. This circumstance, as well as the fact that repeated boiling, to which a sample was subjected, produced no change, bespeaks entire freedom from germs, without any bacteriological examination. The steam apparatus in the stalls for boiling the feed is also used to sterilize the glass receptacles furnished with air-tight rubber stoppers, so that there is no extra cost. A covered wooden tub with shelves of perforated tin plate receives the bottles. By means of a pipe steam is passed into the tube from below. Prior to milking, the udder of the cow, the milk-pail, and the hands of the milker are carefully cleansed. The milk is strained through clean linen directly from the pail into the sterilized bottles. Should a steam apparatus not be accessible, the bottles can be sterilized in a large, covered vessel. Upon the recommendation of the speaker, sterilized milk is so prepared and sold at Hostiwitz, near Prague, during this autumn. Since introducing among his patients milk thus sterilized, he has seen no cases of diarrhœa. Constipation is the rule upon weaning; in which case a small quantity of carbonate of magnesium or phosphate of sodium may be added.—*Wiener medizin. Presse*, Sept. 9, 1888.

Surgical Treatment of Peritonitis.—Leucke, of Strasburg, reports a case of peritonitis coming under his notice, treated by operative procedures, occurring in a youth of sixteen, who drank a glass of beer, and soon afterward felt a severe abdominal pain. He was admitted into hospital with all the signs of acute peritonitis; temperature 106°. The abdomen was opened the same evening, and half a litre of pus removed; it was then washed out with a weak sublimate solution, and a thick drainage-tube was placed in Douglas's pouch. The patient went on well for six weeks, when a subphrenic abscess developed on the right side, which soon broke into the pleural cavity. Resection of the seventh rib was performed, and drainage instituted with perfect success. There was doubtless a latent intestinal ulcer with first perforative peritonitis, and, subsequently, localized peritonitis, which broke through the pleura. Dr. Heuser, of Bremen, has lately operated in three cases of perforation of the vermiform appendix. Two of the operations were successful, but in the third there were metastatic abscesses in the liver, which soon caused death. In each case the abscess was sharply defined, though without extensive adhesions. Dr. Heuser thinks that many such cases which end fatally might be saved by surgical treatment. Professor Czerny, of Heidelberg, operated in perforative peritonitis in an obscure case; a large quantity of odorless gas escaped, and the stomach was found adherent to the liver and anterior abdominal wall. The intestines were normal. Unfortunately, no attempt was made to free the stomach, and the patient died on the fourth day. On *post-mortem* examination there was found a gastric ulcer and subphrenic peritonitis. An odorless gas in such cases indicates perforation of the stomach; a fetid gas intestinal perforation.—*British Medical Journal*, Sept. 15, 1888.

Electricity in Goitre.—In a case of goitre which had been treated for two years with no success, Weinbaum obtained a cure by use of the galvanic current. The electrodes were gold needles and were thrust into the sides of the tumor for several millimetres and a moderate current applied for fifteen minutes. A superficial eschar often formed at the negative pole, but this wholly dis-

appeared with the ending of the treatment, which included one hundred and five *séances*.

His second was more successful than the first, only fifty applications being necessary.—*Lyon Médical*, Sept. 1888.

Cocaine Anæsthesia in Surgical Practice.—Jaffé (*Aerztl. Practiker*, No. 16) recommends the more extended application of cocaine anæsthesia in surgical practice, in many cases obviating the use of chloroform, with its dangers, and rendering an assistant unnecessary. He uses a five per cent. solution to which he adds an antiseptic, according to the following formula:

R.—Cocainæ hydrochlor.	. .	gr. xxiv.
Acid. carbolic.	. . .	gr. x.
Aquæ dest.	. . . .	f ℥j.—M.

Of this, two or three divisions of a Pravaz syringe are injected at several points in a line corresponding to the course of the proposed incision. In four or five minutes the anæsthesia is usually complete, and the incision can be made without the consciousness of the patient. In operations upon the extremities the suggestion of Corning, that after the injection the part above be constricted by a rubber tube, is most practical. By this means, besides the artificial anæmia, a notable prolongation of the anæsthesia is secured. Ordinarily the influence lasts from twenty to thirty minutes. Should sensibility to pain return during the course of the operation, a few drops of cocaine are placed in the open wound, the operation is suspended for a few minutes and is then again proceeded with. After the removal of a tumor, the wound is disinfected in the usual manner and closed by a few stitches. The passage of the needle is felt by sensitive persons, but is not perceived as actual pain. Intoxication may arise, but is rare if some care is observed; still it is wise to have at hand a quantity of amyl nitrite, which has proved itself the most effective antidote. A list of operations, from the experience of the author and from that of others, in which cocaine anæsthesia proved satisfactory, follows. Among these were the removal of foreign growths, neoplasms of small and moderate size, incisions for paronychia, abscesses, furuncles and phlegmons, removal of ingrowing nails, tracheotomies and herniotomies.—*Münchener medicin. Wochenschr.*, Aug. 28, 1888.

Splenectomy.—A successful operation for the removal of a floating spleen has been performed in Trieste, by Liebman. The patient was a woman, aged twenty-eight years, who in her third pregnancy noticed a hard round tumor in her abdomen toward the left side, below the level of the umbilicus. For some time the swelling remained stationary, but five months before she came under the care of Dr. Liebman, it began to grow rapidly and to cause great pain, especially when she moved about. She became quite unfit for work, and on November 24, 1887, was admitted into the Ospedale Civico. On examination, the liver and spleen appeared to be normal in size, the area of dulness corresponding to what was supposed to be the latter, extending in the left axillary line from the eighth to the tenth rib, whilst its vertical diameter seemed to be about seven centimetres. The abdomen contained a roundish but somewhat oblong tumor about the size of a small adult head, which appeared to rest on the upper margin of the pelvis. The mass, which was situated rather to the left of the middle line, was evidently intraperitoneal. Its surface was smooth, with a kind of notch in the middle. It was movable in every direction, and could be carried up to the margin of the ribs on the right side as well as on the left, but could not be pushed into the hypochondrium beyond that point. There was no adhesion to the abdominal wall in front. A distinct systolic *bruit* could be heard over various parts of the mass. The uterus was normal, but followed the tumor when the latter was pushed toward the right, but not when it was carried over to the left side or in an upward direction. The tumor could be freely handled and moved about without pain. There was no albumin in the urine, of which rather more than a litre was passed in the twenty-four hours, and there was no disturbance of digestion. A diagnosis of ovarian or mesenteric tumor was made, and laparotomy was determined on. On December 13th Dr. Liebman opened the abdominal cavity by a median incision eighteen centimetres in length, and divided the peritoneum, which was remarkably thin and transparent along the whole length of the wound. The ovaries were atrophied, and neither they nor the uterus had any connection with the tumor. On drawing the latter out of the abdomen it proved to be the spleen, enlarged to four times its natural size, whilst *in situ* its convex surface had been directed upward and forward, and was adherent for a great part of its extent to the omentum. The mesenteric vessels were tied and all the attachments of the tumor carefully divided between double ligatures, till only the pedicle (formed by the vessels. etc., entering the hilum), which was as thick as the little finger, remained. This was then divided into three bundles, each of which was tied separately, the end of the last ligature being finally passed round the whole for additional safety. The pedicle was further secured by a second ligature two centimetres and a half higher up; and, lastly, it was again tied close to the spleen. It was then divided between the two last-mentioned ligatures, and the spleen removed. The organ measured seventeen centimetres in length and ten in width, and weighed 600 grammes. Having satisfied himself that there was no blood in the peritoneal cavity, the operator closed the abdominal wound with seven deep sutures taking in the peritoneum, and five superficial ones. A Listerian dressing was applied. The patient rallied from the operation, and, with the exception of a good deal of tympanites, did well till the eighth day, when the sutures were removed, the wound having healed without suppuration. On the night of December 21st menstruation began. A good deal of pain accompanied the discharge, and there was some pyrexia. Soon extensive parametritis set in, which, however, yielded to general treatment. The patient remained weak and anæmic for some time, but finally left the hospital completely cured on March 25th.—*British Med. Journal*, September 15, 1888.

Destruction of Corns and Warts.—Mason recommends the following, a small portion of which is to be painted over the growth:

R.—Lactic acid	. . . . .	10 parts,
Salicylic acid	. . . .	10 "
Flexible collodion	. . .	80 " —M.

—*Les Nouveaux Remèdes*, Aug. 1888.

The Diuretic Action of Beer.—Mori (*Archiv f. Hygenie*, Bd. 7, S. 319) conducted a series of experiments in the Munich Institute of Hygiene to determine to what extent the use of beer affected the secretion of urine, to which ingredient the action was due and how this action was to be physiologically explained. After the author established the action of beer beyond a doubt, he endeavored to learn whether it was shared by other alcoholic liquors, and found that wine possessed a still more powerful diuretic influence. The use of carbonic acid water and of diluted wine spirit (four per cent.) increased the amount of urine for several hours, the increase with the latter being the most marked. The author hence concludes that it is the alcohol to which is due the increased diuresis of beer and other alcoholic liquors. As a result of experiments with the other constituents of beer he finds that the ingestion of a decoction of hops gives rise to an irritation of the urogenital apparatus (beer urethritis) which may be prevented by the simultaneous use of small quantities of nutmeg. At the conclusion of his work, the author endeavors to explain theoretically the alcoholic diuresis.—*Centralbl. f. die ges. Therap.*, August, 1888.

Paste for Toothache.—

Acid. arseniosi	2 parts.
Cocaine muriate	2 "
Menthol cryst.	0.5 part.
Glycerine q. s. to make a paste.	

Introduce into the cavity of the aching tooth.—*Amer. Journ. of Pharm.*, August, 1888.

Sterilization of Surgical Instruments.—By means of experiments at the Hygienic Institute, at Berlin, Dr. H. Davidsohn (*Berlin. klin. Wochenschr.*, No. 35) has determined that the simplest and safest method of destroying germs contained in the blood or pus adhering to instruments, is to boil the latter at 212° F. for five minutes. Anthrax spores, as well as other pathogenic germs, such as tubercle bacilli, the micrococci of pus, etc., are by this means effectively destroyed. After an operation, the instruments are placed in cold water and the pus brushed off; water is passed through syringes and canulæ, which are left filled. The instruments are then boiled for five minutes in a covered water bath, at a temperature of 212° F. After removal, they are dried with a sterilized cloth. When they are to be employed again, they are boiled for five minutes, removed, and permitted to cool, and then used without immersion in a disinfecting fluid. The method is safe; it does not injure the instruments; it is convenient; it does not occupy much time; it is cheap; and it may be carried out in any private house. It should be observed that the boiling must be done in a covered vessel, as the water in an open vessel only reaches 212° F. at the bottom.—*Munchener medicin. Wochenschr.*, September 4, 1888.

Chloride of Ethylene.—M. Dubois has been experimenting with chloride of ethylene on dogs, and finds that it is an anæsthetic far superior to chloroform. He gave it by inhalation, and among the singular effects it produced was an opalescence of the cornea. Both corneæ assumed a bluish tint like thin porcelain, which gave a peculiar staring effect to the dog's eyes.

Contrary to expectation, no sloughing followed, but at the end of several months the cornea cleared up and regained a normal appearance.—*Gazette Hebdomad. de Med. et Chirurg.*, September 7, 1888.

The Vomiting of Pregnancy.—In connection with a case of obstinate vomiting in a pregnant woman who declined the induction of abortion, fatal in twenty-five days, Jaffé, of Frankfort (Volkmann's *Sammlung klinischer Vorträge*), discusses hyperemesis gravidarum. Three varieties of vomiting of pregnancy are to be distinguished. In the one, the vomiting occurs only in the morning, on an empty stomach. This is the most frequent, and the prognosis is good. In the second, which is not rare, the woman vomits in the morning and also during the day after every meal, though but a part of the food. The appetite is good, and the nutrition is not affected. With the occurrence of fœtal movements the disorder disappears. The third variety, the persistent vomiting, is rare. It begins with conception or later on. Whether primigravida or multigravida are the more often affected has not yet been determined. The etiology is unknown. To say that the affection is a reflex neurosis, brought about by irritation of the uterine nerves, is indefinite. The course of the disorder may be divided into three stages. In the first, all food is rejected, there is no fever, but there are thirst, epigastric pain, pytalism, frequently constipation, anæmia, and emaciation. In the second stage, there is moderate fever, the tongue is dry, and the epigastric pain persists. The breath is offensive, the urine is concentrated and contains albumin and casts, the results of a nephritis induced by inanition. The emaciation and debility increase. In the third stage, there is high fever, delirium sets in, the patient becomes soporose and dies. The diagnosis is easy. The distinction is to be made as to gastric disorders and neuroses. The prognosis is very dubious. It is influenced by the time at which the hyper-emesis occurs and by the life or death of the fœtus. Dietetic-medicinal treatment is useless, as a rule. Opium and bromides act best. When local disorders exist, the appropriate remedies are effective—for uterine displacements, reposition and pessaries, for inflammations, astringents. Should the dietetic-medicinal treatment fail, the pregnancy should be ended; but the third stage shall not have been reached, for in this the patient is hopelessly lost.—*Wiener medizin. Presse*, Sept. 9, 1888.

Pseudo-ulcers of the Tongue.—Velpeau has already described imaginary tumors of the female breast as a special class not to be operated upon; they consist in somewhat hard and sensitive lobules of the gland and intercostal neuralgias, with localized pains in the gland. Verneuil (*Bulletin de l'Académie de Médecine de Paris*, Séance du September, 1887) makes a similar classification of certain ulcers of the tongue: painfulness and a pseudo-ulcer depressing the spiritus of the patient are the factors. The author has seen five such cases, which resemble one another. They are pure lingual neuralgias; a true ulcer is not to be discovered; a psychical condition seems to predispose to the disease. Three causes may be assumed, the arthritic diathesis, false teeth, and tabes. The prognosis as to life is favorable, as to longevity unfavorable. Bromide of potassium and moral treatment are most effective.—*Medicin. Chirurg. Rundschau*, August 1.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

PHILADELPHIA.

SATURDAY, OCTOBER 6, 1888.

INTRAPERITONEAL RUPTURE OF THE BLADDER.

SINCE the brilliantly successful cases of recovery after abdominal section for intraperitoneal rupture of the bladder by MacCormac and Holmes more than a year had elapsed until the July journals brought us reports of three new cases which all terminated in recovery. One is recorded by Mr. Halstrom (*Lancet*), another by Dr. H. H. Grant (*Journal Amer. Med. Assoc.*), and the third by Dr. A. Blum (*Archives gén. de Méd.*).

These cases, together with those already tabulated by Morton, and by Grant in his present paper, make a total of 16 cases operated upon. Of these, 7 have recovered and 9 have died, a mortality of fifty-six per cent. But if from this we deduct 8 fatal cases which were not operated upon until an average time of 28 hours after the receipt of injury the death-rate diminishes very greatly, whilst if, further, we deduct the ninth death, which was due to faulty suture of the bladder and subsequent intraperitoneal leakage, the percentage of deaths following operative relief becomes *nil*. Therefore, may we not justly conclude that such rupture of the bladder, provided that but a few hours have elapsed since the occurrence of injury, and that no serious concomitant accident, such as crush of the pelvis, is also present, should be amenable to surgical technique, such as has been described by MacCormac and Holmes, with a death-rate no higher than that of uncomplicated ovariotomy?

The technique has proved practically perfect from its incipiency, and no improvements upon it have even been suggested. But diagnosis, on the contrary, is sadly behind the perfection of the relieving measures. Many a man even yet dies for want of an unequivocal sign or series of signs or symptoms which will prove intraperitoneal rupture of the bladder, and, even granting the possession of such certain tests, many would even then continue to die because of the frequent absence of symptoms calling attention to the bladder as the seat of injury until it may have become too late to interfere, as violent peritonitis will have commenced or the patient has entered a state of fatal toxemia from absorption of urinary excreta and products.

These points are well exemplified in the report of Blum's case, which, by the way, is the first operation of the kind which has been reported from France. In abstract it is as follows: An intoxicated stoker was run over by a heavy wagon and very shortly afterward admitted to the Hospital Riboisière. The wheels had only passed over his thigh, but witnesses stated that the horse had stepped upon his abdomen. The bruised extremity constituted the patient's chief complaint, although he also had great desire to micturate but could not. A catheter was, therefore, introduced and normal quantities of clear urine were from time to time by that means withdrawn. No other abdominal symptoms were noted until he had been in the hospital nearly twenty-four hours, when signs of rapidly developing peritonitis were observed. At that time more clear urine was withdrawn by catheter. Upon the following day as the abdominal symptoms had become accentuated operation for *peritonitis* was undertaken. This was forty hours after the accident. A large quantity of clear fluid, having the appearances of urine flowed from the peritoneal cavity when it was opened and signs of acute peritonitis were there present. Not until now was rupture of the bladder even suspected, but upon examination of that organ a one inch tear was discovered in the upper portion of its wall a little to the left of the median line. There was no bloody infiltration of the edges of the bladder wound. Ten Lembert sutures were required to close the rent. The peritoneum was cleansed, the superficial wound closed, and a permanent drain left in the abdomen. Convalescence was uninterrupted and his recovery rapid, an unaccountable acute cystitis on the thirteenth day being the only drawback. This lasted for but a day or two and did not interrupt his progress.

As exemplified in the above and other cases, a formerly much-thought-of diagnostic sign has been proved of but little worth either as a positive or negative one. This is the presence or absence of sanguinolent urine, for in several reported cases clear urine has been repeatedly and in large quantities withdrawn from bladders which have afterward been found badly torn, whilst bloody urine is even more frequently withdrawn from an intact bladder. Likewise, it has been shown that absence of urine or the withdrawal of large amounts, are signs not much to be relied upon in forming a diagnosis. The question whether a drain shall be left in the abdominal cavity or not is still an undecided question, but we should be inclined to do so in any case if more than a few hours had passed since the accident or if any signs of peritonitis were present at the time of operation.

Two things we would suggest in forming a diagnosis of vesical rupture; first, always to *think of the possibility of injury of that viscus* in any serious or obscure accident; and second, to add to our present tests for its occurrence the *gentle introduction of hydrogen gas into the organ* and noting whether it escapes into and distends the general cavity of the peritoneum or simply distends the bladder itself. This experiment we have tried upon both male and female bladders before and after artificial rupture, and have met with such successful results as to justify the belief that it is a diagnostic sign of great promise. Possibly an extraperitoneal rent might make its presence known during such a test by giving rise to emphysema of the surrounding tissues.

YELLOW FEVER IN THE SOUTH.

It is a question of grave doubt whether the imposition of land quarantine against localities in which yellow fever prevails is justified by our knowledge of the nature and mode of propagation of this disease. The consensus of medical opinion is opposed to the contagiousness of yellow fever, but favors the view of its miasmatic origin. It is believed that the cause is a living miasm developed in a locality under favorable conditions of climate and soil, and those who suffer from the morbific agent do so only within the area of its generation and occupation. Under certain circumstances the peculiar emanation may be air-born, as is believed to have been the case at Bermuda, where successive outbreaks of yellow fever occurred without there being any other source from which it could have been derived. But then it does not give rise to the disease until after it undergoes further development in a congenial soil under favorable climatic condition. Or, the potential agent may be carried to distant places in the foul hold of a ship, which for the time becomes a locality engendering the disease but affecting only those who come within reach of the emanations from it. The spread of the disease at such places depends on whether the local conditions are favorable or not for the further development of the miasm.

There is not sufficient evidence to sustain the opinion that the importation of cases from fever-smitten localities to healthy places will give rise to outbreaks of the disease. Another characteristic of yellow fever is that it is chiefly developed in cities and towns which have maritime commerce, whether that be upon the seacoast or upon rivers. It is not by the traffic of the great thoroughfares of land, but by means of commerce carried on by ships, that it is diffused. It would seem, therefore, that strict sanitation broadly applied, particularly to vessels from localities where the disease prevails and to the localities themselves, and the removal of the healthy unacclimated population from the area of fever prevalence, are the best means of checking the spread of the disease.

Inland quarantine, which inflicts unnecessary hardships, paralyzes trade, and leads to demoralization, does not seem to be warranted by the facts at our command. The accounts which appear in the daily press descriptive of the plans being pursued in the South, show how mischievous demoralization may become when it acquires the ascendency over calm and judicious direction of scientific measures.

The ninth volume of the invaluable *Index Catalogue of the Library of the Surgeon-General's Office* has just appeared. It contains 1054 pages, and extends from "Medicine (popular)" to "Nywelt." It includes 13,151 author-titles, representing 6834 volumes, and 12,818 pamphlets, and 9999 subject-titles of separate books and pamphlets, and 29,120 titles of articles in periodicals. Like its predecessors, it has been compiled under the supervision of Surgeon John S. Billings, and its publication is one of the most gratifying evidences of the intelligent liberality of the National Government.

The President has directed Dr. George M. Sternberg, Surgeon, United States Army, to proceed to

Decatur, Ala., and to such other points in the infected districts of the Southern States as he may deem necessary to continue his scientific investigations of the yellow fever.

AMONG the new books announced for the autumn we notice *The Fatal Illness of Frederick the Noble*, by Sir Morell Mackenzie; *Lectures and Essays on Diseases of the Nervous System*, by Dr. J. S. Bristowe; on *The Artificial Feeding of Infants, and the Diseases which Arise from Faults of Diet in Early Life*, by Dr. W. B. Cheadle; *A Treatise on Gout*, by Sir Dyer Duckworth; *A Text-book of Human Anatomy*, by Dr. Macalister; a translation of von Jaksch's *Text-book of Clinical Diagnosis*, and a work by Mr. Lawson Tait on *The Diseases of Women and Abdominal Surgery*.

THE Members of the Municipal Chamber of Rio de Janeiro are raising a subscription for the purpose of sending a testimonial to Charcot and the Italian physicians who attended their Emperor.

AN Italian society for internal medicine will shortly be organized at Rome, for the furtherance of practical and scientific interests. Among the organizers are Baccelli, Cantani, Bozzolo, de Renzi, Cardarelli, and others. Evidently this new organization is a further outcome of the stimulus given by Leyden in the foundation of the Society for Internal Medicine. The first Congress will be held in Rome from the 15th to the 18th of October of this year. Among the papers already promised are: "Diabetes and its Treatment," by Cantani; "The Etiology and Therapy of Pneumonia," by Bozzolo and Maragliano; "The Treatment of Tuberculosis," by de Renzi and Riva; "Fever and Antipyretics," by Murri et Rossoni; "The Therapeutics of Cardiac Diseases," by Giovanni and Rummo.

AT the last Congress of Polish Physicians and Naturalists, upon the suggestion of Prof. Rydygier, a Society of Polish Surgeons was formed, the first meeting of which will be held next year, in connection with the opening of the surgical clinic recently erected at Cracow.

THE election of Prof. Gerhardt as Rector of the University of Berlin for 1888–9, has been confirmed by the Emperor.

BIEDERMANN, of Prague, will succeed Preyer at the University of Jena.

SOCIETY PROCEEDINGS.

ASSOCIATION OF AMERICAN PHYSICIANS.

Third Annual Meeting,
Held at Washington, September 18, 19, and 20, 1888.

(Specially reported for THE MEDICAL NEWS.)

SEPTEMBER 18TH.—MORNING SESSION.

The PRESIDENT, DR. WILLIAM H. DRAPER, of New York, called the Association to order and delivered

THE PRESIDENT'S ADDRESS.

He said: We are met as "friends in council," to present and compare the results of our individual experience, to discuss the questions which vex us, and to add something, if possible, to the enlargement of the science and the improvement of the art which constitute the aim and purpose of our lives. The Council has decreed that there must be a formal introduction to this function, and, instead of following the excellent example of my predecessors, and showing my respect for your precious time, I am compelled to subject you to an infliction from which I would gladly stay my hand.

From its beginning the medical art has been struggling to rid itself of superstitions and delusions. It has always been hampered by the tyranny of tradition, and in our day it is bewildered by the revelations of science. How to assimilate the discoveries in the etiology of disease, in physiology, in organic chemistry, and in psychology, and how to make them all contribute to more exact diagnosis and more rational therapeutics are the great problems which ever lie in the path and confront the conscience and the resources of the practical physician. As I have said, there is always the danger that science may become prematurely practical, and art, therefore, falsely scientific. It is well to remember that in one sense practical is always in advance of scientific medicine, and that in another it is always in its train. It is always in advance, because it is ever referring new problems to science to solve; it is in its train, because it has continually to test and digest the theorems which science suggests for their solution.

There is no better illustration of this statement than that which is afforded by the history of parasitism, the latest and most portentous contribution which science has made to the theory and practice of the healing art. The observations and speculations of practical physicians may be said to have led up to this discovery, and the revelations of scientific investigation have suggested the theorems which are now being tested by the practical physician. Already the applications of these theorems may be said to have reformed surgery, and to have given a new and hopeful direction to the rational treatment of disease, but it is not yet safe to affirm that the doctrine of parasitism may not be forging new errors in diagnosis, and beguiling us into dangerous paths in therapeutics.

Bacteriology indeed affords a curious and interesting example how, in the cycle of human knowledge, history repeats itself, and how ancient ideas present themselves clothed in new forms, but revealing the same essential nature. For what is the germ theory of disease but a concrete form of the abstract idea that disease is an entity, an enemy that invades and destroys, that must be contended with as a foe, and exorcised as a demon? It

is the old "deus ex machina" come back to us to explain the mystery of disease. This time he is, to be sure, tangible; we can distinguish the variety of his hosts, and count his battalions. He is no longer the "pestilence that walketh in darkness," and we are entering upon the crusade against him as if he were the cause of all our woes. He is verily become a germ of universal discord.

But not only has the germ theory revived, in more exact and tangible form, the ancient pathology; it has reinaugurated, as a natural and necessary sequence, experimental efforts to destroy the germ; and as, in the olden time, the attempts to exorcise the demon often led to the destruction of the victim, so, in these latter days, there is danger lest the war upon parasites should add new and worse perils to their hosts. It is still possible that we may not only exaggerate the influence of germs in the production of disease, but the necessity also of destroying them at all hazards, as the only principle involved in antagonizing their effects. We may well believe that we are on the eve of momentous changes in the healing art, resulting from discoveries in bacteriology, but these changes must come mainly from the independent and judicious application of these new ideas to the study and treatment of disease by the practical physician at the bedside.

Already the relations of bacteria to the pathology and treatment of fever furnish an illustration of the way in which clinical observation enlarges and complicates the problem which the pathologist has to solve. Until we know how microörganisms produce fever, whether by their irritation of nervous centres, or by the increased oxidation incident to their multiplication, or by the development of ptomaines, or in some other as yet unexplained way; until we know whether the fever they produce, however produced, is a salutary or a dangerous process, to be antagonized or let alone, we are really in no better position to treat fever rationally than we were before the etiological relation of bacteria to fever was suspected. Were it not that clinical observation and experience are thus continually complicating the problem and opposing new obstacles to the precepts of experimental pathology, a check would not so soon have been given to the indiscriminate use of antipyretics and parasiticides.

I have cited bacteriology as one illustration out of many which might be given, of the independent nature and special aim of scientific medicine, and to show how practical medicine must pursue, in dealing with scientific theorems, an equally independent method in testing and applying the precepts which these theorems suggest. And as scientific medicine has divided and specialized its work, in the many departments of science which contribute to our knowledge, so practical medicine, by the specialization of its aims and the division of its labor, illustrates the independent growth and progress of the medical art.

In the Congress which has gathered here at this time we have a significant acknowledgment of this fact, and an abundant confirmation, if any were needed, not simply of the mutual dependence of the science and art of medicine, but of their independent developments, science ever seeking to solve the problems in the path of art, and art determining for itself its own limits and possibilities.

Dr. W. W. Johnston, of Washington, then read a paper entitled,

Geographical Distribution of Typhoid Fever in the United States.

Typhoid fever, he said, is admitted to be a very generally distributed disease in the United States, but there is a great difference of opinion as to what constitutes typhoid fever—what symptoms are essential to its recognition. The difficulties lie in the fact that typhoid fever is frequently a very mild disease, with few of the characteristic symptoms; and that sometimes the illness is so slight that its true nature is not recognized until some sudden accident, as hemorrhage from the bowels or perforation, reveals its true nature. The difficulty is increased still more by the simultaneous occurrence, in malarial districts, of forms of fever which have some of the symptoms of typhoid and some of malarial fever. The question is to determine to which category such obscure or doubtful cases belong. In the present paper the effort was made, by a study of the prevailing forms of continued fever in different portions of the country, to determine the relative value of their symptoms, and to arrive at more precise rules of diagnosis. Such a study reveals the fact that the principal forms of fever recognized are: (1) true typical typhoid fever; (2) true typical malarial (remittent or bilious) fever; (3) adynamic malarial fever; (4) typho-malarial fever; (5) anomalous obscure forms appear as simple, continued fever, gastric fever, autumnal fever, etc. An analysis of the symptoms given by physicians in different parts of the country shows that great difference of opinion prevails as to the symptoms of these fevers; but such an analysis and comparison show also that true typical typhoid fever and true remittent fever are clearly defined; that "adynamic remittent fever" is a term which is used to designate a class of fevers consisting partly of remittent fevers, and partly of typhoid fever of a typical character. In regard to typho-malarial fever, no fixed ideas exist as to what symptoms indicate it; and so great is the confusion, and so hopeless the task of giving this disease an appropriate place, it is clear that much would be gained by abandoning the terms altogether. As regards the obscure forms mentioned, there is the tendency to class many of them under the head of mild or typical typhoid fever. But there is a great deal yet to be learned about these forms; and much progress can be made by a close study of the microörganisms found in the blood of these cases, and by a closer study and unbiassed appreciation of their symptoms.

Dr. George M. Sternberg, U. S. A., said that the subject is one that had engaged his serious attention at different times, and he quite agreed with Dr. Johnston in his conclusions with reference to typho-malarial fever. He thought that term should be abandoned, and from his own study and observation he had been led to think that at least a majority of such cases should be regarded as a mild form of typhoid. From his experience in the extreme west, where malarial fever does not appear, he has seen cases which were typical examples of typhoid. In reviewing the Army statistics collected during the war, he found some years since that typho-malarial fever had a very low mortality, and yet the prevailing idea was that it was typhoid fever with malarial complications, and it was difficult to understand how the complicated disease could

have a lower mortality than simple typhoid fever. His own view with regard to it was, that the line has been drawn between the mild and severe typhoid.

DR. OSLER, of Philadelphia, said that there was no doubt that from the extensive and widespread researches of Laveran we have been able to show, by the characteristic changes in the blood, a decided difference between malaria and typhoid fever. He spoke with considerable emphasis on this point, because these observations and researches have been repeated all over the world: in Algiers, in France, in Italy, and in Baltimore, Philadelphia, Boston, and New York in the United States, and recently in India by a most elaborate series of observations by Dr. Carter. The characteristic changes in malaria are as distinctly determined in the blood as are those of tuberculosis of the lungs in the sputa. He desired to impress upon the Association the extreme value of these observations of Laveran. A practical physician can no longer overlook them in discriminating between the different forms of fever.

DR. F. PEYRE PORCHER, of Charleston, said that it struck him as very remarkable that Dr. Johnston did not speak once of irritative fever. Dr. Wood, in his treatise, has devoted a whole chapter to its consideration. He thought gastric remittent fever was a distinct disease. Irritative fever exists on a mountain plateau and in cities.

DR. JAMES C. WILSON, of Philadelphia, said that Dr. Johnston's maps indicating the regional prevalence of typhoid fever fully conform to the views entertained by those physicians who have devoted themselves to the study of fevers in cities. In newly settled countries malarial fever prevails, and after a time typhoid and malaria exist side by side. In addition to the test which has been proposed by Dr. Osler, it seemed to him there is another which has scarcely received the attention it demands, and that is the etiological study The outbreak of a fever of a doubtful type in a village should, in all cases, be subjected to the etiological test, and if there prevail a number of such cases, the character of which can hardly be definitely recognized side by side with typical cases of enteric fever, the weight of opinion must be in the way of viewing these cases as types of that disease. Confusion in the diagnosis is not only dangerous in regard to the treatment, but, what is of much more consequence, it retards our knowledge of the fevers of this country.

DR. J. E. REEVES, of Chattanooga, said that more than a quarter of a century ago he had made clinical observations on the subject of enteric fever. He had been following up these observations, feeling more or less interested in the subject, and has gone through epidemics, some very mild, others malignant and exceedingly fatal. He firmly believed that typhoid fever is as communicable as any other of our infectious or contagious diseases. In the observations to which he alluded he tried to discover and run down the history of typhoid fever in Northwest Virginia. He discovered that the first case of the disease recognized in all that wild expanse of country could be traced directly to a previous case, which was brought from Athens, Ohio, in 1832. It is the general impression that, since the epidemic of cholera in 1832, typhoid fever has become the type of the fevers all along the elevated regions. He observed this fact, also, that in the low grounds or lower levels frequently typhoid fever exists with the malarial type of the disease, but as we ascend the hill country the pure, unmixed type prevails. He has been unable to discover the conditions which are to guide us in separating the two affections, and accordingly to direct the treatment. Whenever he found a broad, flabby, creamy tongue with indentations of the teeth, he found that quinine was not only permissible, but decidedly beneficial. By the use of a few doses he was enabled to eliminate the malarial element. Some seasons the disease is exceedingly mild, probably not one fatal case in twenty. At other times the disease is exceedingly malignant, and probably one out of four will die. It is a disease peculiar to youth and middle life. He has seen children not more than six months old having pure uncomplicated typhoid fever. He has seen it very rarely in the octogenarian. His conclusion is, therefore, that the typhoid fever may prevail anywhere the infection may be carried. Wherever it finds a lodging place we will there have a centre, from which the disease may spread over the entire country.

DR. JOHNSTON, in closing, said that he did not intend to present a complete study of the disease, but tried to show that the prevailing opinions in this country were based upon clinical observation. In the absence of the study of microörganisms great errors existed, and we must start upon a new basis.

DR. JAMES H. HUTCHINSON, of Philadelphia, then read a paper on

THE MANAGEMENT OF THE STAGE OF CONVALESCENCE IN TYPHOID FEVER.

He reviewed the question of diet in convalescence of typhoid; called attention to the exhausted and irritable condition of the patient; and favored the use of a light diet, as a rule, for the first ten days or so. Rest, gradual return to exercise, fresh air, and mental repose were advised; also care about exposure to cold and about constipation. The causes of relapses were discussed.

DR. J. E. REEVES said that he had hoped, from the title of the paper, that the author would allude to some of the accidents which frequently occur; without the slightest cause, during the third or fourth week, patients are sometimes suddenly seized with pain in the abdomen—in a word, with all the symptoms of perforation, and yet they recover. He had himself witnessed seven such examples. He had on four or five occasions seen patients, after they had been able to be out of doors for five or six days, seized with some hallucination, as that their lives were threatened, with permanent impairment of mind succeeding. He could furnish several examples of derangement of mind following typhoid fever without any perceptible cause. The fact is, the period of convalescence in typhoid fever is to him a most anxious one as regards the welfare of his patients.

DR. GEORGE L. PEABODY, of New York, desired a word of explanation with regard to the administration of solid food to convalescents in typhoid fever. He believed that there are a number of patients to whom the administration of solid food would not be judicious, viz., patients who have suffered from severe attacks of the disease. Patients who are anæmic and markedly depressed in their nervous systems are not, as a rule, clamorous for solid food. These patients, he thought, should not be given any solid food. On the other hand, there are patients who have had the ordinary series of

symptoms of typhoid fever, lasting three or four weeks, who oftentimes regain their appetite and desire for solid food days before the fever has left them. As a rule, he thought with such patients it was safe to begin with a small allowance of finely divided meat once or twice a day if they bear it well. He has done this several times where a recrudescence of the fever followed. He had in his experience met with a number of examples in which the administration of small amounts of solid food to patients, after the fever had left, was not only not harmful, but had been of aid; and he did not think he had ever seen any bad results follow the practice. The administration of an egg is just as likely to do harm as finely divided meat.

Another point he would like to refer to, and that is the subject of ulcers as the cause of diarrhœa, and on this point he must differ from Dr. Hutchinson. He did not believe the presence of ulcers bore any relation to the presence of diarrhœa. He had too often followed a case of typhoid fever to the autopsy table to agree with Dr. Hutchinson in this regard. Diarrhœa, he believed, was due to the catarrhal condition of the intestines, which may or may not be present in any given case. On this account it seemed to him, if there be no diarrhœa present and no specially profound depression, it is perfectly proper to administer solid food soon after the period of fever had ceased.

Dr. William Ord, of London, said that he came from the other side of the Atlantic, and would put forward his experience with that of Dr. Hutchinson. In regard to diet, he would agree with him, but he was also in agreement, from frequent experience, with Dr. Peabody. He had been naturally under the influence of his colleague, Murchison, within the past few years. On more than one occasion of late, he has had warning that one must be guided to a certain extent by the desire of the patient for food, and he has learned to give into this desire in general. He would quote a case which occurred a month or two ago. It was a girl in St. Thomas's Hospital, who had a severe attack of typhoid fever, and convalescence had set in. Then, without any existing condition to account for it, she began to have a large range of temperature, rising steadily in the evening and falling in the morning, till at the end of three days the range of temperature was from 3° to 5°. With this she became slightly delirious, and menaced her physician when he came around. Then, for two or three days more, the temperature was still higher with more disorder in her mind and craving for food. Now he tried the effect of giving her solid food. She was allowed at once boiled sole. Within twenty-four hours after taking the fish her temperature became normal for four hours, her delirium ceased, and from that time on she made an uninterrupted recovery. This is an instance of what we have to do in all cases of convalescence, viz., the study of the individual as well as of the fever.

With regard to diarrhœa, he would say there is a good deal of reason in Sir William Jenner's explanation that where diarrhœa is conspicuously present there is also a conspicuous presence of ulceration in the large intestine, where it is apt to be associated with extensive catarrh. Certainly, in epidemics which he had watched from year to year in London, the existence of these things has been very notable. Where there is much diarrhœa, there is considerable ulceration existing in the large intestine, which post-mortems have enabled us to verify. This bears also on the question of relapse. It was only ten or twelve years ago that many relapses were noticed in London. Up to that time they had the typical form of diarrhœa, then they had epidemics in which constipations were more marked, and then the trouble of relapses, by which he meant not recrudescence, but a complete second attack. When constipation existed, they used to give castor oil. After long study of these cases, he has come to the conclusion that the relapses were, in all probability, due to an infection from within; that long constipation had allowed time for germs to produce a second infection.

There are one or two points in relation to sequelæ he would like to ask Dr. Hutchinson. Very often, in long-continued cases of typhoid fever, we have periostitis and phlebitis, and he thought deep ulceration in the larynx was a common occurrence. He would like to know if these ulcers have been often observed in this country. Phlebitis is a thing that always puzzled him, and with regard to which he would like to have some information.

Dr. F. P. Kinnicutt, of New York, believed that relapses in typhoid fever were simply the result of re-infection and not of imprudence in diet. He believed we frequently see recrudescences of many of the symptoms from imprudence in diet, and it seemed to him that, although there are undoubtedly cases carefully selected in which solid food may be safely given and possibly with benefit, shortly after the disappearance of the fever, there are also cases in which solid food may work ruin to the patient. The advice, if given generally, would be abused, and he thought the rule mentioned by Dr. Hutchinson is the best one for the profession to follow—careful regulation of diet during the first ten days. There are many cases, however, which may be benefited by solid food after the disappearance of the fever.

Dr. F. C. Shattuck, of Boston, said that mention had been made of relapses, and also of recrudescence. He had noticed, during the stage of convalescence in typhoid fever, a persistent rise of temperature, which was neither recrudescence nor relapse, and which did not disappear until the patient got out. It seemed to be a bed fever. He is satisfied of the existence of this fever, and thought it important that we should recognize its existence, and not be alarmed by it. Certainly, it seemed to him the more we see of temperature, the more we think its ways are past finding out, and the less significance we are disposed to attach to it.

Dr. J. C. Wilson, of Philadelphia, said that the question of diet, during the early period of convalescence, is one of such importance, and such divergent views have been expressed here, that he ventured to ask Dr. Ord in regard to the single case he related, as to the diet of the patient prior to the mania he spoke of. Is it not possible that this patient's mania might have been due to defective nutrition or starvation?

Dr. Ord said that previous to the administration of solid food the patient had been given beef tea and milk, in the proportion of two parts of beef tea to one of milk, as freely as the patient could take it, and two days before the occurrence of the maniacal symptoms two eggs a day had been given in addition.

Dr. Hutchinson said that the sequelæ of typhoid fever are very frequent in this country, as shown by

Dr. Keen, of Philadelphia, in his Toner Lecture. For instance, there is an endarteritis and also an orchitis which are very common after typhoid fever. Dr. DaCosta some years ago called attention to the fact that a low grade of fever occurred in convalescence, which was cured by the patient's being ordered out of bed. On the other hand, a recrudescence will occur if the patient gets out of bed too soon. Recrudescences are also frequently due to masturbation, to which patients at this stage of the disease appear to be peculiarly liable. The sequelæ are very numerous and are all mentioned by Dr. Keen in the lecture previously referred to.

DR. GEORGE ROSS, of Montreal, then read a paper on

SOME FORMS OF PARALYSIS AFTER TYPHOID FEVER.

He first showed that while typhoid is a great strain on the nervous system, bringing to light its weaker points, and causing general exhaustion and anæmia, it produces sometimes nervous lesions in addition to these. These lesions consist in proliferation of connective tissue (interstitial neuritis) about the nerve trunks, usually, but also parenchymatous degenerations of the spinal cells and cerebral cortex. The results are paralysis, paraplegia, and sometimes loss of sensation. These are, however, usually recovered from. They are undoubtedly caused by the typhoid poison, not the fever exhaustion, or the anæmia. The signs of exhaustion of the nervous system are constant, and generally in proportion to the severity of the fever. The nervous phenomena are almost invariably both motor and sensory. The variety of forms taken is very great, though mainly the nervous injury is manifested by pains, areas of increased cutaneous sensibility, and paralysis.

DR. ORD said that there were some things in the paper which interested him very much. He could not say that he had seen many of these cases of peripheral neuritis. They are rare in his practice. So also he would say that paraplegia, dependent upon other causes than peripheral neuritis, is rare. He had observed indications of cerebral weakness, long-continued imbecility, remarkably protracted silence, and difficulty of articulation. He had seen cases after a very severe attack, in which there had been a long period of comparative uneasiness, in which the patient had spoken at the rate of a word every two or three seconds; and in more than one case he had seen a patient come out of a condition of uneasiness, be unable to speak at all, and recover the power of speech only after several days. In one case in a marked degree he found the patient unable to speak at first, and that he had in fact lost the faculty of remembering words and had to learn to speak over again. This was more apt to occur in young children from seven to eight years of age, and in one case he had seen the process of learning to speak had to be recommenced and developed as originally. He thought all these changes were rather due to changes in the central nervous system than in the periphery; also to inflammatory changes penetrating the tissues. He found it convenient in dealing with these and other sequelæ, as well as the complications of enteric fever, to classify them in his own mind. He has been accustomed to classify them, first under the head of complications which were, so to speak, inherent in this particular kind of fever, and probably those forms of neuritis and cerebral weaknesses are among the characteristic weaknesses. Then he should take those belonging to fever in general, and those complications and sequelæ which are accidental and to a large degree personal. It had been noted by one of the speakers that typhoid fever probably awakens latent mischief in those cases which are followed by phthisis. He thought there was good reason to believe that it has the general power of arousing existing mischief, which was up to the time veiled. In people of rheumatic tendency, we will find it awakening a rheumatic condition. It seems to have the quality of bringing out things which were masked and hidden before.

DR. FRANCIS MINOT, of Boston, said that one idea which struck him on hearing Dr. Ross's paper read, was the possibility of these different sequelæ of typhoid fever being caused by more than one germ entering the system. There are certain diseases, we know, which apparently have the same microbe; as, for instance, pneumonia and cerebro-spinal meningitis. The germ from the healthy human saliva will produce pneumonia in an animal, and in its tissues will be found the true pneumonic germ, and possibly some of those additions to disease may be caused by the same germ entering afterward. Among the sequelæ of typhoid fever are dumbness, which may be due to some other germ acting after the fever has run its course. He had seen a patient of eighteen who was unable to speak a single word after a severe attack of chorea.

DR. M. ALLEN STARR, of New York, said that it was pretty well admitted that neuritis may be due to infectious causes, and yet it seemed to him that a word of caution may be uttered in regard to ascribing all cases that follow typhoid to the influence of the typhoid germ. It seemed to him that if all the cases of neuritis following typhoid were due to the typhoid infection, neuritis would be much more frequent than it is. He had looked into the matter somewhat, and found that neuritis was a very infrequent sequel of typhoid fever. He had seen within the past few years cases of general peripheral neuritis following typhoid. In all cases they were alcoholic. We know that alcohol is one of the frequent exciting causes of multiple neuritis, and it is doubtful whether neuritis following typhoid is due to the typhoid germ, or to alcohol taken during the disease.

There is another class of cases to which Dr. Ross alluded, viz.: those in which the neuritis is due to one or two nerves being involved. Is it not possible in those cases that, instead of the neuritis being due to any infection, it is simply the result of pressure upon those nerves? He has had three cases lately under observation of distinct peripheral neuritis limited to one nerve, which were due to pressure of the body upon the bed while the patients lay in a comatose state. Could not the neuritis of typhoid fever be explained by this means? It seemed to him this question might be answered by some of the gentlemen present. He did not know but that Dr. Ross's cases belonged to that form of typhoid fever in which there were central changes in the cord. These cases must be, he thought, very carefully distinguished from those with marked signs of general multiple neuritis.

DR. OSLER, of Philadelphia, thought that those who had followed the pathological history of late paralysis, would bear him out in stating that writers are divided into two classes, one stating that the late palsy is due to a neuritis, and the other that it is due to a polio-myelitis. This is also true of arsenical poisoning. Both clinical

and experimental evidence seemed to him to agree upon the fact that we may have a toxic myelitis or a toxic neuritis. Now in this disease it is the same; we may have typhoid fever lighting up a myelitis or a neuritis.

Dr. H. C. Wood, of Philadelphia, remarked that those who had studied the course of lead palsy had had to deal with this same problem, finding either central or peripheral paralysis, myelitis, or neuritis; and never able to say why one or the other occurred in a given case.

Dr. Francis Delafield, of New York, said that, although the lesions that have been described are not, after all, very common, yet they are such as belong to the disease. It seemed to him that the poisons of the severe infectious diseases behave in very much the same way as some of the mineral poisons; that is, they produce an acute degeneration of certain parts of the body, and with this acute degeneration there may or may not be added inflammatory changes, and the poisons of the infectious disease had the same capacity for producing acute inflammation that the mineral poisons have, but they differ as to the parts affected; thus, in diphtheria, it is the nerves that are affected; in typhoid fever we find the spleen swollen and changed; and so on, as we review the different diseases. That would seem to him the condition of things in typhoid fever, as regards the nervous system.

Dr. Ross, in conclusion, said that he had confined himself entirely, in his paper, to an account of those forms of paralysis which are of common occurrence, and avoided any reference to the cerebral manifestations occasionally met with in typhoid fever. He had seen cases which bore out the remarks made by Dr. Ord, and especially had he been interested in those severe forms of mental derangement which come on during convalescence, and last for an unexpected length of time. The possibility of alcoholic neuritis is universally admitted. He could not say the matter was looked into in the cases reported by him. That an alcoholic neuritis could be set up by partaking of small quantities of alcohol in an illness extending through eight or ten weeks was, he thought, unreasonable to suppose. As to the theory of pressure as a possible cause of neuritis, of course it was only in certain cases, such as those mentioned, that the theory could be entertained. Of course, there is, in the first place, the fact, alluded to by several speakers, of the existence of several forms of neuritis after the system has suffered from various febrile diseases, and another is a greater degree of severity of these forms of paralysis after the existence of pressure upon a nerve for a certain time. The fact that certain of these cases end in atrophy, and that some of them are actually permanent is, he thought, against the idea that a neuritis of such severity has been set up by pressure on a nerve. He thought we should endeavor to make a distinction between myelitis and neuritis. He had seen, in an epidemic a few years ago, a few cases of myelitis, and the prognosis in such is very bad. The disease progresses from bad to worse, and a fatal result may usually be looked for.

Afternoon Session.

Dr. F. Forcheimer, of Cincinnati, read a paper on

fatty heart.

He concluded, from the examination of 122 cases of obesity of the heart, that its cause is a fat accumulation similar to one in any other part of the body. It may occur at any time of life. Occupation has a bearing, especially change of an active muscular occupation for an inactive life when middle age is passed. Thus, when a man of active outdoor habits retires from business shortly after forty years of age and takes on idle habits, it is liable to occur. Men suffer more than women, because they more often change their habits with the beginning of their later years. Alcohol, and particularly beer, have much to do in causing fatty heart; also tobacco, coffee, and tea; also violent exercises, and prolonged business or emotional troubles.

It was necessary to divide the condition as we meet with it into two forms: first, a surrounding of the heart by masses of fat, with accumulations within or upon the pericardium and between the various septa. This could sometimes be made out during life by an increased area of dulness; but this was difficult owing to the amount of subcutaneous fat usually present on the chest of the patient. We had to depend on autopsies in the main for our information. In the second class the myocardium itself was invaded by a diffused fatty infiltration of oily globules, and its function as a muscle was checked, the muscular fibres atrophied and became distorted and sometimes became degenerated. The latter, however, might be due to the general cause which had led to fatty deposition as well. At any rate, the myocardium became soft, flabby, and easily torn. The results of this were that sometimes hypertrophy, sometimes myocarditis or rupture supervened, but rarely any valvular lesions, also impaired circulation, venous stasis or obstruction.

Symptoms in the first class of cases were not many. The chief one was shortness of breath on exertion or excitement, resulting from sudden accumulation of blood, which was, in this condition, often excessive in amount, and from compression of the lung by the masses of fat around the heart. It came on slowly.

The second class of cases gave a history of sudden accession of heart trouble, dyspnœa at night and after meals, inability to sleep after retiring, angina or cardiac asthma; also, sometimes, apoplectic symptoms were present, due to an accompanying fatty change in the cerebral bloodvessels.

As for objective signs, a dilated heart would give the same objective signs as a fatty heart; we had to judge from all the other symptoms of the patient. Auscultatory percussion told something at times. The rhythm and sounds were to be studied; a bruit was sometimes present, due perhaps to an imperfect contraction, or to anæmia in some cases, or to nervous disturbances. After all, the guiding symptom was the disturbed heart-action taken in conjunction with the presence of obesity. If the parts were not fat, a diagnosis was impossible between fatty heart and several other morbid states.

His plan of treatment was Oertel's, which he did not think dangerous unless there were obstructions to the circulation in the heart, lungs, or elsewhere.

Dr. Jacobi, of New York, said that the author had spoken of fatty heart in connection with general obesity only. He did not know whether he assumed that fatty heart can occur only in such conditions of general obesity. He thought if we take into consideration other cases of fatty degeneration of the heart in which there is no obesity at all, or only a certain amount of it, we may come to a better understanding of the nature of the con-

dition. Fatty degeneration of the heart is to be taken as one of the symptoms of malnutrition. This may be the result of an excess of fats and carbons; it may be the result of a congenital condition leading to the same result. He had a case in mind which he would narrate. A lady, aged thirty-two, had been anæmic all her life, being rather fat. She died with all the symptoms of pernicious anæmia. In her case there was fatty degeneration of the heart and it was very slightly, if at all, enlarged. The cause of the fatty degeneration was malnutrition, which was due to the smallness of all the arteries of the body. The aorta and all the large arteries were very much smaller than normal, but in other respects they were normal. He would say that this condition resulted in insufficient nutrition and consequent insufficient muscular power of the heart resulting in fatty degeneration. The heart muscle undergoes the same changes that every other muscle does. When all the arteries of the body are too small the arteries supplying the heart muscles are also too small. We have to look for fatty degeneration of the heart when we have to deal not only with a surplus but with a want of food.

DR. KINNICUTT said that only a few days ago a gentleman told him he had seen a number of cases treated under the personal supervision of Oertel, and he thought that Oertel had modified his original views.

DR. SHATTUCK said that these cases are not as common in this country as in Germany, and not as common in his section of this country as in parts where there are more Germans. His practical experience with such cases was very small. In reference to the results of Oertel's method of treatment, his remembrance of the report of the discussion which took place at the Wiesbaden Congress was that damage had resulted, under the observation of several of the speakers, which was of a serious nature. It seemed to him there is no question of serious dangers in the Oertel plan of treatment, but these dangers are connected with the difficulty of diagnosis. It seemed to him that disastrous results had followed Oertel's plan of treatment, where it was applied to cases to which it did not belong—that is, in which the diagnosis was obscure.

DR. JAMES TYSON, of Philadelphia, said in regard to the diagnosis of this condition of fatty degeneration, it occurred to him that true fatty degeneration is not associated with obesity as is fatty infiltration, but is rather the result of chronic Bright's, or chronic endocardial disease. So that the diagnosis from this standpoint resolves itself into this: given a case of obesity with the symptoms of weak heart and the absence of any one of these conditions, either acute or chronic, we must come to the conclusion that we have a fatty infiltration which might be safely treated by Oertel's method.

DR. H. C. WOOD said that he thought the Oertel plan of treatment when applied to a certain class of cases was of great use, but the application of it is always attended with danger if we have a case in which the symptoms are severe. In the *London Medical Record* there are reported cases of sudden death due to the Oertel plan of treatment. The theory of the Oertel method is that the heart is a muscle and must be strengthened by exercise like any other muscle that has been wasted by want of use. But the heart never suffers loss in this way, because it must always perform its function. If we have a heart in which the muscular fibres are very seriously involved, we may have a heart which will give out under the strain and the symptoms become intensified. He thought the great danger of the method lies largely in the impossibility of diagnosticating how far the morbid process has gone on in the particular case. The method should only be used under very careful supervision, and with the distinct understanding, on the part of the patient, that there is a certain amount of risk in it.

DR. KINNICUTT explained that Oertel himself was very far from merely prescribing free mountain climbing. On the contrary, he graduated the distances to be walked very carefully, even to the distance in feet. His study of the individual patient was minute. He prescribed the diet and the times of rest; in brief, he took every element of the case into account.

DR. WOOD rejoined that he knew the Oertel method called for a withdrawal of fluids from the diet, stopping the use of alcohol, and the giving of a light diet free from fats; but that its peculiar feature was the exercise, and that was apt to be overdone and carelessly employed.

DR. FORCHEIMER, in closing the discussion, said he would simply summarize the results. The objection urged by Prof. Wood is the one put forward by everyone. The idea of a patient with a weak heart climbing up to the top of a mountain three or four thousand feet high is something stupendous, and he would naturally expect him to drop down and die. In fact, Oertel does not wish anything like that done. He first lets his patients walk a certain distance, then further, and so on gradually increasing the distance in proportion to his capability. It was upon him he made the experiments published in his book. The principal thing Oertel insists upon, in order to give the heart less work, is to abstain from fluids; in the first place his diet consists in a mixed dietary with an absolute reduction in the quantity of food taken in the twenty-four hours. He allows no oils except in small quantities. No harm will come to patients with weak hearts who climb mountains according to Oertel's plan of treatment. On the contrary, the fat in the heart substance was actually made to disappear, and the muscular fibres gradually grew through increased use and took the place of the fat. The only objection to the method was, that certain observers had reported that harm had come from its use. These charges were not further specified, and we had no means of knowing that the cases on which it was based had been of the class amenable to Oertel's method or that his ideas had been accurately carried out in regard to either diet or a strict graduation of exercise.

(To be concluded.)

THE ASSOCIATION OF AMERICAN OBSTETRICIANS AND GYNECOLOGISTS.

First Annual Meeting,
Held at Washington, September 18, 19, and 20, 1888.

TUESDAY, SEPTEMBER 18TH.

(Specially reported for THE MEDICAL NEWS.)

DR. A. CORDES, of Geneva, Switzerland, forwarded through the Secretary a paper upon

THE TREATMENT OF ENDOMETRITIS BY FUMING NITRIC ACID.

He described three cases of chronic endometritis successfully treated by the injection of from one-half to one

drachm of this caustic. Precautions were always taken to neutralize the acid in the vagina by a saline solution.

Dr. Cordes also reported four cases of

PUERPERAL ECLAMPSIA.

His treatment consisted of bromide of sodium in full doses; chloral hydrate per rectum; leeches behind the ears, and the use of the forceps in the interest of the child. Three of his four patients recovered. In a case in which he injected sodium bromide hypodermatically sloughing followed. In these cases he believes in as few vaginal examinations as possible, as they tend to produce convulsions.

Dr. Joseph Price, of Philadelphia, in discussing the subject of eclampsia, described the case of a primigravida, aged thirty-eight, in whom treatment by hydragogue cathartics and bromides was begun early in pregnancy. The child was delivered by forceps, labor being induced at eight months, and mother and child lived.

Dr. Joseph Price, of Philadelphia, then read a paper on

DRAINAGE IN ABDOMINAL AND PELVIC SURGERY.

He considered it important that the indications for drainage be as clearly defined in abdominal and pelvic as in other surgery. Regarding this, however, there is great diversity of opinion. He thought that if it can be shown that the drainage tube is not injurious, it should be frequently employed. Regarding the causation of the formation of fluid in the abdominal cavity he had seen an abundant exudate when but small adhesion of tissues was present. In a case seen recently there were extensive adhesions which were separated without the occurrence of oozing. A profuse discharge occurred subsequently, however, which was readily evacuated by the tube. Disease of the Fallopian tubes may occasion great effusion of fluid after an operation. In cases in which the tubes are not diseased and no adhesions are present he would not employ a drainage tube; he styles such cases simple cases. The cautery, at the time of operation, will often check oozing; the internal administration of salines in repeated doses is exceedingly useful to remove fluid effused after operation. Regarding damage caused by the drainage tube, he knew of no case in which it had been injurious. If properly cleaned, the tube is not a source of infection. There is also little danger that the tube will perforate or injure the peritoneum. To prevent omental adhesions he employs a packing of gauze or cotton-wick sterilized; this should be frequently renewed.

Dr. Price considered irrigation a valuable procedure in abdominal surgery; at the time of operation he retracts the tissues above and behind the uterus by three fingers forming a speculum; he then introduces water in a constant stream by siphon (Tait) or by a syringe. In this way he removes shreds which would otherwise remain. For irrigation he uses water only, sterilized by boiling; he believes antiseptic fluids to be injurious to the abdominal cavity, as they cause adhesions and subsequent pain. When the discharge is sweet, clean, and scant he removes the tube. He does not believe in drainage through the vagina. Hernia does not result from the tube, but from too long an incision; getting up too early, and neglecting to use a proper abdominal bandage.

Dr. F. Cushing, of San Francisco, forwarded a paper entitled

A CONTRIBUTION TO THE STUDY OF PELVIC ABSCESS,

which was read by the Secretary. He considered salpingitis and pyosalpinx the most frequent causes of this condition. Post-mortem examinations reveal the frequency of tubal inflammation. Gonorrhœa in the male is the most frequent cause. A case was cited in which direct infection from the husband was proved by the demonstration of the presence of the gonococcus on microscopic examination. Two cases of pelvic abscess post-partum were reported, one of which ruptured through the sacro-sciatic notch. Dr. Cushing prefers the aspirator as a means of diagnosis in ordinary cases; in complicated cases he performs laparotomy. The prognosis is ordinarily good. The treatment is evacuation; for pyosalpinx, abdominal section. A dilating trocar and soft rubber T drainage tube devised by the author were shown; the trocar resembled a uterine dilator, sharpened at the points. As an antiseptic hydronaphthol is preferred. When one evacuation by puncture does not suffice laparotomy must be done.

In the discussion of these papers, Dr. Eastman, of Indianapolis, stated that he had sharpened the points of ordinary uterine dressing forceps, using them to puncture a suspected pelvic accumulation. He drains for the first suspicion of pus. He regards permanent abdominal drainage a misnomer, as nature closes any opening with lymph. He closes abdominal wounds with especial care to prevent hernia, and brings the linea alba together with all possible accuracy. In 51 abdominal sections he has had but 1 hernia. Pelvic drainage is often needed, but should be made under the guidance afforded by abdominal section.

Dr. Montgomery, of Philadelphia, thought a clear understanding of the indications for drainage essential. The general condition of a patient is a guide to the probable occurrence of effusion. Patients should be carefully examined before operation, and the condition of the emunctories noted. The care of a patient after operation may obviate the necessity for drainage; fluids should not be given freely; the dressings should be applied tightly. If a tube is used, a small one is preferable; it should be carefully cleansed, and dental sheet rubber (rubber dam) may be used about it to prevent the infiltration of fluid. Sinuses forming after the use of a tube frequently necessitate laparotomy. In a large sac, with abundant adhesions, drainage per vaginam is best.

Dr. Marcy, of Boston, thought it of primary importance to remove the focus of suppuration, when drainage would not be needed. A drainage tube does not remove the source of the patient's danger, and the abdomen should be reopened if danger arises after operation. If drainage be employed, it should be *with gravity*, into Douglas's cul-de-sac, through a double tube.

Dr. Vander Veer, of Albany, instanced the success of the late Dr. Peaslee as an illustration of his belief in the importance of so operating that drainage is not needed. Abdominal section is safest. He avoids the use of a tube if possible. To prevent hernia he tightens the lowest stitch when the tube is removed. The incision is carefully closed; the drainage tube is fitted to the case.

DR. PRICE, in closing, said that he does not remove uterine appendages for pain, but for perceptible lesions. When cases are operated upon before extensive tissue changes have occurred, drainage is seldom needed; late and neglected cases require drainage. In operating especial attention should be given to removing all foci of disease in the broad ligaments. Forcible uterine dilatation, he had observed, is a frequent cause of pyosalpinx. He thought hernia is due to long incision; an incision admitting two fingers is ample. He had also seen hernia caused by the serre-nœud. In closing the abdomen he uses three or four sutures to the inch; including twice as much fascia (of the linea alba) as skin or peritoneum in his stitch. He had never seen a drainage tube, amid healthy intestines, occluded by lymph. He drains in about forty-five per cent. of his cases.

THURSDAY, SEPTEMBER 20TH.

DR. FRANKLIN TOWNSEND, of Albany, read a paper on the

PATHOLOGY OF EXTRAUTERINE PREGNANCY.

He believed that extrauterine fecundation is frequent. Ova may perish in the peritoneal cavity or become attached and live. A former inflammation in the peritoneum may afford a nidus for the growth of an ovum; pregnancy may occur at any portion of the genital tract. Tubal pregnancy is frequent; ovarian pregnancy is extremely rare. By primary abdominal pregnancy is understood the development of a fœtus to maturity in the abdomen; in secondary abdominal pregnancy the fœtus dies, a lithopædion resulting. In these cases the uterus often enlarges as in normal pregnancy; decidua forms, and many of the symptoms of abortion are present. A lithopædion was exhibited which had been carried in the abdomen of a woman for fifty years, the patient dying of another affection at seventy-six. In this case the tubes were normal, the uterus somewhat enlarged. After ineffectual labor pains the health of the patient declined, but became restored; menstruation was reëstablished and ceased normally; labor pains recurred at intervals during the patient's life.

DR. JOSEPH PRICE then read a paper upon

TUBAL PREGNANCY.

From a practical standpoint, these cases should be considered before rupture, at rupture, and after rupture of the tube. Before rupture the diagnosis is not positive; the symptoms present may be caused by various conditions. These cases are not generally seen until after rupture; patients are often anxious to conceive, which makes their subjective symptoms of little value. Amenorrhœa; pain severe, paroxysmal, long continued, caused by distention of the tube; continuous hemorrhage, with a discharge lighter in color than blood, and with the expulsion of the decidua vera, are symptoms present. The uterus is enlarged and displaced by a movable cystic mass. Rupture generally occurs at the twelfth or fourteenth week of pregnancy. Intraperitoneal rupture is attended by agonizing pain, shock, and subsequent peritonitis. Such an accident is not uncommon in multiparæ, and may be followed by death some time later. Dr. Formad, of Philadelphia, in the course of recent post-mortem examinations, had found eighteen such cases. Rupture may be attended by symptoms much less severe. The pain may resemble colic; hemorrhage may be inconsiderable. Peritonitis is usually absent; examination reveals a boggy mass in one broad ligament. The case may take a chronic course; the fœtus may survive and grow. In a case operated on by him at Camden, N. J., fœtal movements could be discovered on one side of the uterus. The sac in these cases is less movable than the gravid uterus; in the case already described the uterus was flattened by the pressure of the sac; when the sac was ruptured, it contracted normally. The cervix is displaced, and the pelvis is occupied by the fœtal sac. If the fœtus develops to term, spurious labor occurs; the fœtus may remain *in situ*.

DR. MONTGOMERY, of Philadelphia, in discussing the subject, thought a differential diagnosis was possible quite early. Different varieties of extrauterine pregnancy rupture at different periods. The symptoms of early rupture are those described by Dr. Price; he had seen two cases in which the usual signs of early pregnancy were present in which rupture was announced by collapse and pain: one recovered without laparotomy; the other recovered after operation. In the early stages, he believed electricity the best means of treatment; he does not approve of puncture; he would place one pole of a faradic current over the abdomen, and the other against the sac, in the vagina; ten or fifteen minutes' treatment for several successive days is generally sufficient. The subsequent growth of the placenta has not been proven. Electricity should be employed in the first four months only; should positive symptoms of rupture be present, laparotomy should be performed at once. After the fourth month he would destroy the life of the fœtus by electricity, and wait for the placental bloodvessels to become occluded. When the fœtus is viable he would operate in the interests of mother and child. In operating he would close the sac above, and drain through the dependent opening per vaginam.

DR. WATHEN, of Louisville, did not believe abdominal pregnancy possible without a previous peritoneal lesion. Tubal disease is the most frequent cause of extrauterine pregnancy. A diagnosis is rarely possible early, and cases cured by electricity are mistakes in diagnosis.

DR. BALDY, of Philadelphia, agreed with the preceding speaker. Electricity does not injure any pelvic tumor, but does not remove the sac, which is a source of danger. It occasionally produces rupture and death. Early diagnosis he thought impossible, and cited a case in which the usual signs of extrauterine pregnancy were present, but operation revealed an ovarian cyst.

DR. BYFORD, JR., of Chicago, thought that many cases rupture, but recover. Hæmatoma is often caused by extrauterine pregnancy. With care a diagnosis can often be made. He preferred electrical treatment in the first three months.

DR. MCMURTRIE, of Kentucky, described a case in which he operated, the child being in the abdomen, the membranes absorbed, and the cord shrivelled. The placenta was very large and decomposed. Very severe hemorrhage followed the attempt to detach and remove it; the patient died shortly after. He would advise waiting until the child had been dead for some time before operating.

DR. VANDER VEER closed the discussion. He believed that diagnosis is possible in some cases; in others not. The usual signs of pregnancy, with a new

growth behind or at the side of the uterus, are present, Those who use electricity report forty cases treated in America, with one death, before the fourth month of gestation. Early laparotomy, however, he considered the better means of treatment, as it removes the entire mass. After the fourth month he would wait until the child dies. Primary laparotomy is gaining ground, however, for these cases.

He reported two cases of neglected tubal pregnancy, followed by death from septic infection. He exhibited fœtal bones from a third case, in which the mother had conceived while carrying a dead fœtus, encysted near the rectum. He believed that Breisky's recent case, in which he removed the placenta, had shown that it should always be removed in such cases.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Tenth Annual Meeting,
Held at Washington, September 18, 19, and 20, 1888.

(Specially reported for THE MEDICAL NEWS.)

TUESDAY, SEPTEMBER 18TH.—AFTERNOON SESSION.

DR. CLINTON WAGNER, of New York, presented a paper on

RESIDENCE AT CERTAIN HIGH ALTITUDES AS A MEANS OF CURE FOR LARYNGEAL PHTHISIS.

He called attention to the fact that thirty-three per cent. of all cases of pulmonary consumption are in addition laryngeal, and proceeded to the discussion of the relative advantages of high altitudes, as represented by Davos-Platz and Colorado Springs, and lower altitudes, where the atmosphere is moist and warm. The objections to a high altitude depend upon the dryness of the air and the rapid atmospheric changes, but this may be overcome by instructing the patient to breathe through his nose, and by great care to avoid exposure. Dr. Wagner believes laryngeal phthisis is invariably secondary. He also reported four cases of this disease cured at Colorado Springs, but believes that climatological changes are of no value in this affection, provided the condition has passed from that of induration into ulceration. In the winter-time such patients in high climates should retire at sundown from the outside air.

DR. GLASGOW, of St. Louis, expressed the belief that high altitudes are harmful.

DR. SHIRLEY, of Detroit, thought that equally advantageous results are obtained simply by an ordinary change of air, as, for example, a visit to the seashore.

DR. JOHN N. MACKENZIE, of Baltimore, read a paper on

A HITHERTO UNDESCRIBED NEUROSIS OF THE AURAL APPARATUS CLOSELY ALLIED TO CORYZA SYMPATHETICA,

which, as he expressed it, resembles very closely what might be called "hay fever of the ear." In the one patient which he had seen the attacks have come on regularly every summer for twenty-three years, beginning soon after marriage while at the White Sulphur Springs, in Virginia. One of the chief symptoms is severe itching of the auditory canal, Eustachian tube, and throat. It always is unilateral during one season, but sometimes alternates in two successive seasons. He believes the condition to depend upon disorder of the sympathetic, particularly the spheno-palatine ganglion. In the discussion which followed, Dr. Shirley spoke of the great doubt which exists as to the real function of this group of cells, and expressed the opinion that this ganglion really has no vaso-motor action upon the throat.

DR. SAJOUS, of Philadelphia, spoke of a somewhat similar case under his care which was, however, secondary to nasal disorder.

DR. HARRISON ALLEN could not see why the Eustachian tube might not be affected in a similar manner to the nasal cavities by hay fever.

DR. MACKENZIE, in closing the discussion, quoted the results of Prevost, who, on stimulating the spheno-palatine ganglia, produced running of the nose and swelling of the mucous membrane.

DR. BRYSON DELAVAN followed with a paper entitled

FURTHER INVESTIGATIONS AS TO THE EXISTENCE OF A CORTICAL MOTOR CENTRE FOR THE HUMAN LARYNX,

and referred to a paper read by him during the Eighth International Medical Congress at Copenhagen. He believes that this centre exists in the region of Broca's third convolution, and cited the opinions of Landois and Garel, which supported this view. Garel saw a case of laryngeal palsy, with a lesion in this neighborhood; but in a case examined by Dr. Delavan no lesion could be found on macroscopical examination except marked atheroma of the bloodvessels. No microscopical sections have as yet been made.

WEDNESDAY, SEPTEMBER 19TH.—MORNING SESSION.

DR. JOHN O. ROE, of Rochester, read a paper on

INTERNAL ŒSOPHAGOTOMY, WITH THE REPORT OF SUCCESSFUL CASES.

He expressed the opinion that multiple incisions are preferable to dilatation for stricture; but this evidently was not the unanimous opinion of the rest of the Association, since the assertion provoked a considerable amount of discussion, in which opposite views were advanced. Among those taking part were Drs. Rice, of New York; Ingals, of Chicago; Langmaid, of Boston; Sajous, of Philadelphia; and Delavan, of New York. Dr. Rice, having advocated the employment of cocaine previous to the introduction of the œsophageal bougie, was criticised by Dr. Sajous, who thought such a measure fraught with danger, owing to the fact that the anæsthesia produced prevented the patient from aiding us in our direction of the instrument, and eliminated the useful symptom of pain. He also pointed out that if a soft spot existed near the growth, it was very readily punctured under such circumstances.

DR. BEVERLY ROBINSON, of New York, then read a paper on

DYSPEPSIA, AS REFLECTED IN THE MUCOUS MEMBRANE OF THE UPPER AIR-PASSAGES.

He stated that if catarrh of the upper air-passages has already appeared, the dyspepsia increases it to a very large extent, as the gases thrown off act as irritants, and the sour fluids, consisting largely of butyric acid and correlated compounds, also tend to make it worse. On the other hand, the dyspepsia may be the result of catarrh, and depend upon the fact that so much of the increased

secretion is swallowed as to disorder digestion and produce gastric irritation. The cure of the catarrh in these cases cures the dyspepsia. Another point which he thought might possess a causative action is, that the air passing through diseased air-passages may become so fetid as, when swallowed, to produce abnormal conditions.

Dr. Shirley, in discussing the question before the Society, thought that the constitutional condition of the patient is too often overlooked, and spoke highly of the value of exercise, diet, and other similar measures for the relief of such states. He also believed in the attention of the physician to the constitutional treatment as represented by drugs. He also thinks that the catarrh does not produce the dyspepsia so commonly as the dyspepsia produces the catarrh. Fresh air, and a large amount of outdoor exercise are extremely valuable.

Dr. Daly, of Pittsburg, thought the two conditions balanced one another. He has given up the use of tonics, such as strychnia, and relies upon small doses of calomel once or twice a week, which he usually follows by a moderate dose of a fluid extract of senna.

Dr. Robinson, in closing the discussion, said he had been very loath to speak so frequently before the Association upon this subject, as he had written of it in past years, but that he regarded it as being one of great importance, and thought it should receive much attention. He is of the opinion that, while drugs are not perhaps of as great value as some have thought, they are nevertheless much more useful than surgical interference so frequently resorted to, and he wished the Association to understand that he insisted upon this point most strongly. He has seen cases burned, cut, scraped, and snared, and fail to get well, when a few small points attended to from the standpoint of the general practitioner have produced a cure.

Dr. Harrison Allen, of Philadelphia, next read a valuable and exhaustive research on the

ANATOMY OF THE NASAL CHAMBERS,

in which he demonstrated several very interesting anatomical facts not generally well understood, both by means of skulls and wet preparations. The Association seemed much interested in the practical bearing of this paper.

Dr. Delavan spoke of the great value of this line of study, and of how many surgeons operate without the anatomical or pathological knowledge which is so essential for success. He also mentioned the fact that in quite a number of skulls examined by him, deformity of the nasal chambers was the rule rather than the exception.

Dr. Wm. C. Jarvis, of New York, followed with a paper entitled

NOTES ON A CASE OF NASAL CARIES, COMPLICATED WITH MENINGITIS, SUCCESSFULLY TREATED BY MEANS OF THE SURGICAL DRILL.

The case was one of a man with a distinct specific history producing very severe nasal symptoms accompanied by caries of the bone and preceded by the complete destruction of the mucous membrane covering the parts. The pain was excessive and so constant that the patient had to be kept constantly under the influence of anodynes. There was also much headache, tinnitus aurium, with hyperæsthesia of the scalp. The secretion was excessively fetid and life to the patient was a misery. There were great emaciation, weakness, and inability to perform any of the ordinary business of life. The treatment consisted first in the administration of anodynes, morphia to relieve the pain, the use of large doses of iodide of potash, and the disinfection of the nasal chambers by the thorough circulation through them of antiseptic solutions. Notwithstanding these precautions, meningitis developed, and the case became so serious that Dr. Loomis, of New York, was called in consultation. The man's appearance at this time was so exceedingly feeble that the prognosis given was particularly unfavorable and death was looked forward to as imminent. At Dr. Loomis' suggestion, however, the amount of the iodide was increased from 20 to 60 grains three times a day. This was continued for some time, the man rapidly improved and soon recovered sufficiently to permit of operative procedures directed toward the alleviation of the local disease. This was accomplished by the employment of a special surgical drill, by means of which the dead bone was removed.

AFTERNOON SESSION.

Dr. Clarence C. Rice, of New York, read a paper upon

ANTISEPTIC NASAL SURGERY.

He had come to discard tampons of antiseptic material, and the insufflation of antiseptics in powder, and relied chiefly on solutions, to be used by the patient in spray, from an atomizer. He conducted his operations under antiseptic precautions, and believed that he had obtained more speedy healing of tissues and freedom from untoward results in this way. He rarely had seen troublesome hemorrhage, but this was probably because he operated, removing rather less tissue than many. He usually kept his patient in his office for some time after operation; a cotton plug was inserted into the nostril, to cause coagulation which would extend to the point of operation and check bleeding; the application of cotton directly to denuded tissues he did not favor.

Dr. Harrison Allen, of Philadelphia, employed antiseptic precautions in nasal surgery, but had not observed any marked improvement in his results.

Dr. Charles E. Sajous, of Philadelphia, had two cases in his practice before he employed antiseptics which were apparently septic infection; since employing antiseptics he has had no trouble.

Dr. Frank Donaldson, of Baltimore, thought carbolic acid the best agent for promoting the healing of tissues after nasal operations.

Dr. E. Fletcher Ingals, of Chicago, prefers carbolic acid in about four per cent. solution. After operating he insufflates boric acid and iodoform into the nostril; to control hemorrhage he plugs the nose with strips of bichloride gauze soaked in a syrupy liquid composed of gallic, tannic, and carbolic acids, in glycerine; this plug he allows to remain from twelve to fifteen hours.

AMERICAN OPHTHALMOLOGICAL SOCIETY.

Special Meeting, held at Washington, September 18, 1888.

(Specially reported for The Medical News.)

MORNING SESSION.

In absence of both the President and Vice-President, Dr. Henry W. Williams, of Boston, was called to the chair.

Dr. David Webster, of New York, read a paper on

TENOTOMIES FOR THE CORRECTION OF HETEROPHORIA, WITH RESULTS.

Of forty cases, he had operated on twenty-five but once, sixteen had been subjected to a second operation, and three had been previously operated on by other surgeons. In three tenotomy had been done on the inferior rectus, in seven on the superior, in nineteen on the external and in twenty-six on the internal rectus. The operation had been done by raising the centre of the tendon, at its insertion, with the forceps, snipping it with the scissors, and then, with or without a strabismus hook, dividing each way until in all cases the whole width of the tendon was divided. The eyes were now tested, sometimes showing no effect on the deviation; snips were made equally on both sides of the tendon until a sufficient effect was obtained. Slight over-correction was aimed at and usually attained. He had three times been, subsequently, compelled to diminish the effect, by readjustment of the divided tendon. All operations were done under cocaine. In a single case there was reason to regret the operation. Of four epileptics, none were cured; in one there was a temporary suspension of the fits, which subsequently returned; and one thought the fits were favorably modified. Two cases of chorea seemed benefited, though not cured. In three men suffering from attacks apparently allied to hysteria, the results were strikingly good. In most of the cases the operation was done for headache or other symptoms of muscular asthenopia. The conclusions he had reached were: No person should have tenotomy done for heterophoria alone without symptoms of strain due to it. Very slight degrees of tendency to deviation may require correction. All other methods of treatment should be tried before resort is had to operation. The operation should be done under cocaine, and the effect produced from time to time tested with prisms. In judiciously selected cases the results are quite as good as are obtained with most other surgical procedures.

Dr. Henry Noyes, of New York, had no faith in spirit-level estimations of hyperphoria. These vertical deviations of the visual axes are frequently due to asymmetrical development of the bones of the face and orbit. He had in former years employed both prisms and tenotomy to remedy considerable degrees of vertical insufficiency, but without ultimate benefit. He was not willing to operate in any case in which there was not a distinct surplus of power in the muscle the tendon of which he proposed to cut.

Dr. Edward Jackson, of Philadelphia, confirmed the observation that, if neighboring tissues were left undisturbed, the entire division of the tendon might not have the slightest immediate effect on the ocular movements. The graduation of the effect is here secured by graduation of the incision of surrounding tissue, not by a partial division of the tendon itself.

Dr. O. D. Pomeroy, of New York, felt that he was unable to tell by inspection whether a tendon was completely divided or not.

Dr. Samuel Theobald, of Baltimore, discussed the question:

IS ASTIGMATISM A FACTOR IN THE CAUSATION OF GLAUCOMA?

He had observed that the direction of the meridians of greatest and least refraction in astigmatism determines in a marked degree the amount of asthenopia and other ill consequences. When the meridian of least refraction is vertical, or nearly so, there is more asthenopia, headache, or likelihood of pathological changes in the eye, than when it is horizontal, or nearly so. The non-asthenopic astigmatic eyes are rarely of this sort. Astigmatism in which the meridian of least refraction approaches the vertical is comparatively uncommon, and it must be regarded as a wider departure from emmetropia than the more common form. Because of the persistent effort on the part of the ciliary muscle to correct it, this variety of astigmatism is more difficult to detect than the commoner form, as the whole of it often cannot be rendered manifest at the first examination, even by the aid of a mydriatic. It was this less common, more troublesome variety of astigmatism, that the writer had, in almost every instance, found associated with glaucoma. Hyperæmia of the ciliary muscle and choroid was a common result of astigmatism, and especially of this form. It would be likely to induce an undue flow of fluid into the vitreous chamber; and if, in such an eye, the anterior drainage apparatus happened to be defective, a glaucomatous condition would be apt to result. Cases of fully developed glaucoma in which this troublesome form of astigmatism was present, and others of astigmatism, mostly of this character, in which glaucoma seemed to be threatening, were related.

Dr. Peter A. Callan, of New York, read a paper on the

TREATMENT OF ULCERS OF THE CORNEA.

Most of the ulcers occurring in young persons and children are really phlyctenules of the cornea; neglect and lid friction causing absorption and the formation of an ulcer. The treatment for these cases is the application of a salve of the yellow oxide of mercury (two to ten per cent.), between the eyelids once daily, with atropine and cocaine if necessary. Tonics, regulated diet, open-air exercise, airy sleeping quarters, coquilles of smoke glass; but no dark rooms or bandages. The ulcers, due to conjunctival inflammations, need no especial treatment, other than that applied to the form of disease causing the trouble. In gonorrhœal ophthalmia, ophthalmia neonatorum, or granular lids, we always redouble our effects when the cornea is likely to become involved, cut the outer canthus, apply leeches or ice-compresses, etc. Especial reference was made to those ulcers occurring without apparent cause, due, however, to some constitutional trouble, malaria, syphilis, etc. The treatment for these is, to find out the constitutional ailment and give the proper remedy; and, locally, to cocainize the eye, and with a piece of absorbent cotton wrapped on a holder, clean the ulcer. Then with another piece of cotton on the holder, having dipped it into a two per cent. solution of silver nitrate, swab the ulcer, trying to leave no part of it untouched with the solution. This may have to be repeated two or three times, in the course of as many days. Bathe the eye with hot water (120° to 130° F.) three times daily, for one-half hour. If much corneal irritation exists, bathe with boric acid solution, use atropia and cocaine after each bathing, and keep the eye bandaged. The point is to get a clean wound, and that is better and more safely done with silver nitrate than by any other

means known to the writer. Besides cleaning the ulcer, the silver stimulates the repair.

Dr. J. O. Tansley, of New York, did not think that cocaine acts at all beneficially in phlyctenular disease. Eserine was of decided benefit.

Dr. H. W. Williams had watched the various methods of treatment in vogue for over forty years. He had learned that even the dusting of calomel caused severe pain. He favored mild applications, and especially liked to use eserine, or, as less likely to cause painful spasm, pilocarpine.

Dr. Carl Koller, of New York, had learned from his teacher, Arlt, that one of the principal indications in corneal ulcer was for the bandage. This was to be applied in different conditions for different reasons; some ulcers would heal under the bandage alone. Any increased secretion was, however, a positive contra-indication to the use of the bandage.

Dr. W. F. Mittendorf, of New York, thought the electro-cautery should be used on sluggish ulcers and on those which are inclined to spread rapidly.

Drs. F. M. Wilson, L. H. Taylor, J. O. Tansley, and H. W. Williams had found antipyrin of great service in relieving the pain of corneal ulcers and other painful affections of the eye.

Dr. P. A. Callan had used the galvano-cautery extensively, it was capable of doing harm as well as good. He had seen it open the anterior chamber when not intended, and increase the size of the cicatrix by the unnecessary destruction of sound tissue. The bandage would do harm to eyes with phlyctenular disease; its use should be confined to cases of ulcer due to constitutional causes.

Afternoon Session.

Dr. Edward Jackson, of Philadelphia, proposed to designate by the name

meridional astigmatism,

one of the defects of the eye now grouped under the name "normal irregular astigmatism," which it was of practical importance to study separately, viz., the variations of refraction in different parts of the same meridian, which cause the refraction of the eye to vary from the centre of the pupil to the margin. He recognized two forms of it: a positive, the more common, and resembling spherical aberration, in which the centre of the pupil was most hyperopic or least myopic, and a negative, in which the centre was the least hyperopic or most myopic. For practical purposes, it was to be recognized, and its amount determined by the shadow-test, with which it caused both an erect and inverted image of the retinal light area to be seen at once, from the neighborhood of the point of reversal. The defect was of practical importance, on account of the uncertainty it sometimes caused in the results of testing for ametropia with test-lenses, on account of the difference in the correcting glass required when the pupil was contracted from that required when it was dilated, and because of its occasional influence on visual acuteness.

the numbering of prisms according to refractive power.

The Committee appointed at the annual meeting to consider this subject, consisting of Drs. Edward Jackson, S. M. Burnett, and H. D. Noyes, made a report recommending the adoption of the following propositions:

1. Prisms ought to be designated by the number of degrees "minimum deviation" they produce.

2. Where intervals of less than one degree are desired, half degrees and quarter degrees should be used.

3. To indicate what degrees of deviation are meant the letter "d" shall be added. Thus "prism 2° d." will indicate a prism that produces a minimum deviation of two degrees.

acute cocaine conjunctivitis.

Dr. W. F. Mittendorf, of New York, thought that undesirable effects, due to its use by persons with an idiosyncrasy toward it, were to be expected with cocaine as with other drugs. He reported three cases, in which its use caused violent acute conjunctivitis, with tense swelling of the lids and profuse acrid muco-purulent discharge. Two of the patients were elderly women, in one of whom there was eczema of the lids, and a return of the conjunctivitis on resuming the use of the drug. The third case was that of a man who had three successive attacks brought on by the instillation of different samples of cocaine.

Dr. John Green, of St. Louis, had observed that eyes intolerant of other mydriatics were similarly affected by cocaine. He had seen great hyperæmia caused by its continued use.

Dr. E. Jackson found that cocaine very frequently caused subsequent hyperæmia, usually culminating three or four hours after its application, and frequently attended with discomfort and smarting. He had seen very serious damage to the cornea from the use of cocaine at short intervals in conjunctivitis; and on that account would never place it in the hands of a patient for the relief of constant or frequently recurring pain.

Dr. W. W. Seely, of Cincinnati, had noticed that when the conjunctiva was liable to be irritated by mydriatics, it was similarly sensitive to the contact of other alkaloidal solutions.

exhibition of apparatus.

Dr. J. Oscroft Tansley exhibited a box with glass sides, with lenses and screens, into which the light of a magic-lantern could be thrown, and the course of the rays made evident by filling the box with smoke. This was for demonstrating the facts of refraction to students.

Dr. Swan M. Burnet, of Washington, exhibited the Javal ophthalmometer, and a disk of lenses for use in testing refraction by the shadow-test. This disk was adjustable for different heights, and could be swung back against the wall, to which it was attached, when not in use.

blepharospasm.

Dr. Carl Koller, of New York, regarded this as a symptom arising from different conditions. Cases might be classed under three heads, viz.: the neurotic, the hysterical, and the reflex. The last class was the one he wished to speak of particularly. The condition was often kept up by a small fissure near one canthus, usually the outer, and resembled the spasm of fissure of the anus. This spasm could be stopped, and the fissure allowed to heal by cutting the muscle, but for the eye this was rarely necessary. It was commonly sufficient to treat the cor-

neal or conjunctival trouble, which was the original cause of the reflex spasm, to cauterize the raw surface of the fissure with blue-stone, giving it a chance to heal under the protection of the coagulum formed, and to apply an ointment of yellow oxide of mercury to the lids. In these cases cocaine gave but little relief, and only when applied in considerable quantities.

CASE OF MONOCULAR NEURO-RETINITIS.

Dr. R. H. Derby, of New York, reported the case. It occurred in a young girl, with a history of syphilis in her father, but no previous manifestation of a taint in herself. It began with a dimness of vision, and central scotoma, quickly followed by optic neuritis. The swelling of the papilla increased until it reached 7 D., and light perception was lost. But under the use of large doses of potassium iodide and mercurial inunctions the swelling was reduced, and vision returned and improved until it reached seven-tenths of the normal.

EXTRACTION OF THE DISLOCATED LENS WITH THE AID OF THE BIDENT.

Dr. Oren D. Pomeroy, of New York, reported five cases, all giving satisfactory results, including fair vision. The bident, devised by the late Dr. C. R. Agnew, seeemd not to have come into general use, although those who had tried it liked it very much. The patient was to be kept face downward until the lens was in the anterior chamber, ether given, and before placing the patient on his back the bident introduced, taking care not to press the lens too firmly against the cornea. The corneal incision was then to be made and the lens extracted with a sharp hook, or lens scoop. The writer recommended the use of the bident, in the extraction of the dislocated lens, as safe and effectual in preventing the return of the lens to the deeper parts of the eye.

Adjourned.

AMERICAN OTOLOGICAL SOCIETY.

Special Meeting, held at Washington, September 18, 1888.

(Specially reported for The Medical News.)

The President, Dr. J. S. Prout, of Brooklyn, called the Society to order and stated that as the meeting was held solely for the consideration of scientific matters, all members of the profession present were invited to seats with the Society and to join in the discussions.

Dr. S. O. Richey, of Washington, read a paper on

THE PRIMARY PHYSIOLOGICAL PURPOSE OF THE MEMBRANA TYMPANI.

From a study of the anatomical development of the ear, from the lower to the higher forms of life, the writer concluded: 1st. The primary purpose of the tympanic membrane is that of protection to the tympanic cavity from the evaporating influence of the air. 2d. Being necessary for the protection of the cavity it is modified into part of a transmitting mechanism, a secondary physiological purpose. 3d. A permanent opening of the membrane may temporarily improve hearing, but is harmful to the ultimate condition of the organ. 4th. The tendency of the membrane to heal is an effort on the part of nature to preserve the function of hearing from the effects of disease, or ill-advised surgical interference.

Dr. Gorham Bacon, of New York, reported a case of

CEREBRAL ABSCESS, FOLLOWING EXTENSIVE NECROSIS OF THE TEMPORAL BONE; OPERATION; DEATH FROM SECONDARY HEMORRHAGE; AUTOPSY.

A man of thirty, with a history of good general health, but a purulent discharge, of two years' standing, from the left ear, was first seen September, 1887. Small polypi and granulations were removed, but it was difficult to keep open a proper channel for drainage, and there was extensive necrosis with the formation of a large sinus. In December there was pain. January 10th, there was left facial paralysis, and at the last of the month an abscess was opened above and back of the ear, which was found to communicate with the sinus leading up and forward from the meatus. A drainage tube was introduced and the track kept washed out with a solution of mercuric bichloride. March 7th, after doing well, he complained of great pain in the forehead and neck, became very restless, with temperature of over 102°, and aphasia so complete that his only response was "Yes, sir." Next day there was a boggy swelling over the left malar bone and eyelids. Dr. R. F. Wier now saw the case. An opening was made over the mastoid, but no trouble was found there. The sinus was then opened, the temporal muscle being divided, exploration with the finger revealed a pulsating tumor toward the base of the brain, which was opened, yielding a half ounce of pus. Next day he was better, but at the end of forty-eight hours grew more stupid. A counter-opening was then made over Broca's convolution. No pus was found, but a drainage tube was introduced and passed through the brain-substance to the other opening. Again his condition improved, but secondary hemorrhage, due to injury of the middle cerebral artery by the introduction of the tube, proved fatal forty-eight hours later.

SUPPURATIVE OTITIS WITH METASTATIC IRIDO-CHOROIDITIS, WITH ABSCESS OF THE NECK.

Dr. O. D. Pomeroy, of New York, reported the case. The patient, a man of fifty, was first seen for iritis with adhesions, which became general; and were followed by pus in the anterior chamber. In spite of an opening through the cornea the pus from the vitreous chamber penetrated the upper part of the sclera and the upper lid. The globe was enucleated. For some months the man had complained of great soreness of the side of the neck with some swelling. After loss of the eye these increased and deep fluctuation was detected. An incision gave exit to four ounces of pus, and at the same time pus was made too well up from the external auditory meatus. After this recovery was rapid. He had a history of suppurative otitis months before, but had believed himself entirely cured of it for some time.

Dr. C H. Burnett, of Philadelphia, read a paper on

CHRONIC PURULENT INFLAMMATION OF THE TYMPANIC ATTIC,

based on notes of the disease, additional to ten cases already published elsewhere. The chief obstacle to cure in these cases is the limited drainage through the membrana flaccida above the short process of the malleus, where the perforation in such cases is usually seated. The drainage is further retarded by the fact that the dis-

ease is in and about the head and body of the malleus and incus, and then acts as a dam to the free outflow of matter. This in turn decomposes, keeps up the disease, and renders the patient liable to intracranial abscess or general pyæmia.

In the treatment the chief considerations, therefore, are cleansing and draining this upper cavity of the tympanum. This is best done by injection, by means of the tympanic syringe, of peroxide of hydrogen, carbolic acid solutions from three per cent. to five per cent., and by enlarging the perforation and exposing the attic, either by scratching off some of the edge of the margo tympanicus, or by excision of the membrana tympani, and removal of the ossicula—*i. e.*, the malleus and the incus.

EXCISION OF THE DRUM-HEAD AND OSSICLES FOR THE CURE OF CHRONIC PURULENT INFLAMMATION OF THE ATTIC OF THE TYMPANUM.

DR. SAMUEL SEXTON, of New York, found most cases of persistent otorrhœa to be of this class. The striking advances in joint surgery, by removal of diseased tissue, antisepsis, and free drainage. had led him to attempt a similar treatment of these cases, which also presented chronic inflammation, bone disease, and very imperfect drainage. In such cases the best results by other modes of treatment left the tympanum greatly altered, the hearing very imperfect, the discharge constantly liable to recur, and if, as was very likely, obstructed, to cause painful inflammation with danger of extension toward the brain. An experience of three years convinced him that much was to be hoped from excision, both as to permanent relief and safety and improvement of hearing.

THE EMPLOYMENT OF BORIC ACID, IN SOLUTION, IN THE TREATMENT OF OTITIS MEDIA SUPPURATIVA.

DR. SAMUEL THEOBALD, of Baltimore, stated that in the ordinary cases of chronic suppurativa otitis media, in which there is usually extensive destruction of the drum-head, he uses boric acid, in powder, applying it by means of insufflation; but in acute cases, and in chronic cases in which the destruction of the drum-head is not extensive, and in which a closure of the perforation may be anticipated, he prefers to use a saturated solution of boric acid. The advantages which he claims for the solution, in such cases, are, that the healing of the perforation in the drum-head is more certain to be brought about when it is used than when the powder is employed, since the latter, by too suddenly drying the ear, and also by its mechanical action, frequently prevents the restoration of the membrane; that in acute cases it is safer, as it cannot obstruct the free escape of discharge from the middle ear, as the powder sometimes does; and that it can be applied more effectually than the powder can by unskilled hands. In his own practice no serious consequences had ever resulted from the application of boric acid powder to the ear; but reference was made to the three fatal cases of suppurative inflammation of the middle ear reported by Dr. Gruening, in which the fatal result was attributed to the introduction, in two of the cases, by packing, in the other by insufflation, of boric acid powder into the auditory canal. The strength of the solution which he commonly employed is fifteen grains to the ounce. If the discharge is profuse, the ear is syringed with this three times a day, and less frequently as the otorrhœa declines. In office practice it is more convenient, after having cleansed the ear by means of the syringe or cotton holder and the Politzer bag, to instil the boric acid solution (saturated) with a pipette.

NASAL DIFFICULTIES IN EAR DISEASE.

DR. J. O. TANSLEY, of New York, said that he had for years recognized the intimate connection between nasal and ear diseases. The latter are caused by partial or complete occlusion of one or both nostrils by hypertrophies, deviated septum, etc., which prevent the expulsion of abnormal secretions and the desiccating effect of the air passing over the normal mucous membrane. Hypertrophied tissue on the lower posterior aspect of the inferior turbinated bone may cause accumulation, although the passages are quite sufficient for purposes of respiration. Hypertrophies pressing directly on and irritating or occluding the Eustachian tubes, are certain to cause ear disease; and bands of tissue, apparently cicatricial, in the pharynx, must be divided. Hypertrophy of the posterior wall of the pharynx sometimes causes complete occlusion. Atrophic rhinitis, with patulous Eustachian tubes, or simple secretive catarrhs may cause trouble. The indications for treatment were: 1. To combat the blood dyscrasia or catarrhal diathesis. 2. To cure the catarrhally inflamed mucous membrane, and restore its normal function. 3. To free the nasal and naso-pharyngeal cavities from all obstruction and encourage nasal breathing. To remove hypertrophies he commonly employed the snare, avoiding the galvanocautery, in these cases, for fear of starting up a suppurative process in the middle ear, which was commonly irritated and full of secretion. In the after-treatment recourse was had to sprays, mild solutions of silver nitrate, and tannin and glycerin.

DR. CLARENCE J. BLAKE, of Boston, then read a paper on

THE INFLUENCE OF THE USE OF THE TELEPHONE ON HEARING POWER.

This influence must be injurious because the extremely low intensity, as demonstrated by experiment, of the sounds to be caught from the telephone compelled a strain of the ear which soon fatigued it and made it especially liable to injury by the accidental sounds of comparatively high intensity, which were constantly liable to be heard.

DR. C. H. BURNETT said he had seen several patients who believed that the continued use of the telephone had impaired their hearing.

DR. O. D. POMEROY gave the case of a patient who said the use of the telephone fatigued her very much, and she thought had made her decidedly worse.

CORRESPONDENCE.

CONGRESS NOTES.

(*From our Special Correspondent.*)

THE financial showing of the dinner to the guests of the recent Medical Congress held in Washington in September, as set forth in the printed circular from the Chairman of the Committee of Arrangements, is very satisfactory and must be a cause of congratulation to those who participated. There were one hundred and forty-one

actual subscribers, who paid in full $26, and thirty-one guests. The actual cost of the dinner to each subscriber was $12.23, leaving a surplus Dinner Fund of $1095.80, thus allowing a rebate to each subscriber of $7.77. This surplus fund will be held and invested, with the consent of the subscribers, to be put to a similar use in 1891. The Chairman also states that the expenses incurred by the Committee have been paid in full without any demand on the treasury of the Congress.

As Washington is to be the triennial meeting place for the Congress, future Committees of Arrangements would do well to look carefully after the comforts of their visitors regarding two important adjuncts, viz., hotel accommodations and proper treatment by the railroads. With regard to the hotel accomodations there seems to have been considerable unfavorable criticism. Washington is peculiarly situated in this respect; it has become a show place, and is filled periodically with excursionists; these excursionists are billeted, as it were, upon the hotels—that is, with their excursion tickets they frequently receive hotel coupons, receiving accommodations at a reduced rate. This has demoralized all the large hotels, for these excursionists do not demand a high order of table or service, and the hotels take rank accordingly with those, for example, at many of our seaside resorts—which are shunned by the experienced visitor. The way to enjoy Washington, with due regard to digestion and creature comforts, is to put up at some of the smaller hotels, which are more like flats and receive transients, or are conducted upon the European plan, and to take one's meals either at the clubs or at some of the restaurants. Washington will be found to provide both, and quite satisfactorily. After all, the man who lives in another city with his home comforts around him, had better try his own hotels under similar circumstances, and see if by that means he cannot take off a little of the sharp edge of criticism. Those who have gone from Washington to some of its neighboring cities to medical and scientific congresses, have also their side of the story to tell.

With regard to the accommodation from railroads in reduced fare, etc., decided measures should be taken to correct evils which have grown up, from a want of good faith somewhere. Take, for instance, the experience of the Committee of Arrangements at this Congress. Application upon application was made to the Chairman for his signature to certificates of attendance upon the Congress, from people who made no pretence of being medical men or of having the slightest interest in the Congress. They were informed by agents that they could procure these tickets during the session of the Congress, and return at reduced rate by obtaining this signature. Consequently they were thrown out of their chances and had to pay full rates both ways, when they might have saved a few dollars by procuring a round trip ticket. These facts tell their own story, that in the past such an evasion of the rules was an understood thing, and also explain, while they do not mitigate or excuse, the action of some companies in refusing, or making the obtaining of rebates so troublesome and vexatious to members, as to cause much indignation and feeling against these companies. It is time that a decided expression of opinion should be had in this matter, and future Committees of Arrangements for similar purposes should protect themselves and their visitors against annoyances and mortification. The rebates, after all, are in many cases but a small matter; the visitor will take advantage of them, as a matter of course, if offered to him, but he would rather pay the price twice over than to be subjected to such annoyances and looked upon with suspicion. Let there be a thorough, honest understanding, or let the whole matter alone.

Washington, October 1, 1888.

STERILIZED MILK.

To the Editor of The Medical News,

Sir: In The Medical News of July 7th, page 12, Dr. Baruch states that milk steamed as advised by Dr. Rotch and myself is not sterile, and that the test taken by us was the failure of the milk to turn sour. Deeming the subject of a pure milk supply one of great importance, not only to infants, but also to adults, both in prophylaxis and treatment, I desire to make a few remarks on Dr. Baruch's treatment.

In the first place, neither Rotch (*Archiv. Pediat.*, August, 1887, p. 4) nor Jeffries (*Amer. Journ. of Med. Sciences*, May, 1888, p. 496) claimed that one steaming made milk sterile; it may, or may not, as I proved. Owing, however, to the very small number of spores capable of resisting a temperature of 212° F. occurring in milk as delivered, the number of bacteria in steamed milk is practically nil. From such milk the child will obtain fewer bacteria than from the mother's nipple.

The objection that this milk may not be absolutely sterile may, therefore, in a question of practice, not theory, be discarded as a bogle. So long as babes continue to put everything into their mouths and suck their toes, no mother need lay awake from fear of the few bacteria her fond child has taken in steamed milk.

In order to keep the milk for a long time, it must be steamed on three successive days. This does sterilize it, as experience in bacteriological laboratories, the world over, shows. It is an easily prepared and almost universal fluid medium for the growth of pure cultures. Any complicated apparatus to super-heat milk is unnecessary, expensive, impracticable; to place it, contained in an ordinary flask, in a cooking steamer for fifteen or twenty minutes is neither one of the three.

In closing, I would remark that if Dr. Baruch will reread my article he will find that I did not take the fact that such milk failed to turn sour as evidence of sterility. On the contrary, I made a count and reported at length the number of bacteria found by the plate method *after one steaming*.

Were the question a personal one I should have passed it by, but believing that thousands of lives can be saved, and many thousand cases of disease avoided by steaming the milk as advised, it seems to be simply duty to defend the method against careless stricture, while standing ready to try to remove any solid objections that may be raised.

Yours, etc.,

J. Amory Jeffries.

91 Newbury Street, Boston.

GALL-STONES IN A GIRL FIFTEEN YEARS OLD.

To the Editor of The Medical News,

Sir: On the 26th of September, 1888, I made a post-mortem examination of a mulatto girl, fifteen years old, who had died of typhoid fever.

I found in the gall-bladder forty-two gall-stones, about the size of small peas, the surface a pale yellow, of a greasy feel, and with irregular, club-shaped prominences; the body of the stone brownish. The gall-bladder was normal. No history of biliary colic.

Gall-stones at so early an age are so rare that this case seems to me worthy of record.

D. S. Lamb, M.D.

Army Medical Museum,
Washington, D. C.

NEWS ITEMS.

Disinfecting Letters.—The terrible scourge of yellow fever which is making such havoc in Jacksonville, Florida, is not from present appearances likely to spread outside of the district to which it is now confined. Rigid quarantine provisions are enforced in all directions around the unfortunate city, and personal access to the outside world is practically impossible to its inhabitants. Neither is there cause to fear infection being communicated through the mail. Letters from the stricken section are fumigated in a novel way, so that there is little or no chance for the disease being brought northward. The letters are all stopped when they reach the quarantine lines. Each letter is put under a machine with a long arm attached, and this is provided with little teeth punctured at the ends. A powder that is used for fumigating purposes is forced through the arm and down through the teeth. The arm comes down on each letter, and while the little teeth are perforating the letter the powder is blown in between the sheets, disinfecting the letter thoroughly. Then it is forwarded to the person to whom it is addressed. Some complaint has been heard of damage to letters, but so long as they remain legible a little disfigurement should be welcome as a proof of protection.—*American Analyst*, September 15, 1888.

NOTES AND QUERIES.

"CEREBRAL LOCALIZATION."

To the Editor of The Medical News,

Sir: One of the speakers on "Cerebral Localization," before the late Congress, fell into an error that implies want of correct information, and might, indeed, be considered an inhospitable act.

In the course of the discussion in question, it was said that we owe to Putnam the discovery of the fact that irritation of the subjacent white matter causes the same results as when the gray motor areas above are excited. Now, it was Dr. J. Burdon-Sanderson who announced this in a communication to the Royal Society, a few weeks after Dr. Ferrier's paper had appeared. This was in 1874. Very truly,

Roberts Bartholow, M.D.

Philadelphia, September, 1888.

TASTELESS PREPARATION OF IRON.

To the Editor of The Medical News,

Sir: Will you kindly oblige an old subscriber by giving me a description of, or a formula for Creuse's tasteless preparation of iron, recommended by Bartholow (see page 135, *Materia Medica and Therapeutics*, ed. of 1888) as the most convenient form for the administration of the tincture of the chloride.

I have been unable to find any information on this point from sources at my command, and an answer will be thankfully appreciated. Respectfully yours,

O. D. Doane, M.D.

The Dalles, Oregon, Sept. 10, 1888.

[Creuse sought to remove the styptic and otherwise disagreeable taste of chalybeates, by the addition of an alkaline citrate. The tincture of the chloride lends itself best to this treatment. To one ounce of the tincture add about two hundred grains of citrate of potassium.—Ed.]

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM SEPTEMBER 25 TO OCTOBER 1, 1888.

By direction of the President, George M. Sternberg, *Major and Surgeon* (U. S. Army), will proceed to Decatur, Alabama, and to such other points in the infected districts of the Southern States as he may deem necessary, to continue his scientific investigations of yellow fever.—Par. 8, *S. O. 224, A. G. O., Washington*, September 26, 1888.

Under authority from Headquarters of the Army, A. G. O., dated September 22, 1888, Major Charles B. Throckmorton, and Batteries "K" and "M," Second Artillery, comprising the garrison of Jackson Barracks, New Orleans, La., will proceed at once, by sea, to New York Harbor, and, upon arrival there, will take post at Fort Wadsworth, New York Harbor. A small guard of enlisted men will be left at Jackson Barracks. *Major and Surgeon* John W. Williams will accompany the troops to New York Harbor. *Major and Surgeon* Harvey E. Brown will remain at Jackson Barracks.—Par. 12, *S. O. 202, Headquarters Division of the Atlantic, Governor's Island, New York City*, September 26, 1888.

White, Robert H. *Major and Surgeon* (U. S. Army).—Is granted leave of absence for one month, with permission to apply for an extension of one month.—Par. 7, *S. O. 199, Headquarters Division of the Atlantic, Governor's Island, New York City*, September 22, 1888.

By direction of the Acting Secretary of War, leave of absence for six months, on surgeon's certificate of disability, with permission to leave the Division of the Missouri, is granted Ezra Woodruff, *Captain and Assistant Surgeon*.—Par. 5, *S. O. 223, A. G. O.*, September 25, 1888.

By direction of the Acting Secretary of War, Washington Matthews, *Captain and Assistant Surgeon*, is detailed as a member of the Army Medical Examining Board appointed to meet in New York City, October 1, 1888, by Special Orders, No. 203, September 1, 1888, from this office, vice George M. Sternberg, Major and Surgeon, hereby relieved from his detail as a member of the Board.—Par. 3, *S. O. 224, A. G. O., Washington*, September 26, 1888.

Upon the recommendation of Captain and Assistant Surgeon Daniel Weisel, Senior Medical Officer, Camp of Instruction of the Fifth Cavalry, J. Van R. Hoff, *Captain and Assistant Surgeon*, is assigned in charge of the active operations of the Hospital Corps in that camp.—Par. 2, *S. O. 121, Headquarters Department of the Missouri, Fort Leavenworth, Kansas*, September 22, 1888.

By direction of the Acting Secretary of War, leave of absence, to include May 3, 1889, is granted George F. Wilson, *Captain and Assistant Surgeon*.—Par. 14, *S. O. 223, A. G. O.*, September 25, 1888.

The resignation of George F. Wilson, *Captain and Assistant Surgeon*, has been accepted by the President, to take effect May 31, 1889.—Par. 15, *S. O. 223, A. G. O*, September 25, 1888.

By direction of the Acting Secretary of War, the following named officers of the Medical Department will report, in person, on October 9, 1888, to the President of the Army Medical Examining Board, Army Building, New York City, for examination for promotion: Benjamin Munday, *Captain and Assistant Surgeon*; William O. Owen, Jr., *Captain and Assistant Surgeon*. Upon the completion of their examination, to rejoin their stations.—Par. 15, *S. O. 225, A. G. O., Washington*, September 27, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING SEPTEMBER 29, 1888.

Hudson, Adrian, *Medical Inspector*.—Ordered for examination, preliminary to promotion, to Medical Director.

Bates, Newton L., *Medical Inspector*.—Ordered for examination, preliminary to promotion, to Medical Director.

Cooke, George H., *Surgeon*.—Ordered for examination preliminary for promotion as Medical Inspector.

Bradley, Michael, *Medical Inspector*.—Ordered as a member of the Naval Examining Board.

Wells, Henry M., *Medical Inspector*.—Relieved from duty as a member of the Naval Examining Board.

Simons, Manly H., *Surgeon*.—Ordered to Widows' Island Naval Hospital.

Heffenger, A. C., *Passed Assistant Surgeon*.—Detached from Naval Hospital, Widows' Island, and wait orders.

THE RELATIVE IMPORTANCE OF DIFFERENT CLIMATIC ELEMENTS IN THE TREATMENT OF PHTHISIS.[1]

BY EDWARD T. BRUEN, M D.,
ASSISTANT PROFESSOR OF PHYSICAL DIAGNOSIS IN THE UNIVERSITY OF PENNSYLVANIA.

THERE have always been popular descriptions of climate from the pens of travellers and valetudinarians, which have been more or less impartial, as the writers were more or less interested in the development of a special resort. In recent years the study of physical geography has widened our knowledge of the various climates of the globe, but exact statistics of the effect of climate on the physiology of the thoracic organs are still wanting, as well as a knowledge of the effect of climate upon bacterial organisms. Moreover, in our own land changes have been induced by the settlement of the country, so that it is still true that a definite scientific idea of the real healing property possessed by climate is yet to be formulated, and it is difficult to settle positively the relative importance of the different meteorological elements.

In this article I shall only consider the effect of different climatic elements upon a single disease. From the standpoint of the clinician the relative advantages of different climatic elements in the treatment of phthisis depend upon the view which may be adopted of the etiology of the disease.

Experimental evidence, by inoculation of tubercular material, seems to afford cumulative testimony as to the specific character of phthisis, viz., that tuberculosis is an infectious disease, and that the tubercle bacilli are the infecting agents; but a careful analysis of the history of tuberculosis indicates that both bacillary infection and unhygienic surroundings are necessary to bring about the disease.

A glance at the modes of tubercular infection may afford a hint as to the relative value of climate in the management of impending phthisis. Many French[2] and German observers have shown that the majority of pleurisies, which are not traumatic, pyæmic, or rheumatic, are tubercular. Bacilli can enter a part only by means of the canals or ducts which penetrate it, or by the blood or lymphatic vessels. Infection of the individual can occur by means of the respiratory system, the alimentary canal, the genito-urinary tract, and even the outer epithelial surface. It has been further shown that bacilli may enter the body by means of the alimentary canal, without causing any lesion at the place of entrance; for example, in the mesenteric phthisis of children. Baumgarten has even shown that the bacilli may be directly inherited, and transmitted from parent to offspring.

This variety in the mode of infection indicates that a broad view should be taken of the influence of climate upon health, and justifies the statement that the relative importance of climatic elements for those predisposed to phthisis resides in the selection of that climate which, in each individual case, tends most toward fortifying the physiological structure; and, therefore, antagonizes the invasion and progress of the disease. An additional support to this view can be drawn from the observations of Metzchinkoff, who has seen the lymph cells of the frog englobe and destroy anthrax bacilli. Wyssokowitsche, also, found the microbes, which he injected into the circulation of animals, taken up by the endothelial cells lining the capillaries of various organs, where they finally became destroyed. Watson Cheyne, in a review of some of his recent experiments, after describing the manner in which large quantities of putrefactive and non-pathogenic bacteria were destroyed when injected into the blood of rabbits, adds, "but this does not occur if the animal is in a bad state of health."

It has been demonstrated that the extent and character of the lesions produced in tuberculosis are due to the number of bacilli which enter a part, and to the manner in which they enter.

There are three characteristic forms of tuberculosis: first, acute, miliary tuberculosis, which is an acute infectious disease, due to general blood infection by large numbers of bacilli entering the blood current. Second, disseminated tuberculosis, in which there is also general infection of the blood; but the bacilli which enter are fewer, or they enter at intervals. Third, the tuberculous pneumonia, affecting larger or smaller portions of the lung parenchyma and due to the aspiration of large numbers of bacilli furnished by a focus of the disease, usually a cavity in the lung.

[1] Read at the opening of a discussion in the Section for Climatology at the meeting of the Congress of American Physicians and Surgeons, at Washington, D. C., September 19, 1888.

[2] Especially Kelch and Vaillard: Bulletins de la Société Médicale des Hôpiteaux de Paris, 83.

In the acute forms of tuberculosis, climatic treatment is certainly unavailing; in the tubercular pneumonias the same is largely true; but in the forms of disseminated tuberculosis, which are more slowly developed, and particularly those in which there is a tendency to the formation of fibrous tissue, the climatic treatment is proportionately valuable. The climate is yet to be discovered which will annihilate the bacillus of tuberculosis, but by appropriate climatic and hygienic treatment we may not only prevent the development of phthisis in those predisposed to the disease, but also strengthen the constitution so that further tubercular invasion may be retarded, and the phthisical process rendered latent. What, then, is the relative importance of different climatic elements in accomplishing this result?

Cullen has written that the air of any place is better for the patient than that in which he grew ill. When one becomes a valetudinarian the habits of previous living are reversed, active out-door exercise is usually substituted for sedentary in-door life; and, in addition, the habits are changed in connection with a salubrious climate.

A striking illustration of the influence of environment is found in Mathews' paper, read before the American Climatological Association, on "Consumption among the Indians." He has shown that the death-rate among the Indians on the reservation, and in those residing in the most highly civilized parts of the United States, is much increased under the influence of civilization—*i. e.*, under the compulsory endeavor to accustom themselves to the food and the habits of an alien and more advanced race, and that climate is no calculable factor in this increase.

A favorable climatic environment to increase general vigor may vary in accordance with the individual idiosyncrasy; with some a cool or cold climate is naturally preferable to warm or hot; some improve in rarefied air, others at the sea level, while it is generally conceded that a dry is preferable to a moist, a sunshiny to a cloudy, climate. Variability is of less essential importance, but is an element of climate which must be considered in individual cases; as, for instance, in those who possess feeble circulations, and who are unable to take much exercise. Again, equability of climate may, on the same grounds, become a factor to be considered from the standpoint of the individual case.

An inquiry instituted in Saxony, at the expense of the government, proved that elevation had nothing to do with immunity from phthisis, very high localities in the Ertz and Reisengebirge exhibiting a large percentage of phthisis as soon as the industrial arts, such as mining and the manufacture of china, were prosecuted there; while, on the other hand, the percentage in the low lands was diminished where the people were engaged in agriculture and cattle raising.

At the period of the discovery of the Sandwich Islands, in 1778, the Hawaians, according to Surgeon-General Wood,[1] were physically and mentally superior to all the other Malayo-Polynesian races. Climate, soil, and general environment having remained the same, we must account by a change in the habits of life, for the astonishing increase of disease, and the deterioration produced by a century of civilization in the Hawaian race.

Fothergill has shown that the effect of town life is to produce a distinct retrogression to a smaller, darker, precocious race of less potentiality than the rustic portion of the community.

Dr. Loomis has claimed for the air of pine forests a valuable antiseptic and corrective property, diminishing putrefactive changes in the lungs, and the multiplication of bacteria. But the influence of life amidst pine forests is, after all, rather to enhance general vigor by the effect of a suitable environment with outdoor life, and not directly by destroying the specific poison of the disease.

Ozone has always been thought to be present in large amounts in the air of pine forests, on the ocean, and at high altitudes. It is said to have the property of chemically purifying the atmosphere by combining with the products of decomposition. Again, Schmidt, of Dorpat, is of the opinion that all processes of oxidation within the organism are accomplished not by oxygen, but by ozone; oxygen outside the body being scarcely able at the temperature of animal heat to bring about the oxidation of highly organized bodies. As we cannot definitely determine the amount of ozone in an atmosphere, it becomes an attribute of climate of uncertain value. Ocean voyages are relatively important chiefly from the character of the cases which receive benefit from them. Ocean climate insures great purity of the atmosphere, and probably ozone in considerable amount, and the regularity of life may prove quieting to the nervous system. The ocean voyage is relatively superior to the seashore because the dampness of the soil at the seashore is avoided. It is also settled that sea air has a beneficial influence upon the catarrhal processes of subacute or chronic bronchitis For phthisical subjects the value of an ocean voyage lies in the bracing influence it exerts on the nutrition of those predisposed to the disease, and is favorable in some forms of fibroid phthisis in which bronchial disorders are prominent features.

It would seem, therefore, that the consideration of the etiology of phthisis would indicate that climate is of value to the individual predisposed to phthisis, not by a single or specific quality of the air, or by any definite combination of meteorological conditions. It is neither more nor less than pure air, uncontaminated by miasm or organic or inorganic

[1] Trans. Section 16, Ninth International Medical Congress

substances. The chief purpose of climatic change is to increase cellular resistive power.

In phthisical subjects, suitable for climate cure, the relative value of different climatic elements may be determined upon simple lines, viz.: that climate most conducive to individual health under ordinary circumstances, a climate in which, according to individual preferences, fresh air, sunshine, and an out-of-door life may be freely enjoyed, and, in consequence, respiration, digestion, and hæmatosis proceed with the greatest activity.

Again, an answer to the question of the relative importance of different climatic elements in the treatment of phthisis may be drawn from a study of the climatic conditions most commonly demanded by physicians.

Dryness of soil is of the first importance, or such porosity of the same as shall practically insure it. If the soil becomes too dry the continual absence of rain may prove a disadvantage, because the air may be filled with dust, from which it is mechanically cleansed by rain or snow carrying downward to the earth not only the solid particles suspended in the air, but also carbonic acid and ammonia. Rain is not an evil, unless it is associated with conditions of soil which favor continued dampness; still a locality subject to long-continued rains is necessarily not so climatic, since high relative humidity of the atmosphere is very undesirable.

The relative humidity of the atmosphere exercises a powerful influence upon animal and vegetable life. It is well known that inhabitants of a dry climate are, as a rule, thin and sallow, while those living in moist insular countries have well-developed figures and fresh, ruddy complexions; so that a very dry atmosphere need not be considered of high relative value in persons simply predisposed to phthisis. It is otherwise with those already infected with phthisis, but even for these the question of atmospheric humidity is relatively less important than porosity of the soil; indeed, at moderate altitudes porosity of soil includes dryness of the air. The maximum dryness of the air is commonly secured at high altitudes, but since many cannot endure the rarefied air, this climatic element must often be sought at moderate elevations, at which porosity of the soil secures dryness of the air, and again, dryness of air must not be secured at the expense of a dusty atmosphere. A dry atmosphere favors inspissation of the blood by increasing transudation of the skin, and will promote inspissation of the liquid elements of catarrhal inflammation, but, as Welch and others have shown, catarrhal inflammation is secondary to microbic infection rather than the reverse.

To those who believe in the specific nature of phthisis the researches of Metzchinkoff on the struggle of the cells of the organism against invading microbes, show that dryness is chiefly of importance as an element of those climates which enhance general vigor. He points out that there are cases in which the organism is invaded by microbes without any resistance being made by the phagocytes or cells which possess the property of absorbing and digesting microbes. Atmospheric dryness is probably unfavorable to the reproduction of the bacilli, but until definite statistics are forthcoming we commonly ascribe a high relative value to a dry atmosphere from its effect in stimulating the general health.

Meteorology has shown that pulmonary phthisis and temperature have nothing in common. Pulmonary consumption, geographically considered, is neither favored by a low temperature nor prevented or cured by a high one. Equability of climate is practically unattainable, and statistics of the health resorts which send us the greatest proportion of benefited cases are those in which great diurnal variation occurs. Many regions in which the climate is equable are notoriously undesirable, as, for instance, the western coast of England, the Netherlands, Norway, the Equator, and the poles.

Equability of temperature only deserves consideration indirectly—that is to say, in connection with individual cases. When changes of temperature are very sudden or very great, a certain amount of vigor is necessary to react properly to them; persons with feeble circulations or advanced pulmonary disease will, therefore, find it necessary to consider equability.

Lastly, rarefied air versus sea-level pressure has been considered as a climatic element of high importance. This conclusion has been reached chiefly by observing that consumption in all latitudes diminishes with altitude. Physicians now are universally ready to recognize that in mountainous regions the air is rarefied and the respiratory activity increased. The air is also usually dry, and Pasteur has proven that organic substances are more numerous near the earth's surface than in the higher strata of the atmosphere, and they continue to diminish the higher we ascend, disappearing entirely when we reach certain heights in the mountains. It has, however, been shown conclusively that the unquestionable good results accruing to consumptives, from a residence in the mountains, are due to other causes than altitude. In elevated regions consumption can be developed the moment the inhabitants adopt an indoor life, associated with the confinement incident to the trades; while in the lowlands outdoor life diminishes the percentage of consumption.

Fifteen years ago MacCormac, an English physician, claimed that pulmonary consumption was an artificial product developed by inspiring air which had previously been expired, "re-breathed" as he expressed it. He went so far as to assert that there would be no pulmonary consumption if everyone would sleep with open doors and windows. Statis-

tics, I believe, will ultimately show that the mere mechanical physiological influences of rarefied air are unimportant in the majority of cases, and we now know that, in some instances, high altitudes prove positively injurious.

The greatest benefit can be secured in the locality which possesses the purest air, a large percentage of ozone, the best drained soil, atmospheric dryness without dust, and the greatest proportion of sunshiny days, and especially where these results are attainable at a moderate altitude. This latter feature should be considered important, because should recovery occur it may be possible to return to ordinary elevations with safety to health; for while statistical proof is wanting it is pretty well established that when an individual becomes acclimated to the rarefied air of high altitudes it is dangerous to health to return to ordinary elevations.

Finally, the position already taken in regard to the relative importance of climatic elements is supported by the character of the cases deemed suitable for climatic treatment. In selecting these cases the question of the special physiological effects of altitudes should be first considered. These specific advantages seem to be mechanical, and are chiefly those which result from the rarefied atmosphere. For example, it has been shown by Dr. Platt that the Peruvians at an elevation of seven thousand to fifteen thousand feet possess short compact bodies and greatly hypertrophied lungs. Residence at high altitudes causes enlargement of the thorax, hypertrophy of the healthy lung tissue, and the development of pulmonary emphysema around tubercular lesions.

High altitudes are generally recommended for those cases free from pyrexia and all acute symptoms; in cases of hereditary or family tubercular predisposition; or in cases which manifest phthisis by early hæmoptysis; and in instances of imperfect thoracic and pulmonary development, in chronic tubercular pneumonia without bronchiectasis, and with tendency to formation of fibroid tissue; in chronic pleurisy in which the lung does not expand after removal of the fluid, and in spasmodic asthma without emphysema.

The climate of altitudes is acknowledged to be injurious to those who possess insufficient lung tissue to carry on respiration adequately in a rarefied atmosphere, such as cases of phthisis with double cavities, with or without pyrexia, and in those cases of tubercular infiltration in which at low levels the pulmonary area scarcely suffices for respiratory purposes. It is thought that in suitable cases evidence of improvement must be drawn from a diminished pulse and respiration rate, together with gain in body-weight, color, and muscular power; but these physical signs are not peculiar to improvement at elevated regions.

High altitudes are then peculiarly undesirable for mechanical reasons, and consequently for special types of disease such as emphysema, chronic bronchitis with bronchiectasis, and in diseases of the heart and great vessels. High altitudes are thought to be unsuitable for cases in which there is great irritability of the nervous system, since the dry air usually found in such latitudes diminishes the water in the blood, and acts as a powerful stimulant to the nervous system, increasing its functional activity and causing excitement and sleeplessness. High altitudes necessarily include variability, consequently are unsuitable for those persons advanced in years or in those younger persons who are too feeble to take exercise.

There are, therefore, a few mechanical effects peculiar to the atmosphere of elevated regions which render the climate of altitudes relatively objectionable in the management of certain cases, but, on the other hand, excluding these, the relative importance of altitude indirectly antagonizing tubercular phthisis has not been shown, and the good results attained in elevated regions for the class of cases already mentioned can be gained at any point possessing dry soil, pure dry air, and sunshine, which will invite exercise and in turn promote hæmatosis and invigorate the general system.

Once more, in selecting a climate the preference of a patient for a warm rather than a cold climate, should be consulted, and in the decision the only essential elements seem to be those already grouped, viz., dry air, porous soil, and abundant sunshine, for in almost all cases the profit to the individual is indirect from the effect of out-door life. In selecting a climate its relative advantages should be set over against the disadvantages of localities not only meterological, but also those relating to the patient's personal comfort and convenience, and as the requirements of a typical climate, though simple, are not easily secured at any one point, localities should also be selected in some measure with a view to the least expense and inconvenience of the individual.

THE COMPARATIVE IMPORTANCE OF DIFFERENT CLIMATIC ATTRIBUTES IN THE TREATMENT OF PULMONARY CONSUMPTION.[1]

By VINCENT Y. BOWDITCH, M.D.,

VISITING PHYSICIAN TO THE CARNEY HOSPITAL, BOSTON; INSTRUCTOR IN BOSTON POLYCLINIC.

In offering my views upon this subject, I shall not presume, even were it possible in the limited time allowed, to give statistical evidence of the results of my own experience in the climatic treatment of phthisis. From the protracted nature of the disease satisfactory data can be given only after

[1] Read at the meeting of the American Climatological Association, Washington, September 19, 1888.

years of close observation of cases, and it is more with the hope of exciting discussion which shall lead to more thorough investigation of this most important subject than of giving new or valuable facts, that I have prepared this paper.

There can be no physician, I imagine, even of many years' experience, who does not feel, at times, a sense of helplessness when asked if a change of climate will be beneficial to his patient, and, if so, what climate shall be chosen. It is then that our lack of proper knowledge on the subject comes over us; it is then that the apparent difference of view, held by equally eminent authorities, makes us feel that the science of climatology is in its infancy only, and that from its very complexity it must have a slow growth.

In taking a broad survey of the different methods of climatic treatment in the last half century, we can say that, regardless of possible differences of detail in treatment of incipient phthisis, the modern method is strongly in favor of selecting cool or even cold invigorating climates by which the general system may be assisted in its efforts to resist disease, as opposed to the former custom of selecting the warmer, more debilitating regions with their generally depressing effects. Even when taking into consideration the greater attention paid now to hygienic matters, which has its favorable effect, yet the results of the modern method show it to be a decided step, in the right direction, for a large class of cases.

Let us now ask: "What in the opinion of eminent authorities are the most important attributes of a climate for the treatment of incipient phthisis?

At the outset we must pause, being brought face to face with the fact that in all tabulations of results, the word phthisis covers a variety of pulmonary affections, and herein lies one of the chief difficulties of our coming to accurate and definite conclusions. By accepting the presence of this well-nigh insurmountable difficulty, and keeping it in mind, we can, nevertheless, draw general conclusions with safety, and judge if the number grows less of those who die from wasting pulmonary diseases, be they of tubercular nature or otherwise, and, if so, what are the reasons of the decrease?

In Dr. Denison's admirable paper of last year, which gives us the key-note of the discussion to-day, he places at the head of the list the quality of *dryness* as opposed to *moisture*. Under this head we may include both dryness of the air and of the soil, and without discussing the question as to how these are largely dependent upon each other, it will be sufficient to say that the researches and opinions of many authorities justify Dr. Denison in placing this attribute at the head of the list.

The investigations of my father, about thirty years ago, as to the cause of consumption in Massachusetts, and shortly afterward, of Buchanan and Simon, in England, point most strongly to soil moisture as a cause of the disease, and, furthermore, show that removal from a damp soil to a dry one has frequently been followed by arrest of the disease. More recent researches in other regions (for instance, those of Dr. Pepper in Pennsylvania two or more years ago) have lead to the same result. Jaccoud, Hermann Weber, and others quoted by them, while they lay the greatest stress upon *altitude*, yet speak of the dryness of the air which accompanies a rarefied atmosphere and the rapid drainage of the soil due to elevation as most important factors in the cure of consumption.

Jaccoud, in his enthusiasm for *altitude* as the most important factor in the treatment of incipient phthisis, lays much stress upon the mechanical effect of expansion, which residence in a rarefied atmosphere has, upon the human chest, and in this view he is supported by Hermann Weber, C.B.J., and C. Theodore Williams, Denison, Solly, and others, and from their observations there is little reason to doubt that the frequent and deep inspirations made by patients upon arriving in mountain regions, to obtain the requisite amount of oxygen from the rarefied air, tend to expand the chest and to dilate the collapsed or obstructed alveoli of a phthisical lung. The full-chested appearance of children in the mountainous regions of Colorado, as noticed by the two authors last named, goes to prove this fact.[1]

Apart from the mechanical effect upon the chest, authorities very generally agree that in altitudes, properly selected, varying from 1500 to 8000 or 10,000 feet, we find a combination of attributes favorable to the cure of incipient phthisis, and in addition to the one already mentioned, viz., *dryness* of the atmosphere and soil, we have the advantage of a cool or cold bracing temperature, clearness and purity of the atmosphere, with a large percentage of sunshine.

While fully acknowledging the weight of the opinions of those who regard altitude as *one* of the most, if not *the* most important element in the climatic treatment of phthisis, yet I must confess to being as yet unwilling to accept this without reservations. It is doubtless true that we find, as Dr. Denison says, at certain high altitudes a greater number of what we now consider the most important

[1] That these effects of altitude have a decidedly beneficial influence on the pulmonary condition there is little reason to doubt, even though Jaccoud persists in saying that the rarefaction of the air causes an *anæmia* of the lungs in conjunction with the other viscera, although other eminent authorities maintain that the lungs share with the skin the increased circulation due to removal of atmospheric pressure, which seems the more rational view. (Lubbock's translation of Jaccoud's "Curability and Treatment of Pulmonary Consumption," p. 293.)

attributes combined than in less elevated regions: but I think we must be guarded in accepting this, lest from the result of future investigations we find that we have gone too far in this direction.

With my present conviction that dryness of soil and atmosphere are the most important factors in the climatic treatment of phthisis, I am much struck by the experience of Dr. Geddings, who for many years has studied the climate of Aiken, in South Carolina, and the results of phthisical patients who have been sent there. The town is situated between 500 and 600 feet only above the level of the sea, not high enough to exert any special mechanical influence on the chest by rarefaction of the air (on which Jaccoud lays so much stress), yet the atmosphere and soil are both very dry, and the bracing quality of the air is a marked feature.

From the results which Dr. Geddings has noticed, and from the experience of a few patients with whose histories I am acquainted, I find myself questioning as to how far the element of altitude *per se* is necessary, and whether other regions resembling the position and climate of Aiken are not to be found, where equally favorable results can be expected. In this connection, moreover, the facts spoken of by several authorities must not be lost sight of, viz., that in certain countries of decidedly low altitude there seems to be an entire immunity from phthisis; for instance, the Kirgheez, in Asiatic Russia, who live on vast steppes, one hundred feet below the sea-level, and the inhabitants of the Faroe Islands and of Iceland, living at a very slight elevation, and under the most unfavorable hygienic conditions, are nearly, if not entirely, free from the disease. So far as I know, these countries have never been used as health resorts for phthisical patients, but probably the depressing effects of living in such communities would far outweigh any possible benefit.

As to the attribute of temperature, or, in other words, *coolness* or *coldness*, as opposed to *warmth*, in the climatic treatment of phthisis, there can be little doubt that, in the majority of cases of incipient disease, the former has the more favorable effect. The good effects of a low temperature lie chiefly in its bracing quality, its tendency to cause dryness of the atmosphere, and its unfavorable influence on the growth of the bacillus outside the human body, a fact which, to those who believe in the theories of Koch, is of marked importance. (The contrary is true of warm, moist, relaxing climates.) The importance of clearness and purity of the atmosphere, with the presence of sunshine, is so self-evident that one need scarcely discuss it. The effect of the lack of these elements upon healthy human beings is sufficient proof of the necessity of their presence in the treatment of disease, more especially in phthisis.

In connection with the comparative importance of different climatic attributes, a word must be said as to the difference between seashore and inland climates. Of necessity, no general law can be laid down on this point, but the weight of opinion may be said to be distinctly in favor of dry, inland climates for the treatment of incipient phthisis. The shores of the Mediterranean are famous as health resorts for consumptives, and although, in the opinion of Jaccoud and Hermann Weber, they are inferior to the inland and mountainous climates, yet a residence in that region is doubtless of great benefit to many; the dryness of the atmosphere, and a large percentage of sunshine being two most noticeable features of the climate.

Opposed to the idea of preference being given to inland climates, is the fact that most of the health resorts for consumptives in England are situated near the sea, where the climate is decidedly moist, and soft. As to the results in the cure of phthisis in these places, compared with those in mountainous regions, I am unable to make any statement, but the preference shown by English physicians, in sending their patients to such dry, mountainous regions as Davos, in Switzerland, speaks strongly in favor of the latter resorts.

Speaking for New England, it can be said that, while exceptional cases may do well, the moist, harsh climate of our northern coast is distinctly bad for consumptives, and it is my custom, as it has been my father's for years before me, to advise removal from the coast, if only to retreat to some comparatively dry region eight or ten miles inland, where the rigor of our harsh, damp winds may be avoided. Very different are the effects of a sea voyage or its equivalent, residence upon an island several miles from the shore. The reason of this difference is not satisfactorily explained, but doubtless the purity of atmosphere, and absolute freedom from dust, have much to do with it. As a cure for phthisis, however, either method may be said to hold a decidedly secondary position.

By comparing these facts again, we find strong evidence in favor of the attribute of atmospheric dryness in the treatment of phthisis.

To state briefly my present views: I believe that properly selected altitudes possess a combination of climatic attributes which, according to our present knowledge, form the best means of cure for cases of incipient phthisis in which there are no symptoms that would contraindicate residence at a great height —*e. g.*, cardiac weakness, excitability of temperament, marked feverishness, or a pronounced emphysematous condition, all of which symptoms are, according to the authorities mentioned, apt to be unfavorably affected by altitude.

At the same time, I believe we have much to learn as to the possibilities of cure in less elevated regions, like Aiken, South Carolina, where the quality of dryness is present with a bracing atmosphere.

Still further, we have a great field before us in the investigation of the effect of residence in comparatively favorable regions near our homes, where, by the establishment of sanitariums, we can combine climatic, hygienic, and medical treatment in such a manner that exile from home and family may not be thought, in the future, of such paramount necessity.

In accordance with my father's and my own custom of recommending, in certain cases, a residence in towns favorably situated within a few miles of Boston, I have, for some time, felt that much more could be accomplished by the establishment of sanitariums for phthisical patients in these regions. I determined to make the attempt to get some suitable institutions for those who cannot afford to go far away from home, in Sharon, Mass., a town situated between 300 and 400 feet above sea-level, about eighteen miles southwest of Boston. The soil is of a very porous nature, the atmosphere of a markedly dry, bracing character, pine forests abound, and a line of hills, moreover, shelter the town from our harshest winds. Through the generosity of one interested in the scheme, a farm favorably situated has been bought, and, relying upon the assistance of wealthy citizens of Boston, I hope, with the assistance of Dr. R. W. Lovett, to show, at some future time, that much can be accomplished in this way.

I was much pleased to find that Dr. Kretzschmar, of Brooklyn, several months ago, had called the attention of the profession in America to the gratifying results of Dettweiler, in his sanatorium at Falkenstein, in Germany; of Brehmer, at Görbersdorf, in Silesia; and other now well-known establishments, situated in not especially salubrious climates. The experience of these physicians in Europe, as well as that of Dr. Trudeau, in the Adirondacks, should give us reason to hope that, by means of similar establishments near our homes, even at a comparatively slight elevation above the sea, we can do a great deal toward arresting the present death-rate from pulmonary consumption.

I cannot conclude better than by quoting Hermann Weber, who, in the fourth division of his exhaustive work on climatology, says: "By erecting well-arranged establishments, under medical supervision, in well-situated places near at hand, a great many of the advantages of more distant climatic health resorts may be gained."

DERMATITIS TUBEROSA DUE TO INGESTION OF THE IODINE COMPOUNDS.[1]

By JAMES NEVINS HYDE, M.D.,
OF CHICAGO, ILLINOIS

A distinguished writer in medicine has recently declared that the reactive effects of the introduction of poisons into the human economy are sometimes presented with features that surprise the most skilful of physicians and are capable of leading to the gravest errors in diagnosis and therapeutics. In the confident belief that this statement furnishes the key to some of the most singular of the anomalies presented to the student of cutaneous medicine, I venture to make a third clinical contribution to the study of the eruptive lesions, pseudo-pemphigoid in type, induced by the ingestion more particularly of the iodide of potassium.

Case I.—On the 1st of March, 1888, I was summoned to one of the Chicago hospitals for the purpose of establishing the nature of a disease with which one of its inmates was affected. The patient, A. C., a girl eighteen years of age, was reported to be suffering from leprosy. She was found occupying one of the most secluded rooms in the building, cut off from contact with all outside save the physicians and the Sister in attendance. She gave the following history:

She was a native of Illinois. Her father had died in the twenty-ninth year of his life of typhoid fever; her mother, at thirty-eight, of some unknown acute disorder, who had, however, before her death contracted a second marriage which resulted in the birth of several children, some living and healthy; others dead in infancy of unknown disorders. Both of these parents had been previously healthy. The patient had never menstruated. She gave a history of vague sensations which she had experienced from time to time about the period of her twelfth year, which may have been more or less associated with a menstrual molimen. One day, in her fourteenth year, she was walking on a railroad track, when, by accident, she stumbled and fell. The whole weight of her body was thrown upon the right elbow which struck upon a steel rail. As the result of this, the joint became first acutely inflamed, and later persistently painful, hot, tender, and enormously swollen. During the next three years a series of recurring abscesses formed about this joint, some of which burst spontaneously, and some of which were opened by a surgeon. Each in the course of a few weeks would heal and be followed in a series of months, varying from two to six, by the occurrence of another abscess, which pursued the same general course, leaving the joint finally swollen and immovable. She had never suffered from any pilary loss, cutaneous affection, soreness of the mouth or tongue, or any other symptom of disorder. Her general health, apart from the accident and its complications mentioned, had been excellent. In January of the present year a final ulcer formed over the affected elbow-joint. She was in consequence brought to the hospital on the 2d of February, 1888, one month before the date of observation. She was then in the following condition:

She was a well-nourished and intelligent girl, presenting the childish appearance common at her age in young women who have never menstruated. She had no febrile symptoms. The eyes and teeth were normal and her senses unimpaired. The right elbow-

[1] Read before the American Dermatological Association, at the First Congress of American Physicians and Surgeons, Washington, September, 1888.

joint was symmetrically and extensively swollen, tender and painful, the arthritis which had resulted from her accident having left the joint in a state of pseudo-ankylosis, the forearm being flexed upon the upper arm midway between pronation and supination at an angle of forty-five degrees. Through a fistulous orifice on the outer face of the joint, a slender spiculum of bone projected, several millimetres in length. There was a faint, irregular scar on the outer face of the right foot which she said had resulted from a small abscess at that spot. There were no other scars upon the surface of the body. Her skin generally was smooth, soft, and entirely free from any cutaneous exanthem.

She was then ordered to take three times in the day, teaspoonful doses of a solution, each ounce of which contained one grain of iodine and one drachm of the iodide of potassium. On the third day after this medication was begun, a number of semi-solid papules appeared on the forehead; and two or three on the dorsum of the hands. There was a moderate coryza which led her to think she had "caught cold." By evening of the same day, the entire scalp and forehead were covered with smaller and larger lesions of the same general character, rapidly increasing in size. On the next morning her hair was cut short on the scalp and a poultice applied. The papules rapidly became large, softish tubercles, covering the scalp and face, closing the eyes, encroaching on the neck, in front and behind, and including the intra-scapular region, as well as the forearms and the hands.

Through the entire month of February the same internal medication was pursued, with constant aggravation of the cutaneous disorder, until my visit on the 1st of March. At this time the appearance of the patient was in the highest degree repulsive. The scalp, from which a cloth was removed spread with a salve, was completely covered with closely packed, pigeon's-egg-sized tubercles, the matted hairs projecting through and between them, all smeared with a puriform mucus, mixed with the fatty basis of the salve. The forehead, temples, cheeks, neck, and back were generally and symmetrically covered with superficially seated, small egg-sized, semi-solid, discrete and confluent, oval, roundish, and irregularly shaped tubercles, of a dull reddish hue, some standing out to the extent of several millimetres prominently from the general surface. Their summit was usually flattish, occasionally fissured and macerated with a mucoid secretion. Many strongly resembled large sized, secreting condylomata. A few presented the appearance of containing boiled sago grains. None were true bullæ, and none when punctured extruded their contents. Some were reported by the nurse as having furnished a profuse, greenish-yellow discharge before they had been cleansed. The forehead, especially the upper portion, was extensively and symmetrically invaded by these rapidly developing nodules, which were closely packed together; the brows and eyelids, particularly upon the right side, were so burdened with the same as to render it difficult to open the eyes. Some had the appearance of an irregular furrow filled with muco-pus at the summit, the general line of this furrow corresponding to the axis of the long, oval-shaped lesion, resembling the sausage-like tumors of mycosis fungoides.

It was almost impossible in the case of the larger of these lesions, so great was their size, to distinguish the individual elements of which they were composed. Some were so marked by lobules and fissures as to suggest that they were compounded of large bean-sized lumps. When incised, pus, blood, serum, and an inspissated, grumous fluid could be expressed from the wound, but the lesions were in no sense chambered. They were evidently masses of softish, vascularized epithelium, secreting superficially a thick, grumous, mucoid fluid, in places commingled with pus. There was little or no subjective sensation produced. The skin of the anterior thorax was scantily invaded. There were two large compound nodules on the flexor aspect of the right forearm; two also on the left hand; one on the dorsal surface of the web between the first and second metacarpal bones, of the size of a fifty-cent piece; another, small coin-sized, on the dorsum of the left index-finger between the distal and middle phalanges. Elsewhere there were no lesions upon the surface of the body. Iodine was detected chemically in the urine.

One of the conspicuous features of this case was the evident failure of correspondence between the eruptive symptoms and the general condition. The patient appeared to be neither weak in body, dejected in mind, nor stricken with any grave malady. She sat up in bed, gave full and intelligent details of her history, laughed heartily over the appearance she presented, and, on the whole, rather made light of her troubles. The remedies she was then taking were ordered discontinued, and she was given merely a ferruginous tonic. The result was a prompt and rapid disappearance of the exanthem. So rapid, indeed, was the subsequent process of involution that even though but two days elapsed before a portrait of the patient's face in oil could be made, a decided subsidence of the tumefaction occurred, and the color of the lesions became markedly less vivid.

The eruption, as it subsided, left distinctly circumscribed, dull red infiltrations, in patches covered with light and dark crusts superimposed upon the secreting surface. Here and there a slight and superficial atrophy of the skin in patches resulted. Two superficial ulcers formed on the back, doubtless as the result of the unavoidable pressure in a recumbent position. At no time were there evidences of general ill health. When the spiculum of bone was removed from the fistulous orifice in the neighborhood of the right elbow-joint, the parts healed without difficulty. In the site of a few of the larger lesions there was a distinct superficial cicatrization. The most characteristic of these scars was seen on the dorsum of the left hand. Here was one as large as a fifty-cent piece, circular in outline, and very slightly raised above the general level of the skin.

In two months after the discontinuance of the iodide, there were no skin lesions visible, beyond the pigmentation of the slightly infiltrated skin in the situation of the previous exanthem. In two

weeks more the drug was again administered in precisely the same dose as before. The eruption again promptly appeared over the scalp and forehead. Unfortunately, the surgeon, under whose direction this test was, at my suggestion, made, left the city soon after ordering the readministration of the remedy, and, as a consequence, more than a week elapsed before the medication could be stopped a second time. During this interval a serious and disfiguring second crop of molluscoid lesions appeared over the forehead, which happened to be neglected in the hot month of midsummer, and, as they secreted mucus very freely, they brought the patient into a condition which was almost as serious as that which had preceded, and which might certainly have been avoided. After this she returned to her country home, with the relapsing tubercles rapidly shrinking in consequence of a final suspension of the drug.

Case II.—H. E., a native of Iowa, a male infant, seven months old, was brought by its parents for examination, on June 2, 1887. They were both healthy-looking, and had had one other child that died in the third month, of some bowel affection. They reported that H. E. had always been a healthy-looking baby, and well nourished since its birth. It took the breast without difficulty. Its digestion was unimpaired, and its nutrition had always been good. At about the seventh week of life, a crust had appeared over the vertex of the scalp, which had been treated by a local physician, who prescribed for it a salve for external application, and a fluid remedy to be used internally. Since that date the present disease had gradually increased, and extended until the condition now noticed was reached. When examined, the child was seen to be well nourished, and to present the following appearance:

The scalp, face, ears, neck, and forearms were the seat of an almost confluent eruption, masking the entire surface involved. This had occluded the external auditory meatus of each ear, completely closed each eye, and rendered the separation of the lids difficult. This eruption was made up of closely packed, confluent, softish, and semi-solid tubercles, of a deep, mahogany-red hue, dry and moist in different parts, of about the size of a large pea. They were roundish or oval in shape, compressed by juxtaposition, or quite commonly flattened at the apex, often presenting there a depression similar to an umbilication, in places smeared with mucus. Some of these lesions suggested in appearance that they had boiled sago-grain contents; in others, far more numerous, there were simply closely packed, flat-topped, deep-red tubercles of the sort already described, looking very much like mollusca with semi-solid contents. They were not interspersed with pustules or bullæ, and bore no signs of traumatism. There were a few softish crusts upon some, composed chiefly of the inspissated smegma collected over the moister lesions. Their thickness added to that of the skin of the part affected, gave the head of the child the appearance of an enormous tumefaction. The neck, in front and behind, was extensively and similarly affected. The skin of the chest was relatively free. The skin of the forearms was covered with isolated lesions of similar character, rarely grouped. The upper arm was free. There were a few lesions of the same sort on the palms of the hands; none elsewhere. The color of this eruption was peculiar. It has been described above as of a dark mahogany hue; it was more empurpled than a deeply congested patch of eczema, and suggested somewhat the very dark color of the lesions in so-called "black measles" (hemorrhagic variola). A significant feature of this case was that noticed in the description which precedes, namely, the toleration of the exanthem by the skin. The child, though frightfully disfigured and unable to open its eyes, lay composed in its mother's lap, its stomach well distended with breast milk, and its chubby limbs resting quietly as it slept. When awake, it uttered no cries, and made no effort to rub or scratch the skin. It was well nourished, took the breast regularly, and slept contentedly in the intervals.

It was afterward learned that this infant had, since the beginning of its treatment, been taking the iodide of potassium in one-grain doses. The remedy had been steadily pushed from the beginning up to the time of this observation.

The eruption began to subside immediately upon the discontinuance of the drug. In three weeks the parents wrote that the child was still enjoying uninterrupted health, and, with the single exception of a small abscess which had burst back of the ear (undoubtedly due to the extensive irritation of the scalp), there had been no interruption in the general improvement. There was a final report that the child was perfectly well, nothing remaining but the pigmentation of the skin where the lesions had existed.

In this case no attempt was made either to reproduce the exanthem by the administration of the drug, or to examine the urine.

In the years 1879 and 1888, respectively, I read before this Association brief papers relative to the bullous eruption induced by ingestion of the iodine compounds. In these contributions attention was called to the literature of the subject as it then existed, which has since been enriched, it may be noted in passing, by the valuable and interesting work of our colleague, Dr. P. A. Morrow, and also by the appearance of the exhaustive monograph on "Iodism," by Dr. Elizabeth M. Bradley, of the faculty of Paris, a work which seems to have resulted from some of the suggestions of Fournier. Papers by Hallopeau, Hardy, and others, have also appeared, and contributed interest to the study of the same general subject. In the last of my two papers an attempt was made to establish a distinction between: (*a*) Cases in which a purely bullous exanthem, produced by ingestion of the iodides, was to be seen in persons of adult or advanced years, cachectic, syphilitic, adynamic, and often moribund at the moment of development of the lesion; (*b*) cases in which a degree of polymorphism was apparent, purely bullous lesions being then commingled with those of

different type; (*c*) cases occurring only in infants, children, and young adults, neither cachectic, syphilitic, nor moribund, oftener eczematous, but otherwise healthy, in which semi-solid, slightly umbilicated lesions resulted from ingestion of the iodine compounds, these lesions resembling condylomata or mollusca, and not conforming to the strictly bullous type.

The two cases reported briefly above, three of those contributed by myself in the papers just cited, and two cases reported respectively by the late Dr. Tilbury Fox and Dr. T. C. Fox, of London, all appear to belong to the last named class. I need not repeat a third time that the late Dr. Tilbury Fox is to be credited with first indicating the special character of this eruption in his use of the terms condylomata and mollusca as descriptive phrases for the designation of these odd-looking lesions. It is, however, proper once more to call attention to the fact, further emphasized by these two additional cases, that the lesions are not strictly bullous, are not chambered, are semi-solid in character, and often furnish a grumous secretion, as does the condyloma, from the flattened surface and flattened grooves of their apices. The lesions, characteristic in site, in appearance, and as to the subjects in whom they are displayed, somewhat resembled those described by Besnier as iodo-potassic anthracoid acne, and also those described by Drs. Duhring and Da Costa, of Philadelphia. They cannot be, however, recognized as strictly identical with those more lately described by Hallopeau as vegetative, and resulting in cicatricial lesions. The patient whose case Hallopeau studied was a feeble, poorly developed man, forty-eight years old, and syphilitic — conditions which seem incompatible with the production of the peculiar lesions described by Fox and myself. Nevertheless, the peculiar cicatrices first described by Hallopeau and recognized also by me in one of the cases above described, seem to be in this connection of special interest. The cicatrices in Hallopeau's case were isolated and depressed, their centre occasionally covered with crusts and vegetations. They were roundish in outline and varied in their size from a split pea to a small coin. A few were somewhat elevated above the surface. On the dorsum of the right hand of his patient was a violaceous cicatricial plaque, two centimetres in diameter, limited by an elevated border. Setting aside for the moment the suspicion that attaches to every such cicatrix in a patient confessedly syphilitic, it must be freely admitted that the description above given applies very exactly to one of the scars which were seen as a result of the exanthem in the first of my two patients. Here a number of delicate polycyclical lines, at the border of a few facial lesions, when examined with great care, seemed to be cicatricial in character, but the then quite recent disappearance of the extensive exanthem on the swollen face led to the suspicion that these cicatrices might later disappear, or be well nigh smoothed to imperceptibility in time. Such, however, was not the case with the distinct scar on the dorsum of the left hand. It was an unmistakable cutaneous cicatrix, of exactly the sort described by Hallopeau in the language given above, and resulted from a lesion induced by the ingestion of a drug.

Dr. Elizabeth Bradley, when her interesting monograph upon this subject was written, seems not to have seen the second of my two papers on this subject, though she carefully collates the facts contained in the first. Celso Pellizari's case exhibited lesions which were subcutaneous in situation, were accompanied by fever, and followed by abscesses. Morrow's remarkable case was that of a moribund patient, presenting strictly bullous lesions belonging to one of the other classes described above.

I have made this contribution to the general subject chiefly because of the interest which seems to me to attach to the first of the two cases here reported, the patient whose face was selected for illustration. The subject of the disease was neither syphilitic nor cachectic. She was suffering from a chronic arthritis, traumatic in origin, which had possibly resulted in localized tuberculosis of the joint affected. Her general condition was excellent; her skin was, and always had been, entirely free from any cutaneous eruption at the time when she first ingested the offending drug. There was no underlying diathesis to modify or induce an eruption. Here, too, was the soft and susceptible skin of a child, the fact of her arriving at what is usually the puberal epoch of her sex being offset by the failure to menstruate as already indicated. This is the first opportunity I have had of studying these condyloma-form lesions under anything like such favorable conditions. Enough is now known of this special form of medicamentous dermatitis to warrant the following conclusions:

First. When the iodine compounds, irrespective of the size of the dose, have been administered to well-nourished infants, children, and persons whose skins are in the condition usually found at these ages, a quasi-bullous rash may gradually appear, whose elements differ from the blebs which occasionally form when the drug has been administered to older persons, syphilitic, cachectic, or in grave conditions of prostration.

Second. The interest attaching to the recognition of the nature of the eruption is partly due to the fact that in the class named it may be superimposed upon an eczematous or seborrhœic condition, for which the iodide has been administered.

Third. The regions invaded are almost exclusively

the scalp, face, neck, upper chest, forearm, and hand.

Fourth. The subjective sensations experienced when the lesions are copiously developed are comparatively insignificant, and the disproportion between the disfigurement produced by the enormous cutaneous nodules and the generally fair condition of the patient is often of the highest diagnostic significance. The lesions are, strictly speaking, neither vesicles, bullæ, pustules, carbuncles, abscesses, nor papules. They are softish, semi-solid, roundish, oval or irregularly shaped tubercles, resembling mollusca and condylomata, flattened or umbilicated, or seamed and furrowed at the summit. They may be isolated and bean-sized, or agglomerated in patches as large as the palm. Whether they have grumous or sago-grain-like contents, or are filled with blood or serum, they secrete, like condylomata, over the free surface, and when covered with light-colored mucoid crusts these are usually furnished by the desiccation of the secretion named, and not by exudation and subsequent drying of the contents of the lesion. In color they are light reddish, dull purplish-red, or violaceous, and are usually well projected from the surface of the skin, being rarely subcutaneous in situation.

Fifth. Involution commonly progresses rapidly after the suspension of the drug, and is very rarely followed by circular, oval, faintly defined, and irregular cicatriform patches, in which the skin is left in an atrophic condition, not distorted or puckered.

These scar-like patches have thus far been studied only in the recent condition; and their condition and appearance after any prolonged period of time cannot now be determined.

CASES OF TETANY, HYSTERICAL CONTRACTION, AND REFLEX CONTRACTION; ILLUSTRATING VARIETIES OF CHRONIC FUNCTIONAL TONIC SPASM.

BY HENRY HUN, M.D.,
PROFESSOR OF DISEASES OF THE NERVOUS SYSTEM AND OF PSYCHOLOGICAL MEDICINE IN THE ALBANY MEDICAL COLLEGE.

CASES of tetany in the adult, although they are not very commonly met with, yet present themselves in a great variety of forms, both in regard to the number and distribution of the muscles involved and in the duration of the contraction. The following case is remarkable in that the muscular spasm was so continuous (lasting many months) and involved the muscles of the body so generally:

CASE I.—M. H., twenty-six years of age, single, a seamstress, entered St. Peter's Hospital July 8, 1887. She had always been healthy till the first part of September, 1886, when, while menstruating, she was holding horses in the rain, and in trying to shelter a little girl, who was with her in the wagon, she, herself, became thoroughly drenched with rain. Almost immediately after this exposure her right hand felt stiff. This abnormal feeling in her hand continued, and two weeks later the muscles of the calf of the legs became cramped and hard, continuing so for about half an hour, during which time she was unable to stand. The next day the spasms returned, and, subsequently, they recurred more and more frequently and attacked the arms also, and, finally, involved all the muscles of the body. These spasms have, from the first, presented an intermittent character, but during the past six or eight months, even in the intervals of the spasms, the muscles do not completely relax but continue stiff. At times, especially when in bed in the morning, she thinks that she is perfectly well, but very soon the rigidity comes on. The acute attacks of spasm are usually confined to her arms and legs, but on several occasions the muscles of respiration have been slightly involved. She has no pain in any part of her body, although the acute attacks of spasm are somewhat painful. She always feels very hot, and even in the coldest weather likes to sit without any extra clothing by an open window.

The patient seems to be weak-minded and childish, but does not appear to be hysterical. At all times, even when asleep, all the muscles, except those of the face, are in a condition of tonic spasm, so that each one feels hard and the outline of each is sharply defined, as though faradized by a strong current. This is true not only of the muscles of the arms and legs but also of the cervical, thoracic, abdominal, and dorsal muscles. The muscles offer considerable resistance to passive extension, but the patient can use her limbs slowly; she walks on tip-toe, the feet are firmly held in the position of talipes equinus, and the hands are firmly held in a position half "clawed" and

half "obstetric" and at times are held rigidly so by an acute attack of spasm. Such spasms can be induced by firm and constant pressure applied just below the axilla over the course of the vessels and nerves, and when such pressure is applied, the patient first complains that her hand is cold and then the spasm comes on. Pressure on the ulnar nerve behind the elbow does not produce the spasm. The facial nerve does not show any exaggerated irritability to mechanical excitation. The superficial and deep reflexes seem to be normal, but the constant spasm interferes with their full development, and the same spasm prevents any satisfactory electrical examination. Absolutely no disturbance of tactile, painful, or thermic sensibility can be detected. No ovarian or spinal tenderness.

The patient remained in the hospital until March 24, 1888. Once she was etherized, which caused a complete relaxation of the muscular contraction, and, when in this condition, her joints were moved freely in all directions. The attacks of acute spasm became less and less frequent, and, finally, ceased entirely, but the tonic contraction continued unchanged. She continued to act in a childish manner and had one or two brief attacks of insanity. Hot baths seemed to produce some relaxation of the muscular contraction at first, but she obtained most relief by being in a very cold room and having but little clothing. Tonics, bromide of potassium, hyoscyamine and other remedies which were tried produced no good effect.

Remarks.—Notwithstanding the fact that in the medical literature to which I have access I have not found any description of a case of tetany in which the muscular spasm continued persistently for weeks and months, yet this case, it seems to me, must be regarded as a case of tetany. In the early part of its course it presented the intermittent form of symmetrically distributed spasm so typical of tetany, and, although later, the muscular contractions became continuous, and during the nine months that the patient was under observation, in the hospital, all her muscles, except those of the face, were so strongly contracted that the contour of every superficial muscle stood out as plainly as in an anatomical dissection, yet even while the muscles were thus continuously contracted, spasms of even more severe and painful muscular contractions occurred at long intervals, and could be at any time induced in the arms by pressure on the nerves and vessels together, but not by pressure on the ulnar nerve alone, and the facial nerve did not show that increased excitability to mechanical irritation which it usually shows in cases of tetany.

The feeling of heat from which the patient constantly suffered, and on account of which she always wished to be in a very cold room, might well be the result of the widespread, strong and constant muscular contraction; and yet, in spite of this constant, excessive muscular contraction, the patient still retained voluntary power over her muscles, and was able to execute a great variety of movements, albeit slowly and with difficulty. This fact, that the patient retained the power of voluntary motion indicates that the lesion or functional disturbance involved the gray matter of the subcortical centres rather than that of the cerebral cortex. The spasm, indeed, was not unlike that which might result reflexly in consequence of some powerful irritation; but no such irritation could be found, and the administration of anthelmintics resulted in no evidence of the presence of intestinal parasites.

If the diagnosis of tetany is correct, the case seems to be one of rheumatic tetany, inasmuch as a severe exposure to rain was the apparent cause of the disease. Usually cases of tetany are easily amenable to treatment, but this case showed no improvement during the time that the patient was in the hospital. The case might, perhaps, be regarded as one of hysterical contraction; and, I think, that it may be instructive to compare it with a case of hysterical contracture which was almost as widespread and was of even longer duration.

Case II.—B. B., twenty-five years of age, single, entered St. Peter's Hospital April 27, 1886. Patient's family history good. Eight years ago she had an attack which was pronounced hip disease, and was under treatment for one year and a half. She recovered quite suddenly and was able to walk with some difficulty. About two years ago she was attacked by a pain in her hip which seemed to draw her knees up, and when she attempted to walk she could only do so on her toes. It was pronounced curvature of the spine by the physician and a plaster jacket was applied, but afforded no relief. Attempts were made to straighten her legs by placing a padded board heavily weighted across her knees. About two months after the removal of the jacket she had a severe pain in her back, which extended up the spine to the base of the skull. Blisters were applied which afforded some relief, and she was able to sit up and move about the room. Since then she has had five similar attacks, and has been bed-ridden. About one year from date of the first attack she began having spasms at short intervals and was unable to take any medicine. The date of the last spasm was about four months ago. Patient complains of loss of sleep and appetite, and also that if she tries to swallow liquid of any kind it runs from her mouth before she can swallow it. During the past two weeks she has taken no food of any sort, as far as can be ascertained. She takes milk in her mouth but seems unable to swallow it. Bowels are constipated. Takes cracked ice freely. Lies in a fixed position and cannot make any movement except with her arms, and they act only imperfectly.

Her legs and thighs are flexed so that the heels almost touch the buttocks. The outlines of the muscles are not visible, and the muscles do not feel hard and contracted unless an effort is made to extend them. By steady traction the legs can be extended, but it is difficult to extend the thighs on the body. The arms are not held in any fixed position, but the head is drawn so far to the right that it almost touches the right shoulder. A couple of days ago there was no particular anæsthesia of the hands or arms, but there was of the legs. To-day there is almost complete anæsthesia and analgesia of both the arms and the legs. When the legs are extended they become flexed again very gradually; and when her attention is diverted they remain extended for some time. Abdomen is much retracted. There is no ovarian tenderness on either side. Extremities cold. Pulse small and rapid.

A few drops of a four per cent. solution of cocaine were dropped into her mouth, after which with some difficulty she managed to swallow a pint of milk. After that she took milk freely, each cupful being preceded by a few drops of the cocaine solution, and a week later she began to take solid food and the cocaine was stopped. At this time she had incontinence of urine and feces and was almost constantly soiled. Her legs, which were completely anæsthetic and analgesic, were straightened by passive motion several times daily, each time causing much pain in her back.

In the middle of May, her general condition having improved somewhat, the daily application of electricity to her legs was commenced, the faradic current being used because it was found to produce a more decided effect on the muscles than the galvanic current. In less than a week the electricity had produced great improvement, sensibility in all its forms had returned completely in the legs, she was herself able to extend her legs almost completely, and the incontinence of urine and feces ceased. She was able to sit up in a rocking chair, but her head continued to be strongly drawn to the right, and she insisted that one leg was shorter than the other, although the apparent shortening was evidently due to a drawing up of the pelvis on that side. The electricity was now applied exclusively to the neck and hip, and at the same time she was confidently assured that the electricity would lengthen her leg; with the result that three days later she could move her head freely in all directions, and the legs were apparently and actually of the same length. By the end of May she was able to walk about without assistance, and on June 6th she was discharged well.

July, 1888. I have seen the patient at intervals during the past two years and she has continued perfectly well.

Remarks.—In this case the spasm, though widespread, was not nearly so general as in the case of tetany; the muscles of the arms and body not being affected and the muscles of the neck being contracted on one side only, such unilateral spasm being common in hysteria and never occurring in tetany. The character of the muscular contraction was altogether different in the two cases; in the case of tetany the muscles were hard and clearly defined and evidently at all times firmly contracted, while in the case of hysteria the muscles felt soft and were apparently scarcely contracted at all unless an effort was made to extend them. The contraction seemed rather to be a voluntary one, which was only made when it was necessary in order to keep her limbs in the fixed position. In the case of tetany, notwithstanding the muscular spasm, the patient was able to move her limbs, although slowly and with difficulty; while in the case of hysteria, as is usual in such cases, with the spasm was combined an apparent muscular paralysis. In the second case there was a history of previous attacks of various kinds with sudden recoveries, and there were also disturbances in sensibility and in the organic reflexes which disappeared with great rapidity under treatment.

Very characteristic, furthermore, was the deportment of the two women. In the case of tetany the patient was a naturally acting woman, although of weak intellect; but in this last case, as well as in the case of the boy presently to be described, there was a certain attempt to produce a theatrical effect which is hard to describe but is easily recognized. The whole attitude of the patients seemed to demand sympathy, and at the same time it was evident that they were watching most intently every action of the physician and attendants.

One of the fixed ideas which the hysterical patient cherished the longest, was that one of her legs was shorter than the other, and it required a very decided assurance that the shortening would disappear under the use of strong electric currents, before she abandoned that idea. Such localized muscular spasms are common in hysterical subjects and not infrequently give rise to errors in diagnosis, and such spasms also occur in persons with irritable nervous systems, apparently as the result of some peripheral irritation, in which case they have been called reflex spasms. The following case may serve as an illustration of errors of diagnosis from such reflex spasm.

Case III.—W. W., twelve years of age. He states that he has never been sick, except that, in the spring of 1882, a lump suddenly appeared in the left lumbar region, persisted for about a week, and then disappeared just previous to the arrival of a surgeon who had been sent for to examine it. In the fall of the same year it was noticed that he limped badly. A surgeon of considerable prominence examined the

leg and thought that the left leg was decidedly shorter than the right, that the left trochanter major was above the line connecting the anterior superior spinous process of the ileum with the tuberosity of the ischium and that the left hip was dislocated. He accordingly gave the boy ether, and while manipulating and moving the thigh before he attempted to reduce it, the "dislocation," to his surprise, was suddenly reduced. A few days later, without any fall or accident, the same condition of things returned, and the boy was again etherized and the "dislocation" was again easily reduced. Ten days later, the boy went to bed as well as ever, and in the morning his hip was again "dislocated."

On that morning I examined the boy for the first time. He was lying in bed without pain and could move himself about easily. The left leg was held stiffly extended and was apparently two inches shorter than the right. On actual measurement, however, the legs were found to be of equal length, and the apparent shortening was due to a drawing up of the pelvis on the left side. All the muscles about the left hip-joint were hard and evidently firmly contracted, and just above the trochanter major was a bunch of contracted muscle which bore some resemblance to the trochanter major itself and might have been mistaken for it. The hip-joint was held stiffly by the muscular contraction and resisted passive motion. The right tibialis anticus muscle was also in a condition of chronic spasm. No anæsthesia. Long prepuce, which could not be retracted. The boy remained in the same condition for thirty-six hours, when the surgeon, whom I had not seen, came and reduced the "dislocation" under ether; "the bones going into place," he said, "with a sharp click."

A month later, without any known cause, the same symptoms again appeared. At that time I saw the boy with the surgeon, and we agreed that it was simply a case of muscular spasm, and, on giving the boy ether, without any manipulation whatever the hip returned to its normal condition. A month later the boy was circumcised, an adherence of the prepuce being found at a point close to the corona. The boy remained under observation for some time after the operation, but there was no return of the spasm, and I heard from him some two years later, and learned that there had been no return of the spasm in that time.

REMARKS.—It is doubtless true that the influence of an adherent prepuce in producing nervous disturbances reflexly has been greatly exaggerated; and, in such a case as the one just described, it is very difficult to say whether the boy suffered from an hysterical or a reflex contraction. After he had been given ether for the last time, he was made to understand very plainly that the doctors understood his case and that he would not be able to deceive them again, and the moral effect of this might have had quite as much to do with preventing further attacks as had the circumcision; and, certainly, after the last etherization there was no return of the spasm during the month which elapsed before he was circumcised. There are, however, many cases of spasmodic and convulsive attacks in "nervous" children, which are relieved by removing or freeing an adherent prepuce, and in which the cure can hardly be explained by any moral effect of the operation, but seems to be due to the removal of the irritation.

The three cases described above all probably depend upon some alteration in the central nervous organs; but the alteration, if it exists, has not, as yet, been detected, and they must be considered as examples of functional spasm. Organic diseases of the motor tract in the central nervous organs may give rise to continuous tonic spasms, which are usually confined to one limb or to one side of the body; and tonic spasms of a transitory character occur in the "occupation neuroses" and in other forms of nervous disease; but it is probable that all forms of chronic functional tonic spasm are varieties either of tetany or of hysterical contraction, or of reflex contraction.

MEDICAL PROGRESS.

The Treatment of Syphilis by Inunction.—FOURNIER, of Paris (*Rev. Gén. de Clinique et Thérapeut.*), in a clinical lecture, dwells upon the treatment of syphilis by inunction. The patient is first placed under a tonic regime; laxatives are not prescribed; the patient eats as much meat as he pleases; he takes walks—in fact, he is advised to spend much time in the open air; hydrotherapy and sea baths are ordered. Among ointments for inunction, that of the bichloride of mercury and the ordinary blue ointment are to be preferred. Recently, soaps, composed of equal parts of mercury and soap, have been proposed. The disadvantages of these are, that the inunction requires too much time. The dose of the ointment (unguent. hydrarg.) at first is a drachm; in the course of time it can be increased to a drachm and a half and two drachms. In the case of women and children, in view of the lesser tolerance, correspondingly smaller doses must be used. With children, thirty-five grains should not be exceeded. This dose is sometimes indispensable, but it should be remembered that fifteen to thirty grains may be given to infants only a few days old, without harm. In cases of severe syphilis, syphilis of the brain, and during a course of treatment with sulphur baths, in adults, the dose mentioned may be exceeded. Every application should be made with a definite quantity of ointment—for instance, seven drachms of mercurial ointment are ordered for one week, in seven equal parts. As a rule, the inunction should be performed but once a day, preferably before retiring for the night. The lecturer applies the friction to the side of the chest. This offers a large extent of surface, and the patient himself may undertake the application.

Two precautions are to be observed: 1. The ointment should not be rubbed into the scrotum, the groin, the pubes, and the axilla, because of too ready absorption. 2. To avoid irritation of the skin, the site of application should be varied, alternating the left and right sides of the chest, the inner surfaces of the arms and thighs. The friction is continued fifteen minutes for a drachm of the ointment, thirty minutes for a drachm and a half or two drachms. The application must not be a mere anointing, but the skin must actually be rubbed, but not with great energy. The parts treated are covered with cotton, linen, or flannel; if the chest, held in place by a binder; if the arm, by a shirt sleeve, etc. The ointment remains upon the affected part throughout the night, and is removed in the morning with soap and water. Twice a week a thorough bath is enjoined. Nothing definite can be stated relative to the number of applications. If the patient can be kept under observation, the treatment should be continued for from two to four months. It is agreed that it should not be too long continued, because, after a certain time, the mercury is no longer tolerated by the system. If the treatment becomes objectionable, the inunction may be omitted for a few days, to be again renewed.—*Deutsche medicin. Wochenschr.*, September 20, 1888.

Phenacetine.—There are three varieties of phenacetine: orthocet-phenatidine, paracet-phenatidine, and melacet-phenatidine, and Dujardin-Beaumetz has found, after much investigation, that the second named variety is the only one to be relied on. With this he obtains positive results and claims its superiority over antipyrine, in that it causes no eruptions. It may be given for much the same uses as antipyrine, but is, *par excellence*, the analgesic. He gives from fifteen to thirty grains in capsules. —*Journal de Médecine*, September, 1888.

Parkinson's Disease.—In the *Lyon Médical*, M. Gauthier reviews the standing of this affection, and concludes that it is not a neurosis; that the symptoms are exclusive muscular; and that the rigidity is produced directly by muscular causes without the intervention of any nervous element. He characterizes it as idio-muscular, but thinks it may be due to phosphaturia, with which these patients are often afflicted. In turn, the phosphaturia may be originated from purely muscular causes.

Treatment of Neuralgia.—Dr. Green reports in the *Medical Press and Circular* for September, 1888, good results from the use of chloride of ammonium in twenty grain doses. One of his most obstinate cases, which had resisted treatment for months, was speedily cured by this drug.

Phenacetine for Migraine.—Rabuske gave phenacetine to a female patient who was subject to prolonged and excessively painful attacks of *migraine*, with the happiest results. Arsenic, antipyrine, and electricity had all failed, and the patient's life became a burden. Phenacetine, in eight grain doses, morning and evening, effected a cure. —*Deutsche medicin. Wochen.*, September, 1888.

For Diabetes.—M. Constantine Paul recommends the following mixture for those who demand the sweet flavor and are prohibited sugar. A teaspoonful contains twenty-five centigrammes of saccharin, sufficient to sweeten a glass of water:

R.—Saccharin	. . . . .	6 parts.
Sodii bicarb.	. . . .	4 "
Alcohol (40 per cent.)	. .	100 "
Ol. menth.	. . . . .	gtt. xx.—M.

—*Am. Journal of Pharmacy.*

The Action of Strophanthus.—A. Mairet, Combemale, and Geognier, who on November 5, 1887, presented to the Paris Société de Biologie a report of their studies upon the action of strophanthus, now confirm the clinical observations that diuresis is produced and the blood pressure raised, that the pulse is slowed, but contradict the hypothesis hitherto generally received that the cause lies in the action of the drug upon the heart. Strophanthus has a specific action neither upon the cardiac muscle, nor upon ths cardiac ganglia, nor upon the medulla oblongata. Furthermore, they believe that the remedy acts solely as an irritant and more especially upon the kidneys. They found confirmation of this view at autopsies in effusions into the endocardium, into the lungs, in hepatic stasis and irritation of the kidneys.—*Deutsche medicin. Wochenschr.*, August 2.

Translucency of Tumors.—While translucency of tumors is generally conceded to belong to those with liquid contents, M. Poncet draws attention to the fact that this property is possessed by many *solid* tumors. He mentions several cases in support of his statement, among them being an enchondroma of the fingers, lipoma of the palm of the hand, and a tendinous cyst of the wrist, all of which permitted the passage of light.—*L'Union Médicale*, August 28, 1888.

The Differential Diagnosis between a Buccal Fistula below the Inner Angle of the Eye and a Lachrymal Fistula.—According to Scheff (*Wiener med. Wochenschr.*, No. 12, 1888), a buccal fistula below the margin of the orbit differs from a lachrymal fistula in that the former is never accurately at the orbital margin, but an eighth to a fifth of an inch below; that a sound never passes upward, but only downward or laterally, posteriorly; that the secretion is always purulent.—*Medicin. Chirurg. Rundschau*, August 1.

Local Treatment of Ulcers.—Rochard recommends frequent dressings if the discharge is abundant, and if there is much pain light coverings saturated with a decoction of marshmallow and poppy leaves. If gangrene threatens, the treatment is to be strictly antiseptic. For indolent ulcers he relies on balsam of Peru, and also has good results from the red oxide of mercury ointment. Iodoform is an antiseptic of great value, and markedly diminishes pain, showing its best results in venereal and phagedenic sores. Occasional cauterizations with nitrate of silver favor healing.—*L'Union Médicale*, September 8, 1888.

Tannic Acid in Burns.—Nikolsky (*St. Petersburg. med. Wochenschr.*) has successfully used a tincture of tannic acid in eighteen cases of burns of the first and second degrees. He directs: Acid. tannic, ʒj, alcohol (95 per

cent.) q. s. (*i. e.*, about ℥j), Ætheris, ℥j. M. s. The solution is to be preserved in a vessel with a glass stopper. The burned part is cleansed with a disinfectant. The tincture is then brushed over the surface until a firm membrane has formed. This is repeated twice or thrice daily, as the membrane ruptures. A dry compress is placed over the wound. The vesicles are incised, their contents expressed with cotton, the surface of the wound dusted with iodoform and then painted with the tincture. The pain is thus much diminished; the treatment is not protracted.—*Deutsche medizin. Wochenschr.*, August 2.

Tuberculosis and Hydrofluoric Acid.—M. Goetz, who has used this medicament quite extensively in pulmonary tuberculosis, concludes that its greatest value is in the restoration of the appetite, and finds this the most constant and favorable of its effects. The night-sweats are very often greatly diminished and, in many cases, the fever is modified. The diarrhœa and cough are not much affected, and he is not yet prepared to say that the *bacillus* is completely destroyed.—*Revue Médicale*, Aug. 20, 1888.

Strychnine in Alcoholism.—Berblinger. (*Russ. Med.*, 1887, No. 38) has permanently cured drunkards of alcoholism by twenty injections of $\frac{1}{100}$ gr. of strychnine.—*Deutsche medizin. Wochenschr.*, August 2; *Prag. med. Wochenschr*, 1888, No. 4.

Local Dressing for Variola.—

℞.—Iodoform	. . . . .	gr. xxx.
Camphoræ pulv.	. . .	gr. lx.
Vaseline	. . . . .	℥ jss.—M.

Apply twice daily where there are smarting and abrasions.—*L'Union Médicale*, September, 1888.

Antipyrin for Uterine Colic.—Windelschmid (*Allg. med. Centr. Ztg.*, No. 53) has had good results from the use of antipyrin in menstrual colic. He gives doses of thirty grains per anum during the menstrual period. Relief generally followed in a quarter of an hour; in one instance the clyster had to be repeated in twelve hours. In two cases in particular, in which all known means were used before and during the period, the pain and cramps lasting at times eight days, the injections, made morning and evening and on the following evening, were followed by the best results. A deep narcotic effect was noticed in conjunction with the sedative influence. Disagreeable complications, barring excessive perspiration and sometimes slight ischuria, did not arise. To avoid any exhaustion a glass of wine or beer was often given. The administration of five grains by the mouth to a seven year old boy was attended with urticaria and high fever of twelve hours' duration.—*Wiener med. Presse*, No. 30, 1888.

Physostigma in Chorea.—Riess has recently recommended the use of physostigma hypodermatically in chorea. He has used it many times with favorable results; finding, in some cases, a total cessation of the convulsive movements in six days. The cases occurred mostly in youthful subjects, and it was not so promising in the graver cases of adults. Still it did not always fail in those cases. He has used it in tetanus, paralysis agitans, spinal sclerosis, and in a case of hysteria in the male, accompanied with great excitability and increase of reflexes, with results that warrant a further trial. The dose was one milligramme.—*Les Nouveaux Remèdes*, No. 17.

Creasote in Carbonic Acid Water.—J. Rosenthal, of Königsberg, recommends (*Berlin. klin. Wochen.*, Nos. 32 and 33) the administration of creasote to the tubercular in carbonic acid water, containing to the pint nine or eighteen grains of creasotum purissimum, with an ounce of Cognac (the dose to be increased until twelve grains are daily administered).—*München. medicin. Wochenschr.*, August 14.

Diarrhœa of Infancy.—Veillard considers the essentials of treatment to be the cleansing of the gastro-intestinal tract of any undigested substances, and of microbes or ptomaines which rapidly develop. He uses castor oil, but prefers phosphate of soda, in doses of five to ten grains, to which he attributes antiseptic properties.—*Journal de Médicine de Paris*, September, 1888.

Hot Water in Hemorrhage from the Stomach.—Flashar (*Allgem. med. Centr. Ztg.*, Nos. 55–58) considers draughts of hot water the safest and pleasantest remedy for hemorrhage from the stomach. Water, as hot as can be borne, is given in quantities of a half to three-quarters of a tumblerful. That coagulation of the blood occurs speedily is often shown by fragments of clot which are subsequently vomited without further hemorrhage.—*Therap. Monatsh.*, August, 1888.

New Disinfectant.—

℞.—Essence of rosemary	. .	100 parts.
Essence of lavender	. .	25 "
Essence of thyme	. .	25 "
Acidi nitrici.	. . . .	200 "—M.

Shake the bottle containing the mixture, pour a little upon a sponge and allow it to evaporate. The vapors will mask any bad odors and destroy germs. This preparation is especially applicable in the sick room.—*Gazette Médical de Nante*, September, 1888.

Antipyrin in Psychiatrical Practice.—Investigations with antipyrin were undertaken by Fischer (*Pest. Med.-Chir. Pr.*, No. 33) at the insane asylum at Buda-Pesth. Given in doses of seven and a half to twenty-two and a half grains, the remedy proved to be a nervine in cases of headache and neuralgia, particularly in the trigeminal neuralgias of the hysterical; the result was unsatisfactory when the headache was the consequence of an already existing pathological change in the cerebrum. Antipyrin was inefficient in epilepsy; in individual cases, however, it manifested a hypnotic influence. It is not a reliable hypnotic.—*München. medizin. Wochenschr.*, Aug. 14.

Ichthyol in Carbuncle.—Félix, of Brussels, reports excellent results from the use of a mixture of ichthyol and camphor cerate, four parts of the former to fifteen of the cerate. He covers the carbuncle thickly with this and, at the end of twenty-four hours, removes the dressing and applies the stick of nitrate of silver to the suppurating points. He finds a rapid reduction of pain and swelling.—*Révue de Thérapeutique*, September, 1888.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 Sansom Street,
Philadelphia.

SATURDAY, OCTOBER 13, 1888.

CEREBRAL LOCALIZATION AT THE WASHINGTON CONGRESS.

While the whole Congress, with its two hundred and forty papers, and its distinguished *personnel*, was a great success, high-water mark was reached in the brilliant discussion on "Cerebral Localization." The abdominal surgeons, for a long time, have had it almost all their own way; but, for once, at least, they have had to yield to their rivals in this new field. Even in literature the *Uncloseted Skeleton* shows the deep and instant impression that cerebral surgery has made, not only in professional circles, but even on the public mind.

Two important papers had been read before the Surgical and Neurological Associations, relating four successful cases of operation: one for a large tumor, one for traumatic epilepsy, and two for focal epilepsy. These papers were in every way worthy of the subject, and awakened a lively interest among the many practical surgeons and neurologists in attendance. Following these, came the general discussion in the Congress itself. The novelty of the subject, and the admirable papers then read by Mills and Park, alone would have made this worthy of notice; but when we add the able discussion, and especially the thoughtful and polished addresses of Ferrier and Horsley, it becomes a notable event in American surgery.

It is a pleasure to notice that the whole subject of cerebral surgery is Anglo-Saxon in its origin, and thus far Anglo-Saxon in its development, with the single exception of Durante's case of tumor. No operation has been reported up to the present time, we believe, that is not either English or American.

The Congress will give a most important impetus to intra-cranial surgery, an impetus that will be both an advantage and a danger. The advantage will be that, as one speaker said, we shall rapidly "make experience," and learn how far we can go, and what we can prudently do. The danger is, that we shall have speedy reports, we fear, of operations that are evidently unwise, and that may possibly bring discredit on the whole subject. It will but repeat, however, what has already occurred in other new operations, and the use of new drugs, and will be its own correetive. Oscillation to each extreme always precedes rest.

We think it was clearly manifested in the discussion on these papers, however, that exploratory operations on the cranium are justified, as much so as those of the abdomen, and that we shall have to do them, not uncommonly, in order to verify, and sometimes even to make a diagnosis.

The analogy that was drawn by Keen between the viscera of the trunk and the areas in the cerebral cortex, while not, of course, literally true, will, perhaps, give a good many in the profession a clearer idea of the organization of the brain; of the possibility of differentiating the diseases of the various centres by their symptoms, and their physical signs; and of the propriety of operations upon them.

Horsley's address was particularly full of good points. His explanation of the various cortical motor areas in their relation to each other, as not separated by hard and fast lines, but shading into each other, with certain foci of more marked reaction, was very well stated. He insisted, also, that, in operating it is necessary, in order to effect a cure, that the excision should be complete, rather than the cautious excision of only a portion of the area of representation. This completeness, it must be especially remarked, involves the removal of more brain-tissue in the horizontal plane rather than in the vertical. In the vertical direction the transitions from the area of representation for one part of a limb to another, or even from one entire limb to another, is very much more marked than in the antero-posterior direction. The effect of antiseptics in speedily dulling, and even obliterating the response of the cortex to faradism, should be carefully borne in mind, and as soon as the brain is exposed the battery should be used immediately. His ex-

periment of tapping the cord to determine whether the clonic and tonic phases of the convulsion were due to the cortex or to the cord, was one of the most ingenious and brilliant that he has done.

In DR. PARK'S address we regretted to see his measurements expressed so much in "inches." Definite measurements cannot be accurate for all heads or for all ages. We should insist, especially at present in the initial stage of the application of cerebral localization, that the measurements shall not be absolute, but proportionate or relational whenever it is possible so to express them.

Another noticeable point was the hope expressed by FERRIER and other speakers, that even mental affections, especially those pertaining to hallucinations, and probably to other forms of insanity, may yield to surgical therapeutics in the future. At present our knowledge of the localization of the sense centres, still more of those for the emotions or other intellectual processes, is too imperfect for us to dogmatize. It is not unreasonable to hope, however, that experience will give us before long the means to locate, at least, some of the mental functions in particular areas of the cortex, and so lead to their successful treatment. In fact, Macewen has already in part realized this.

Five years ago the *Lancet*, in a leader, denounced Ferrier for his revolutionary ideas on cerebral surgery. It is scarcely too much to hope that, five years hence, the *Lancet* may congratulate Ferrier on his cure of some forms of insanity, as well as of those lesions which even now have been made amenable to the knife.

Another point we cannot help but notice. When Mr. Godlee, four years ago, announced for the first time the removal of a cerebral tumor, the operation was claimed, and rightly so, as one of the most direct and promising results of vivisection. The death of the patient gave rise to the most sarcastic attacks by the anti-vivisectionists. But they should have seen that, like the failure of the first Atlantic cable, it but pointed out the road to success. Of course, cerebral surgery is not wholly due to vivisection. Pathology may claim a large share in its evolution. But it is absolutely certain that, without vivisection, cerebral surgery to-day would not only be an impossibility, but probably would not have been realized for a score or scores of years to come, so indefinite and so inexact are the experiments of nature in disease.

We commend the papers and the discussions of the Congress to the *Zoöphilist*, and to the American Anti-vivisection Society, as a striking example before their very eyes, from day to day, of the active, practical development, and the beneficent results of vivisection.

DIET IN THE CONVALESCENCE OF TYPHOID FEVER.

A PAPER read by DR. HUTCHINSON, of Philadelphia, at the recent meeting of the Association of American Physicians, on the "Management of the Stage of Convalescence in Typhoid Fever," dealt fully with the risks attending this important period of the disease, and elicited a most interesting discussion upon the question of diet, about which opinion in the profession is still divided. DR. PEABODY, of New York, urged that, in mild cases, solid food might be given with advantage on the subsidence of the fever, when an urgent craving existed. He had never seen any ill effects from finely divided meat given once or twice a day. DR. ORD, of London, quoted a remarkable instance in support of the plan of allowing the appetite of the patient to be the guide in diet.

No absolute rule can be laid down, and each case must be considered by itself. The majority of practitioners will continue on the old plan of carefully regulating the diet during the first ten days after the temperature falls to normal. Relapses, we believe with DR. KINNICUTT, are rarely the result of imprudence, but the consequence of reinfection, and the rise in temperature, which we occasionally see after taking solid food, is not often more than a recrudescence of the fever. An early return to mixed diet, if carefully regulated, is rarely followed by grave complications, but almost every one with large experience has met with cases of perforation or peritonitis the result of some grave imprudence on the part of the patient. A deep ulcer may leave only a thin layer of the muscularis covered by the peritoneum, and we have known a full meal of mutton-chops, in the third week of convalescence, to be followed by a fatal peritonitis from perforation.

DR. WILLIAM OSLER, Professor of Clinical Medicine in the University of Pennsylvania, has been elected Professor of Medicine in the Johns Hopkins University and Physician to the Hospital, and the tender of the unsolicited position was accompanied with such substantial inducements as to insure its acceptance. This selection is another proof of the

admirable judgment displayed by the managers of the Hospital in the administration of their great trust.

Dr. Osler's large circle of friends will regard his merited appointment with sincere gratification, although to those in Philadelphia this will be tempered by a feeling of deep personal regret at his removal to another city.

The right of an author's ownership in his lectures has been again affirmed in the Common Pleas Court, on the application of Prof. T. G. Wormley, of the University of Pennsylvania, for a preliminary injunction to restrain W. B. Saunders from publishing and selling certain books containing notes on medical and general chemistry, which Dr. Wormley says are simply a summary and condensation of lectures delivered by him in the University of Pennsylvania, and were published by the defendant without his warrant or authority.

The *University Magazine* is a new monthly, edited by Drs. de Schweinitz and Hare, in the interests of the Medical Department of the University of Pennsylvania. The first number has just been issued, it contains several excellent papers, and gives promise of a healthful and useful life.

An experiment is announced to be tried in Brooklyn, in the way of forming a "protective alliance"—mellifluous synonym of "trades-union"—among the practitioners of medicine of that city, whereby their financial interests will be protected from imposition. This they expect to accomplish by the issue, for private use, of a list of names, commonly known as a "black list," and by the organization of a robust bureau of collection.

A great variety of experiments have been made in the large cities of this and foreign countries, for the protection of the financial rights of medical men, having for their keystone some form of "black list," but they have ordinarily been disappointing and short-lived. However well such lists may operate among grocers, tailors, and the like, there seems to be something radically inappropriate in the application of them to the healing art. The "boycott" too readily becomes an engine of oppression, and too much responsibility rests on a possible error of judgment or feeling of pique, on the part of some colleague, to become a part of the armamentarium of the disciples of Æsculapius.

Dr. Elkanah Williams, of Cincinnati, died on the 5th instant, after a long illness. He was born in Lawrence County, Indiana, on December 19, 1822, and graduated in medicine at the University of Louisville in 1850. In the autumn of 1852 he went to Europe to study ophthalmology, returned to Cincinnati in the spring of 1855, and commenced practice as a specialist in diseases of the eye and ear. In 1860 he was elected Professor of Ophthalmology in the Miami Medical College. He was elected President of the Fifth International Ophthalmological Congress which met in New York in the autumn of 1876. He was the author of several valuable papers in ophthalmological literature. His death removes from our midst one of the pioneers in this country in the development of modern ophthalmology.

In another column will be found the resolutions adopted at a meeting of the medical profession of Cincinnati expressive of the loss they have sustained.

REVIEWS.

An Illustrated Encyclopædic Medical Dictionary. Being a Dictionary of the Technical Terms used by Writers on Medicine and the Collateral Sciences, in the Latin, English, French, and German Languages. By Frank P. Foster, M.D., Editor of the *New York Medical Journal*. Vol. I., 4to. pp. xii. 752. New York: D. Appleton & Co., 1888.

This immense work is designed to give English definitions of all words used in medicine and the collateral sciences, in the English, French, and German languages. If this alone were done, its size need not to be nearly so great. In the present quarto volume, of between seven and eight hundred pages of small type, A, B and only a part of C are included. The first of the four large volumes of Johnson's *Cyclopædia* covers all subjects from A to E inclusive. So that, on its present scale, six volumes at least will be required to complete the work.

The occasion for this bulk is the encyclopædic extension given to the definitions of certain terms. This is very unequally done. Very many words, in each of the three languages, are briefly defined. Others, as *Apparatus*, *Bacillus*, *Bacterium*, and *Bone*, are exhaustively or, at least, elaborately, treated; each covering large numbers of pages. Again, the enumeration of similar French or German and their equivalent English terms is, in several cases, extended greatly; to our view, beyond the real needs of those who are likely to make use of such a dictionary.

Were the whole work to be carried out on a similar scale to that of the articles on *Bacillus* and *Bacterium*, a dozen or perhaps a score of volumes would be required for its completion. But many distinctly medical subjects are very briefly dealt with; more so, relatively, than in the three volumes of Copland's *Dictionary of Medicine*. On a considerable number of subjects, Dunglison's *Med-*

ical Dictionary gives as much, or, sometimes, even more, practical information.

Dr. Foster has been aided in the very great labor of this work by eleven collaborators. Among these, Dr. Duane appears to have taken the largest share. Chemical and botanical terms receive what, in justice, must be called a disproportionate amount of attention and space. Some plants which are seldom, if at all, used in medicine, are as exhaustively treated as would be necessary in a strictly botanical dictionary. While the result thus attained is highly creditable to the learning and industry of their author or authors, it is a question whether the practical value of the work is increased thereby in any like proportion. For our own use we would rather have had a simple medical dictionary of terms in the three languages; for which a single volume, perhaps less in bulk than this, might have sufficed. In favor of the plan adopted, however, we have the judgment, based on editorial experience, of the editor, Dr. F. P. Foster, and that of the able managers of a leading publishing house. We hope that their anticipations of its acceptance by the profession may be fully realized.

SOCIETY PROCEEDINGS.

ASSOCIATION OF AMERICAN PHYSICIANS.

Third Annual Meeting,

Held at Washington, September 18, 19, and 20, 1888.

(Specially reported for THE MEDICAL NEWS.)

(Continued from page 394.)

SEPTEMBER 18TH.—MORNING SESSION.

DR. J. C. WILSON, of Philadelphia, then read a paper on

CAUSAL THERAPEUTICS IN THE INFECTIOUS DISEASES.

Referring to the discussions of Hoffer, Brieger, Vaughan, Bourget, and others in regard to the part played by microorganisms in the production of ptomaines in the living as well as in the dead body, he stated that much had been done within recent years in clearing up the relation between the specific pathogenic germs of the infectious diseases and the symptomatology of these diseases. Efforts to work out a system of therapeutics directed against these germs have thus far been successful only within narrow limits and chiefly in local treatment, as in surgery and midwifery. Not the germs themselves, but the poisonous principles evolved by the germs in their growth and multiplication cause the phenomena of these affections. Is it not possible that, by acting upon the tissues and fluids of the body therapeutically, the function of these toxic principles may be controlled. In the preservation of meats and other articles from decay, it is the substance itself and not the putrefactive germ that is acted upon. In vaccination and preventive treatment by attenuated virus, the organism—not the pathogenic microörganism—is acted upon. The paper was based upon five cases of severe enteric fever successfully treated by hypodermatic injections of calomel, and three cases of phthisis, in which the symptoms were greatly ameliorated without any decided change in the local signs, similarly treated. Dr. Wilson desired the report to be regarded simply as a clinical experiment and as indicating a line of clinical research worthy of investigation. The paper was illustrated by clinical charts showing striking modifications of the usual temperature ranges in these diseases.

DR. GEORGE M. STERNBERG said that this subject was a very prominent one to-day, and every experiment has its value. He then referred to a method of treatment of yellow fever which he had suggested when in Havana recently. Believing that in yellow fever there must be a germ having the alimentary canal as its proper location and knowing that the secretion in the stomach is unusually acid, and finding the contents of the intestines to be acid, he, therefore, used an alkali, the bichloride, in moderate doses by the mouth. The formula he employed was ten grammes of the bicarbonate of sodium to the litre of water with two or three centigrammes of the bichloride of mercury. He has received reports of thirteen typical cases of yellow fever successfully treated in this way in one hospital in Havana. A series of thirteen cases without a single death certainly speaks very strongly in favor of this method of treatment. He was anxiously awaiting further reports on the subject. With reference to the cases of typhoid fever just reported, he thought we needed a still more extended series of cases. Dr. Wilson spoke in one of his cases of constipation and an elevation of temperature at that point. Perhaps it has not occurred generally to physicians that there is a cause for that, independent of the specific agent. There is in the alimentary canal of man a microörganism which generates a fever-producing ptomaine. He had made experiments with this bacillus, both with the recent culture and the sterilized one. Two or three cubic centimetres of this bacillus produce a rise of temperature, as does also the sterilized culture. So we have a fever-producing organism constantly present in our intestines. It is probable that the degree of fever may depend upon this organism, which is normally present in the intestine. From the researches made by Ehrlich in Naples with regard to his cholera bacillus which is normally present in the intestines of healthy persons, and from many recent researches which he had made in Havana, he had come to the conclusion that this bacillus does not confine itself to the large intestine where it belongs, but is found in the small intestine and stomach as well. He simply wished to direct attention to the fact that constipation in these infectious diseases and increased temperature may be due to the production of this ptomaine, and the indication is to keep the bowels cleared out.

DR. I. T. DANA, of Portland, said that the accumulation of evidence has been such as to attract the attention of the profession to the fact that infectious diseases are due to some form of bacteria. It seemed to him that some remedy could be found which might be safely introduced into the human system and destroy those germs. All who have thought of it, and who have experimented, must have come to feel apprehensive lest no medication could be found that could destroy the germs without, at the same time, destroying the individual, but it seemed to him that the suggestions drawn out by this very interesting paper are full of hope. It seemed to him the tissues of the human body may be so changed that they may be able to resist the action of the germ. The tissues may be rendered non-putrefactive. The ptomaine may be destroyed. By modifying the soil or preventing the activity of the ptomaine rather than by destroying the infectious germ itself in the human system he thought it likely that we will be able to modify these infectious diseases.

Dr. George L. Peabody said that at the meeting last year he had reported a number of cases of typhoid fever treated with naphthaline, and that, in a certain small number of those cases, he had seen a distinct abortion of the disease. His total number of aborted cases was only three, but they were distinct abortions of distinct typhoid fever. The three cases in the first ten or fifteen were the only cases in which an abortion of the fever was secured. He was quite convinced that naphthaline, as a means of aborting typhoid fever, is of very little value. He is at present pursuing the study of intestinal antisepsis in this disease, but his results are not sufficiently conclusive to justify him in bringing them before the Association.

Dr. Jacobi said that, in this connection, he would refer to the treatment of diphtheria with the bichloride of mercury. This disease cannot be treated by any other remedy as well as by bichloride. It has the advantage of being readily soluble, and, in sufficient doses, counteracts the specific poison. As far as naphthaline is concerned, he has never seen a case of typhoid fever aborted, but he is positive he has seen the diarrhœa get better, and the odor of the movements, as well as their character, changes in a very short time after its administration. In the diarrhœa of tubercular cases, also, in a large number of cases he had seen good results follow the use of naphthaline, and he is positive it is well worthy of trial.

Dr. W. W. Johnston said that it is necessary that we should recognize the fact that many cases of typhoid fever pursue a downward course, and that we must prove that the remedy materially alters the course of the disease.

Dr. Wilson, in closing, said that he did not claim that this treatment is anything more than a clinical investigation in the direction of general research to discover some method of treatment which appeals more or less directly to the causes of infectious diseases. The prevailing method of treatment is no treatment at all. Symptomatic treatment has no effect upon the general course of the disease, nor does it in any way abort it, and a treatment of expectancy is a confession of our inability to do any more. We are not at all aware of the mode of action of two confessedly curative substances used in the treatment of infectious diseases, viz., quinine in malarial disease, and mercury in syphilis. He was led to make these clinical investigations in consequence of his very successful use of calomel in syphilis, which resisted all other methods of treatment. He has been fortunate enough to escape the production of abscesses in a large number of cases treated in this way. Cases of enteric fever treated after this plan ran a milder course than any he had otherwise treated. His object in presenting this paper to the Association was rather suggestive than instructive, and he trusted no one would regard them as conclusive.

Dr. Frank Donaldson, of Baltimore, then read a paper on

THE DIAGNOSTIC SIGNIFICANCE OF THE PRESYSTOLIC MURMUR,

which will appear in full in an early issue of The Medical News.

Dr. J. K. Thacher, of New Haven, said that in these cases of mitral stenosis in which there is reduplication of the second sound, the aortic valves close first and the pulmonary second. This seems to be due, at least in part, to a prolonged ventricular close-time on the right side caused by exaggerated tension in the pulmonary artery, with, in some cases, a shortened ventricular close-time on the left side, due to diminished aortic pressure.

The murmurs in mitral stenosis depend on the form and size of the auriculo-ventricular orifice and the strength of the current. The latter is determined by the relation of the tension in the left auricle and ventricle. The fact recently set forth by Rolleston that, as seen in dogs, there is a marked depression in the tension-curve of the left ventricle, at the beginning of diastole, seems to me to be applicable to the explanation of the initial diastolic (so-called post-diastolic) murmurs, whatever views are held concerning the suction action of the left ventricle.

Dr. Osler thought that all are agreed that there is one cardiac murmur above another, which is positive and distinct in its diagnostic significance, viz., the presystolic murmur. He had an instance at the University Hospital last year, in which he demonstrated to his class a mitral presystolic murmur. The case was one of cirrhosis of the liver in a child with great enlargement of the spleen. To his astonishment, he found at the autopsy a normal auriculo-ventricular orifice. The heart was pushed up very far. He has recently written out short notes of a case of aortic insufficiency in which there was a distinct presystolic murmur. A woman was sent to his ward in the hospital in an extreme condition of emaciation. He placed his hand over the heart in the apex region and felt a very distinct diastolic thrill and his ear also detected an extremely loud, rough murmur, which he regarded as presystolic. The woman was not in a condition to permit of further examination. At the autopsy the mitral orifice was found to be normal, but there was extreme aortic insufficiency.

Dr. Donaldson, in closing, said in regard to the diagnostic difference between the presystolic and systolic murmur, the rhythm, character, area, and direction of the presystolic sound are different from those of the systolic. Not long since he had a case in which the diagnosis of insufficiency of the aortic valve was very easily made without a sign of presystolic murmur. It has been frequently demonstrated that we find mitral stenosis at the autopsy in cases in which we have found a presystolic murmur during life.

Dr. Robert T. Edes, of Washington, opened a discussion on the

ABSOLUTE AND RELATIVE VALUE OF THE PRESENCE OF ALBUMEN AND CASTS, AND OF RENAL INADEQUACY IN THE DIAGNOSIS AND PROGNOSIS OF DISEASES OF THE KIDNEY.

He said that many can remember when the discovery of the presence of albumen in the urine was regarded as a sentence of death. Albuminuria has held a place in medical literature akin to that of Bright's disease until quite a recent date. He thought there was no reason to discover a symptom, which to a physician can have no significance and to a patient is the source of groundless fears. Casts, he thought, were easier to identify than the different forms of albumen. There can be little doubt in the mind of any one that epithelial casts are very significant. There is probably no form of casts so unfavorable as long, large, straight casts, highly granular and fatty, looking like thin white threads.

They appear to be made up of degenerated cells. Where amyloid casts have appeared he has never known but one instance of recovery. A few casts may accompany a very slight amount of albumen and have no meaning. Where hundreds of persons have been examined the statement of no casts must be received with a certain amount of allowance. It is interesting to note that in oxalic acid poisoning albumen and casts were found in the urine by several observers.

The term renal inadequacy may be made to convey several shades of meaning. He would consider only the inability of the kidney to secrete water, urea, and other solids. He would not dwell upon this fact further than to say that oxaluria had a very serious prognosis.

The point of great interest is whether we can diagnosticate the early stage of chronic nephritis by a diminution in any one of the constituents of the urine. The statement of many text-books is that 30 to 40 grammes are an ordinary excretion for a healthy man. An amount a little below 20 grammes of urea is not to be regarded as below the limits of health. On low diet a patient may excrete 10 grammes of urea a day without any dangerous condition of the kidney. Chronic nephritis should have advanced to a considerable degree of atrophy before it makes itself manifest by diminution in the secretion. It may be safely concluded in cases in which the diagnosis is still doubtful that the determination of the amount of urea passed will give us no assistance. Imperfect nutrition with anæmia is a most frequent cause of diminished urea. It is not passed simply because it is not made. He would consider the presence of casts in the urine as a diagnostic sign of disease of the kidney. As to the examination for the quantity of urea, his impression is that it is almost of no value in diagnosis aside from other symptoms, unless the examinations are carried on for a length of time, and give the total amount, and not merely a percentage, which he considers of no value at all.

DR. EDWARD G. JANEWAY, of New York, said that, if we consider the diagnostic importance of albumen, we are forced to state that it is apt to be over-reached and its absence or presence is very misleading. The existence of an inflammation of the genito-urinary passages leading, as it does, to albuminuria, is liable to add the next greatest difficulty in relying upon albumen in the urine as a diagnostic sign. Fifteen years ago a young man, a patient of his, was supposed to have Bright's disease, from the fact of the presence of albumen in the urine. Suddenly a marked increase in the albumen took place and numerous pus cells were present. Fifteen years have passed since that time and no evidence of kidney disease has been shown by that young man. In diabetes albumen may be present, leading to errors of diagnosis and prognosis. The presence of albumen in small quantities in lead-poisoning does not lead to the fact that the lead produced chronic nephritis. At times albumen is absent from the urine in cases of waxy degeneration of the kidney.

In conclusion, he would say that a large quantity of albumen in the urine of several examinations points to either acute nephritis, large kidney, or waxy degeneration. Casts, while they are amongst the surest signs of disease of the kidney, may be misleading either by their presence or absence. If, by the microscope, we find hyaline casts present we are to consider some kidney trouble existing. A gentleman of good physique, a candidate for life insurance, whose urine contained casts, applied to him for examination. He applied for re-examination and he submitted samples of the night and morning urine. They failed to show casts. It was learned that he was in the habit of boxing for a half hour, perspiring freely, and then taking an alcohol sponge-bath. From this it follows that hyaline casts may appear in the urine, quickly formed and as quickly disappear.

DR. JAMES TYSON, of Philadelphia, then read a paper on

THE RELATION OF ALBUMINURIA TO LIFE ASSURANCE.

He said that medical examiners for life insurance companies have passed candidates who were the subjects of kidney disease. Functional albuminuria means that there is a functional disarrangement somewhere. The majority of medical examiners are not well educated nor well trained. There are three conditions that should govern candidates: 1. The applicant must present the signs of good health, extra-renal. 2. The albuminuria should be unaccompanied by casts. Casts and albumen can only receive one interpretation—structural change in the kidney, either acute or chronic. 3. The quantity of albumen irrespective of casts. If the quantity be large, it is unquestionably a proper cause for rejection. Urine which contains one-fifth its bulk of albumen may be certainly styled a large albuminuria. With regard to the specific gravity of the urine during twenty-four hours, the following rule may be laid down: Albuminuria is less significant when the specific gravity is high. When the specific gravity is above 1020, the assumption is that the albuminuria is functional; if it be 1010, it would be hazardous to accept such a case, however good his health may be, even in the absence of casts. Signs of hypertrophy of the left ventricle associated with albuminuria are conclusive symptoms of renal disease, and should exclude the candidate. In persons over forty years albuminuria is not likely to be functional. Such a person should not be accepted unless he has been long under observation. Persons who are the subjects of true gout should not be accepted, because it is followed sooner or later by kidney symptoms. Retinal affections should also exclude the applicant, even though no albuminuria be present.

DR. JACOBI said that to criticise papers of such excellence would be impossible, but he might be permitted to remind them of a simple anatomical fact which may explain the frequency at least in part of inflammatory diseases of the kidneys and the presence of albumen in children. It is true that children have diseases in which kidney trouble is very common. The anatomical fact to which he referred was that immediately after birth there is a peculiar discrepancy between the development of the renal artery and the growth of the kidney. The arteries do not develop uniformly. There is a certain discrepancy between the increase in growth of the renal artery and the growth of the tissue of the kidney. Besides, the capillaries of the kidneys of the young do not permit the same current of water to be pressed through them in the same time as the capillaries of the adult.

DR. PYE SMITH, of London, said that he had come to learn rather than attempt to give information. We have all felt the difficulty of deciding a case simply from the presence of albumen in the urine. He quite agreed with the author of the paper, as to functional albuminuria

being, at present, the most convenient term for that condition, because it depends upon several states differing very much from one another and only agreeing in the practical fact that none of them implies, structural organic disease of the kidney. Physiological albuminuria is a very mischievous one because it leads to the idea that we can overlook as a normal condition what certainly should always awaken a very grave anxiety. At present there is no physiological ground for believing that a healthy kidney secretes albumen at all. Those of us who have seen cases of physiological albuminuria so called will agree with him in saying that they are cases that must be carefully watched in order to prevent them from going from bad to worse and involving the kidneys in more serious trouble. He happens to be at present physician to a large London insurance company, and he would say that he had tried a great many tests for albumen in the urine, and he was driven back to the old test of heat and nitric acid as the most satisfactory of all. If we introduce new tests and new chemical criteria we would imperil the structure that has been reared during the past fifty years, clinically and pathologically. We cannot do better than keep to the results obtained by those two methods.

Dr. F. P. Kinnicutt said that about seven or eight years ago he published a series of cases of albumen occurring in children and adults, in all of whom the albumen existed in a large amount but without the presence of casts. He had an opportunity to keep these patients under observation up to the present time and in none of them has the health been impaired. In all the cases but one has there been a cessation of the albuminuria. It seemed to him that the future of such cases must be of interest to us.

Dr. F. Peyre Porcher said that in yellow fever albuminuria exists and is one of the most dangerous symptoms of that disease. He thought if yellow fever were treated during the first ten hours by large doses of mercury, quinine, and cold water, it might be reduced down to as little danger as any disease that exists.

Dr. Alfred L. Loomis then read a paper on

THE CARDIAC CHANGES IN CHRONIC BRIGHT'S DISEASE.

There are no more important facts to be remembered in our consideration of any disease than the fundamental law of self-preservation. Many so-called pathological processes become physiological when viewed from this standpoint. The most constant cardiac changes he has met with are dilatation of the heart's cavities, and degeneration of its walls. In those forms of renal disease in which the principal changes are in the Malpighian corpuscles and stroma, he had found no cardiac hypertrophy but the changes characteristic of Bright's heart. In all forms of chronic Bright's disease increased arterial tension and more or less compensatory hypertrophy are rare phenomena. Clinical experience teaches that rheumatic valvular disease of the heart may remain latent for many years, during which the heart will perform its functions effectively. Cardiac changes in chronic Bright's disease have a wide range of variation, and one cannot predict with certainty the exact changes in any given case, but sooner or later a condition of heart failure will be reached which may be designated as Bright's heart. The more marked the symptoms, the more unfavorable the prognosis. We must regard Bright's disease as a constitutional disease in which the repair and waste are imperfectly carried on.

Dr. Francis Delafield said that he wished to draw attention to several of the propositions presented. In the first place, that cardiac hypertrophy is often developed without any changes in the kidneys except thickening of the middle and inner coats of the renal artery. There can be little doubt that disease of the kidney may begin in the arteries of the kidney, but, as a matter of fact, we seldom find such kidneys at the autopsy. We have to look at this question of cardiac hypertrophy, with reference not only to the kidneys but to other parts of the body. In adults and in old persons, we may have a growth of connective tissue in the endocardium, in the arteries, in the lungs, and in the kidneys, and this growth of new connective tissue gives us either the character of a chronic inflammation or, as some people call it, a chronic fibroid degeneration of this part of the body. These changes are much more frequently associated together than otherwise. We do not often find a chronic endocarditis alone, a pulmonary emphysema, or chronic diffuse nephritis, yet they can exist by themselves.

Another thing about these lesions is, that they are often borne for years without giving the patient any trouble at all. On the other hand, we know that these lesions in other people are the most fatal ones that can be developed. What is the cause of this difference? Certainly one reason is, a certain number of these patients develop in the course of their disease a complicated condition of high arterial tension, which comes and goes in such a way that we are unable to explain it, except by the existence of temporary changes in the walls of the bloodvessels. We know it is one of the chief reasons some of these patients do well and some do badly. It is in this temporary condition of the bloodvessels we have to look for the hypertrophy of the heart, rather than in changes in the structural walls of the arteries. Dr. Loomis also states that morbid changes in the glandular structure of the kidneys are usually associated with morbid changes in the cardiac walls, and dilatation of the cardiac cavity. This point of dilatation and degeneration of the heart in connection with Bright's disease seemed to be the principal points of Dr. Loomis's paper. His experience differs from Dr. Loomis's in this respect. For himself, he should say that degeneration and dilatation of the heart without endocarditis, is certainly not the rule in chronic Bright's disease. It is not nearly as common as simple hypertrophy of the left ventricle. In many of these patients, when they do badly, we have the evidence of feeble heart during life, but he did not think, if we examine these hearts after death, we frequently find dilatation or degeneration.

Dr. George L. Peabody wished to allude to one part of the paper in which some observations made by him bear out the statements of Dr. Loomis. Some years ago he reviewed the records of 2000 consecutive autopsies, and though he had not with him the actual figures produced at the time, in a paper subsequently read by him before the Academy of Medicine in New York, he showed the percentage of cases in which the heart was not hypertrophied in well-marked cases of chronic diffuse nephritis. In these 2000 cases the number in which this form of chronic Bright's disease was present was very large, for the reason that in the hospitals of New York they have a

large proportion of cases of chronic Bright's. In those cases in which he had recorded notes and made microscopic examination of the kidney, there was a large percentage of them in which there was no hypertrophy. The observations he has made since have borne out the conclusions reached then. He has long since come to the conclusion that, as a means of assisting in the clinical diagnosis of chronic Bright's disease in this country, we have to abandon the clinical evidence of the size of the heart for the reason that the size of the heart does not vary. These were all hospital cases.

DR. WILLIAM OSLER thought we might divide the cases of chronic interstitial nephritis into two great groups as we see them clinically and in the post-mortem room. One, in which we have hypertrophy of the left ventricle. These are the cases which die suddenly with uræmia or inflammation of serous membranes. They, in his experience, have invariably hypertrophy of the left ventricle. There is another group in which there are marked signs of cardiac failure, often associated with dropsy. These have a dilated heart and dilatation of the muscular substance. He regarded that dilatation as a secondary one due to failure in the nutrition of the muscular substance, and in a considerable proportion of cases degeneration is associated with arterio-sclerosis in the coronary arteries.

DR. LOOMIS, in closing, said that Dr. Delafield must have made his observations in a different way or for a different purpose than he. He was certain that degeneration of the cardiac walls was present in a larger proportion of the cases than one would be led to suppose, unless he had made careful microscopic section.

He did not enter into these investigations with any preconceived views on the subject. He simply took the facts as they came to him. He did not believe the cardiac dilatation was a primary one, but he wished simply to convey the idea that in Bright's disease of the kidneys, whatever the form may be, before the fatal issue is reached, there exists, in a great majority of cases, a degeneration of the cardiac walls. The first unfavorable symptom to him, of a patient with Bright's disease, is the evidence of a failing heart. He did not regard the cardiac hypertrophy as part and parcel of the kidney lesion. It is at the period of middle life we see these degenerative changes, and if Bright's disease develops at this period we are likely to have a hypertrophied heart before the existence of the Bright's disease. He did not say these degenerative changes are the cause of dilatation, but a careful measurement of the cardiac cavities in these hearts that are feeble, where there is some form of degeneration of the muscular fibre, would lead him to believe that degeneration may have occurred only a short time before. In a feeble heart with disturbance in the function of the kidney we must recognize the fact that life cannot be prolonged for a very great length of time.

DR. S. C. CHEW, of Baltimore, read a paper on

THE RELATION BETWEEN CHRONIC INTERSTITIAL NEPHRITIS AND ANGINA PECTORIS.

He said that it is well known that some forms of Bright's disease are likely to be associated with organic changes in the heart, and the manner in which such cardiac changes are brought about has been the subject of many ingenious arguments. He quoted cases illustrating the relation between chronic interstitial nephritis and angina pectoris. Cardiac ischæmia, he thought, is brought about more by obstructed disease of the coronaries than by any other cause. A patient may die of angina pectoris without there being recognized at the post-mortem any vascular lesion whatever.

DR. PEABODY said that the fact which Dr. Chew brought out at the close of his paper of the occurrence of angina pectoris without there being recognized after death, any vascular lesion, is one of great importance when we consider that a patient may die in such an attack and yet leave no lesion. One clinical fact of importance, that has occurred in his experience, is the frequent failure of the vascular dilators to relieve the paroxysm. Nitrite of amyl and nitro-glycerine are of no value except when there is increased arterial tension. These paroxysms are as likely to come on when there is defective arterial tension as when there is an increase.

DR. CHEW, in concluding, said that he wished to refer in his paper only to cases of angina pectoris connected with chronic interstitial nephritis.

AFTERNOON SESSION.

DR. J. M. DA COSTA, of Philadelphia, opened the session with a paper on

THE TREATMENT OF VALVULAR AFFECTIONS OF THE HEART,

which will appear in full in *The American Journal of the Medical Sciences* for November.

DR. F. C. SHATTUCK said that in listening to the paper it occurred to him how very desirable it would be to have a heart tonic which would increase the efficiency of the contractions and at the same time not increase the resistance in the peripheral circulation. He should like to ask Dr. Da Costa as to the possibility of strophanthus supplying that desideratum.

DR. CHEW said that his experience with strophanthus was very various. He at one time thought we had in that drug something that would do good to the heart without in any way lessening its powers. Now he is not so sure of it.

DR. DA COSTA said that judging of strophanthus clinically it does not seem to have the power claimed for it, viz., of acting on the heart as well as the arteries.

DR. BAUMGARTEN, of St. Louis, then read a paper on the

DISTURBANCES OF THE HEART RHYTHM WITH REFERENCE TO THEIR CAUSATION AND THEIR VALUE IN DIAGNOSIS.

He said that intermission and irregularity of the pulse never fail to attract the attention of the physician, and have been the subject of much discussion. Anomalies of rhythm may be classed under four heads:

1. Mere fluctuations in the frequency of the heart's beat.

2. Variations in frequency, as well as amplitude of pulse.

3. All the numerous changes in rhythm.

4. Types of rhythms.

The rhythm of the incompetent heart can be increased by increasing the demands of the heart. A moderate degree of rhythm in the erect posture often ceases when the patient lies down. We may expect moderate degrees of irregularity in anæmic and cachectic patients. Dila-

tation from overwork is sure to produce a small, soft, accelerated pulse, and later on an intermittent or wholly irregular pulse. Irregularities of pulse arise sooner in mitral than in aortic disease. Acute myocarditis is characterized by a rhythmic pulse, small and very frequent, and the irregularity is an essential feature in the diagnosis. Sclerosis and narrowing of the coronary arteries are the cause of rhythm. Weakness of the heart from any cause makes the pulse frequent. In aged people the heart's rhythm is more easily disturbed than in young people.

Dr. E. T. Bruen, of Philadelphia, said that a short time ago he came across an article in the *Transactions of the Pathological Society of London*, in which there were recorded thirty-seven cases of fibroid heart, in which the pulse was markedly slow. He thought it an important matter to recognize, because it will aid us in the exclusion of fatty degeneration of the heart.

Dr. Edes said very few of these irregularities he had noticed particularly. He was glad to call attention to one thing he noticed, and that was the occasional intermission in certain cases of pericarditis in which a beat falls out or becomes much weaker.

Dr. Osler said there were one or two points to which he would refer: certain individuals suffer with extreme irregularity of heart for several years, without its producing the slightest inconvenience. In a foot-note to his article in Pepper's *System of Medicine*, he mentions the case of a man who had extreme irregularity of the heart since his fortieth year. Another point to which he would call attention is, in certain cases of mitral valve-disease extreme irregularity may exist with complete compensation, and an irregularity obstinate to every kind of treatment.

Dr. H. M. Lyman, of Chicago, said that in cases in which there is no valvular lesion, no dilatation of the heart; in which, in fact, the phenomena were merely functional, he had noticed disturbance of the heart-rhythm. Many of them seemed to be entirely due to a disturbance of the excretory organs of the body. He found them manifest themselves in persons of a nervous temperament, overworked, and harassed by business, and presenting no lesions of the kidney or heart, or organic changes of the liver associated with some degree of gastro-intestinal catarrh. Such cases as that he found not appreciably benefited by digitalis, or other heart tonics, but are greatly relieved by measures which tend to stimulate the action of the liver and kidneys. They frequently manifest symptoms of muscular rheumatism. Cases of this kind are very much relieved by laxatives associated with hepatic stimulants, blue pill with a little colocynth. These often give more relief than any specific cardiac drug.

Dr. A. E. Sansom, of London, said that great irregularity of the heart's action is very often consistent with perfect health. He has had several striking illustrations of this. He thought it the bounden duty of the physician, unless this irregularity is associated with cardiac changes, or unless we feel there is dilatation or degeneration, to try and disabuse the patient, and direct his thoughts away from the heart.

Dr. W. H. Draper said that some years ago his attention was called, by an article by Dr. Richardson, of London, to a class of cases which had been alluded to in this discussion, in which irregularity of the heart persisted for many years. Dr. Richardson traced many of these cases to extreme nervous shocks, loss of property, grief from the loss of a relative, etc. He has been able to confirm Dr. Richardson's observation in a number of instances. He would like to ask Dr. Baumgarten if that agreed with his observation.

Dr. Baumgarten, in closing, said that perfect consistency of good health with irregular pulse has been mentioned. The intention of his paper was to try to arrive at a systematic view of all rhythms. Of course, it was not his object to include the exception rather than the rule. The person who observed rhythms with perfect health has, of course, observed a great many more rhythms with imperfect health.

(To be concluded.)

AMERICAN NEUROLOGICAL SOCIETY.

Fourteenth Annual Meeting,
Held at Washington, September 18, 19, and 20, 1888.

(Specially reported for The Medical News.)

Tuesday, September 18th.

The President, Dr. James J. Putnam, of Boston, in his opening address called attention to the value of what practically amounted to collective investigation and referred, in particular, to his own research as to the influence of small quantities of lead upon the organism. He stated that he is now engaged upon a research with the object of discovering whether or not, small quantities of this may exist in the body without producing appreciable effects.

Dr. Philip C. Knapp, of Boston, then read a paper on

NERVOUS AFFECTIONS FOLLOWING INJURY (CONCUSSION OF THE SPINE, RAILWAY SPINE, AND RAILWAY BRAIN).

The principal points to which he called attention were as to whether there are real lesions produced in the majority of these cases, or whether the symptoms do not partake to some extent of an hysterical or psychical character. He quoted largely from both English and German writers in regard to this point, some of whom stated that chronic tabes may result from prolonged concussion, such as that to which railway engineers are subjected. Attention was called to the fact that Page and the reader regard railway spine as commonly being due to lumbago or muscular asthenia and stiffening. Dr. Knapp also reported several cases and the whole tenor of his paper rather supported the functional than the organic idea of the disease.

Dr. Seguin, of New York, in the discussion which followed, spoke about the conditions which might come on in hypnotism as resembling somewhat those symptoms which persons suffering from railway spine might present. That is to say, the auto-suggested symptoms of some hysterical persons might bear a very close resemblance to the statements made by persons under the influence of a sudden nervous shock, such as that produced by railway accident. The speaker also made the statement that he has never seen a patient of this character present symptoms which could not be simulated.

Drs. Lloyd and Deaver, of Philadelphia, reported

A CASE OF FOCAL EPILEPSY, SUCCESSFULLY TREATED BY TREPHINING AND EXCISION OF THE MOTOR CENTRE.

Dr. David Ferrier, of London, at the invitation of

the Association, spoke concerning the interest and value of such cases, and called attention to the fact that as the case had only been operated upon three months ago, it was entirely improper to report it as one completely cured. He cited an instance of a patient under his care who had been operated upon by Mr. Horsley, but in whom the operation eventually proved valueless, although for some months afterward, the fits were almost completely put aside. On the other hand, he cited a second case occurring in his own practice, the result of which was strikingly opposite from that just quoted, and which also was operated upon by Mr. Horsley. The patient just prior to the operation passed almost into the *status epilepticus*, having as many as 3000 fits in fourteen days, but recovered completely after the operation.

Mr. Horsley agreed with Dr. Ferrier in every thing which he had said, and spoke of the great value which such operations possessed. In regard to the question as to whether patients had loss of true tactile sensibility, or whether the apparent loss depended upon loss of muscular power, Mr. Horsley pointed out that if pressure was made of a finger against the nail and cushion of the digit, the patient by the mere sensation in his arm is able to tell what you are doing; but, if the thumb, for example, be grasped by the operator with his thumb and forefinger at the sides of the phalanx, and then passive movements are made, the patient is unable, if sensation is locally impaired, to describe the movements employed. He also pointed out that a very good method of forcing a patient to indicate the point touched was to tell him, when blindfolded, to place the index finger of his opposite hand upon the spot. He also mentioned an instance in which the patient using this method always indicated with his index finger the segment nearer the body than the one actually touched by the physician.

Dr. Gray, of New York, thought that no case should be reported as cured until at least five years after the operation, and cited cases in support of this belief.

Dr. Putnam, of Boston, then reported

A CASE OF INFECTIOUS NEURITIS,

which was illustrated by a large number of colored drawings and microscopical specimens. The age of the patient was twenty-eight years, and the changes particularly noticed were around the nodes of Ranvier. Death occurred from asphyxia.

Dr. Pye Smith, of London, at the request of the Society, spoke of the value of Dr. Putnam's research, which he thought was particularly instructive in view of the fact that so few post-mortem examinations are obtained in such cases. Aside from the question of drink, he was interested as to the influence exerted in the production of the disease by the gouty diathesis.

Wednesday, September 19th.

Dr. L. C. Gray, of New York, presented a paper on

THE DIFFERENTIAL DIAGNOSIS BETWEEN GENERAL PARESIS, CERTAIN FORMS OF INTRACRANIAL SYPHILIS, AND THE CEREBRAL TYPE OF DISSEMINATED SCLEROSIS.

He was of the opinion that the tremors of disseminated sclerosis are entirely cortical in origin. He mentioned the interesting fact, to which attention has already been drawn elsewhere, that the tremor of paralysis agitans and that resulting from electrical stimulation of the cortex in the monkey were identical in that the tremors were at the rate of eight per second.

Dr. Webber, of Boston, spoke of the fact that it was perfectly possible to have disseminated sclerosis with no tremor, and thought the paper very instructive.

Dr. Peterson then read a paper in which he described the results of research carried out by him respecting the

CHARACTER OF VARIOUS TREMORS.

He called attention to the fact that both diseases and drugs may produce such abnormal movement, and reminded the Association of the fact, long since discovered, that tetanus is but a frequent discharge of impulses from nervous centres. The tracings which Dr. Peterson showed were very interesting and had evidently been taken with considerable accuracy by means of a modified sphygmograph.

Dr. Sinkler, of Philadelphia, asked whether Dr. Peterson had ever been able to obtain a simultaneous tracing of both knee and ankle clonus. He replied that he had not.

Drs. Lloyd and Deaver, of Philadelphia, reported a

CASE OF TUMOR OF THE CERVICAL SPINE.

The patient presented all the symptoms of cervical pareplegia before the operation, and died three days afterward.

Dr. Shakespeare, who made the microscopical sections of the spinal cord, made some remarks concerning it, in which he expressed the belief that the morbid process seen under the microscope in the anterior portion of the cord was hemorrhagic in type.

Dr. Sinkler, of Philadelphia, presented a paper on

HEREDITARY CHOREA,

in which he reviewed the literature of the subject very thoroughly, and pointed out that the southeastern portion of Long Island seemed to be the point of residence for the disease. The disease is peculiar, other than owing to its hereditary character, in the fact that it seldom appears except in persons well advanced in adult life, never is cured, often is complicated by insanity, and progressively gets worse.

CORRESPONDENCE.

THE WHITECHAPEL MURDERS.

It has been a source of no little surprise to the writer that, considering the universal attention and numerous conjectures raised by this dreadful series of crimes, no clear idea of the character or purpose of the perpetrator seems to have been obtained. While one writer conjectures that the murderer may be a woman, another sees here but a general lesson, and exemplification of the well-recognized law that filth will breed filth, and this is but the natural consequence of the pestilential moral atmosphere in which the inhabitants of a part of London are reared, and in their turn raise their children. To the writer the probabilities in the case seem to point overwhelmingly to the mainspring of *sexual perversity*, which, in an aggravated form, seeks to gratify its morbid desires by victimizing women of the same class, who have at one time been the source of gratification of the normal instinct. Instances of this kind are not rare in literature, and the instinct to victimize the object of the

passion is shown in a scale of progressive crime, from the simpler forms in which the sexual pervert finds it necessary to bite, or scratch, or stick pins into the woman to excite his desire, or to cut or injure in such a way as to draw blood, all the way up to those frightful cases of fiendish barbarity, in which the life of the victim is demanded as a sacrifice to secure the full enjoyment of the sexual act. The writer has thus been, from the very first reading of the peculiar nature of the Whitechapel crimes, fully in accord with the views of Dr. Mills, expressed in the Philadelphia *Press* of October 3d.

The great liability to error on the part of the officers of the law, in the investigation of such cases as the present, lies in the fact that they are misled in their effort to appreciate the *motive*, and invariably attribute it to an *ordinary criminal instinct*. Such, however, is not the case, and it is as impossible for a sound healthy man to conceive the nature of the impulse which impels the pæderest, or other sexual pervert, as it would be to conceive a new color.

The following examples serve to illustrate the peculiarity the instinct exhibits in these cases of adopting and adhering to one particular mode of expression as well as several grades in the criminality.

Tarnowski quotes from Eulenberg (*Vierteljahresschr. f. gerichtl. Med.*, 1878, Bd. 28, S. 61) a curious case, which is but a type of a large number exactly similar in character. Cases in which the sexual instinct is roused by white objects, more particularly the white underclothes of women. The victim of the passion steals these, and retires to his room with the white garment for the purpose of pollution. Sometimes he will wear the wash for awhile.

Brierre de Boismont (*Gazette Méd.*, July 21, 1849, Tarnowski) cites a case, a type of another class, in which the victim of the appetite seeks to gratify his passion by violating the corpses of young females recently died, which he accomplished in more than one instance, by heavy bribes to the watchers. Another case of violation of the dead was one in which a soldier escaped periodically from his garrison, and dug up recently buried corpses, and with great frenzy tore them open and pulled out the entrails and there polluted himself.

The case of the Marshal of France, Gilles de Rayes (S. Jacob, *Curiosités de l'histoire de France. Causes célèbres.* Paris, 1859), is well known, and has a more direct bearing on the horrible instance under consideration. He was condemned to be burnt to death, in the time of Charles the Seventh, for the violation and murder of more than eight hundred children in the course of eight years. He had lived in retirement in his castles in Bretagne, where he had practised the most frightful cruelties upon children of both sexes. He had first been brought to a desire to commit his crimes by reading Suetonius's description of the orgies of the Emperor Tiberius, Caracalla, and others. He was in the habit of burning the bodies of the children, keeping the prettier heads as mementos. "I enjoyed," says the Marshal in his defence, "in this practice the most indescribable pleasure." He confessed to the King that he had left court on account of this irrepressible desire to violate children, and his fear that he would be guilty of carrying out his practices upon the heir apparent.

The conjecture of the writer seems to be supported in the instance before us by a variety of circumstances. A desire to murder without any *apparent* motive, a desire which practises its cruelties invariably upon women, and that of a certain class; added to this the mutilation of the genitals of the corpse, and, in at least one instance, the peculiar practice of slitting open the belly and drawing out the entrails. In addition to this it is of importance to note the periodic outbreak of the crime, in some measure corresponding to the time necessary to recuperation from violent sexual exhaustion.

It would be of importance to search the corpses, when freshly found, for evidences of violation of this kind, although such is not necessary to establish the truth of the supposition. Sexual perverts of this character never *begin* by the commission of crimes of such frightful atrocity, but yielding to impulses to do slight injury to their victims, find, as time goes on, that it is necessary to practise greater and greater cruelties, to arouse their desires and gratify passion, until a stage like the present is reached. Such has with probability been the history of the present murderer.

Aside from the truth or falsity of these views, the lesson is a valuable one. Such cases have repeatedly occurred, and the tendencies which produce them are, not only in Europe, but even in our own midst, rife to-day. While much that has been previously written on this subject has served more to gratify the fancy of the curious, Tarnowski has shown that there is a definite law pervading the whole, producing the more or less frequent appearance of these monsters, as definite as the law of gravity. The victims of the disease are not confined by any means to the debauched lower classes, but circulate in every social circle. They are mostly children of psycopathic parents, of drunkards, and men who have sowed their wild oats in their youth, who vainly imagine that with their resolution to reform and marriage, all evil consequences are left behind them. Such men either generate women who have no sexual instinct at all, or boys who become masturbators or seek by pæderasty or some other abnormal way to gratify their unchaste feelings. They are wretched, nervous, excitable children of a depraved parent. Excess of wealth and excessive poverty breed such diseases. Men who have no need to work, seek pleasure in excesses in which one vies with another to outstrip him in crime. Men who cannot find work they seek, are driven likewise to excesses to drown despair. What more can the guardians of public health and morals do at present than vigorously stamp upon every appearance of such crimes however slight in their beginning, and elicit a full, free, and healthy discussion of this whole subject by medical men?

Howard A. Kelly,
Assoc. Prof. Obst. Univ. of Penna.

NEWS ITEMS.

The Late Dr. E. Williams.—At a meeting of the medical profession, held October 6, at the Miami Medical College, in response to a special call, to take action on the death of Dr. E. Williams, Dr. John A. Murphy was chosen chairman, and Dr. Robert Sattler, secretary. The following resolutions were adopted:

"The death of Dr. E. Williams, the veteran and distinguished oculist of Cincinnati, deprives the ranks of the medical profession of one of its most noted and use-

ful men, and the community loses also a noble and unselfish friend of humanity.

"As a man he endeared himself by his cheery and genial disposition and his unselfish characteristics to his professional colleagues, both old and young, and no one more generously received the appreciation and gratitude of his patients.

"As a physician he was equally esteemed by the profession and the community for his untiring and energetic efforts to promote the advance of medical knowledge, and in particular in the department of ophthalmology. Faithfully and zealously were his best endeavors and most assiduous energy devoted to this important division of the medical sciences. For a period exceeding thirty years he was active as a specialist and devoted all his attention and time to ophthalmology and otology. Justly does he deserve the credit and distinction of having been foremost among a limited number of men in aiding the introduction and establishment of ophthalmology as a recognized department of medicine and surgery in America.

"Throughout this long period he has been constantly identified with medical education. His superior qualifications as a lecturer and teacher gave him unlimited scope of usefulness as a successful instructor, and gratefully will he be remembered by a countless number of students.

"His unlimited capacity for practical work afforded him additional opportunities to aid in the alleviation of suffering, and with unremitting attention he assumed and discharged faithfully the arduous duties of a college, hospital, and dispensary position.

"He was lavish, it may be even said reckless, in his offerings to charity and poverty-stricken patients; but if he erred in giving his services freely and gratuitously, it was only to carry out his desire to do good for the sake of good, reward or no reward.

"The medical profession of Cincinnati herewith acknowledge their appreciation of Dr. E. Williams as a distinguished physician, and unite in their expression of sorrow and sympathy over the announcement of his death."

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM OCTOBER 2 TO OCTOBER 8, 1888.

WILLIAMS, JOHN W., *Major and Surgeon.*—On duty with the Battalion of the Second Artillery, now at Fort Wadsworth, New York Harbor, is granted leave of absence for one month, with permission to apply to the proper authority for an extension of one month.—Par. 1, *S. O. 209, Headquarters Division of the Atlantic, Governor's Island, New York City*, October 4, 1888.

CRONKHITE, HENRY M., *Major and Surgeon.*—On being relieved by Captain Corbusier, will report for duty to the commanding officer, Little Rock Barracks, Arkansas, reporting by letter to the commanding general Division of the Atlantic.—Par. 10, *S. O. 227, A. G. O., Washington*, September 29, 1888.

ADAIR, GEORGE W., *Captain and Assistant Surgeon.*—Is relieved from duty at Fort Brady, Michigan, and will report for duty to the commanding officer, Fort Robinson, Nebraska, reporting by letter to the commanding general Department of the Platte.—Par. 10, *S. O. 227, A. G. O., Washington*, September 29, 1888.

By direction of the Acting Secretary of War, the following named officers of the Medical Department will report, in person, on the dates set opposite their respective names, to the President of the Army Medical Examining Board, Army Building, New York City, for examination for promotion: *Captain and Assistant Surgeon* JAMES C. MERRILL, October 16, 1888; *Captain and Assistant Surgeon* GEORGE MCCREERY, October 16, 1888; *Captain and Assistant Surgeon* RICHARD W. JOHNSON, October 9, 1888. Upon the completion of their examination, the officers named will rejoin their stations.—Par. 5, *S. O. 231, A. G. O.*, October 4, 1888.

CORBUSIER, WILLIAM H., *Captain and Assistant Surgeon.*—On being relieved by Captain Taylor, will report in person to the commanding officer, Fort Hays, Kansas, for duty at that post, relieving Major and Surgeon Henry M. Cronkhite, and reporting by letter to the commanding general Department of Arizona.—Par. 10, *S. O. 227, A. G. O., Washington*, September 29, 1888.

By direction of the Acting Secretary of War, leave of absence for six months is granted WILLIAM B. DAVIS, *Captain and Assistant Surgeon* (U. S. Army).—Par. 12, *S. O 232, A. G. O.*, October 5, 1888.

By direction of the Acting Secretary of War, the leave of absence granted JOHN M BANISTER, *Captain and Assistant Surgeon*, in S. O. 210, September 10, 1888, from this office, is extended one month.—Par. 2, *S. O. 232, A. G. O.*, October 5, 1888.

TAYLOR, ARTHUR W., *Captain and Assistant Surgeon*—Is relieved from duty at Fort Robinson, Nebraska, and will report in person, without delay, to the commanding officer Fort Grant, Arizona Territory, for duty at that post, relieving Captain and Assistant Surgeon William H. Corbusier, and reporting by letter to the commanding general Department of Arizona.—Par. 10, *S. O. 227, A. G. O., Washington*, September 29, 1888.

RAFFERTY, OGDEN, *Lieutenant and Assistant Surgeon* (U. S. Army).—Will stand relieved from duty in connection with the Division rifle competition, the 7th instant, and, under Par. 6, S. O. 2, c. s., Headquarters Division of the Missouri, will return to his proper station, Fort Clark, Texas.—Par. 5, *S. O. 95, Headquarters Department of Texas.*

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING OCTOBER 6, 1888.

HUDSON, ADRIAN, *Medical Inspector.*—Ordered to the Naval Hospital, Mare Island, California.

GIHON, A. L., *Medical Director.*—Detached from the Naval Hospital, Mare Island, California, and proceed home.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE FOUR WEEKS ENDING OCTOBER 6, 1888.

PURVIANCE, GEORGE, *Surgeon.*—To proceed to Washington, D. C., for special duty, October 3, 1888.

STONER, G. W., *Surgeon*—Detailed as Chairman of Board to select a site for the Marine Hospital at Evansville, Indiana, October 5, 1888.

GOLDSBOROUGH, C. B., *Surgeon.*—Leave of absence extended fifteen days, on account of sickness, September 28, 1888.

SEATON, NORMAN, *Assistant Surgeon.*—Detailed as Recorder of Board to select a site for the Marine Hospital at Evansville, Indiana, October 5, 1888.

FATTIC, J. B., *Assistant Surgeon.*—To rejoin his station at St. Louis, Missouri, October 5, 1888.

MAGRUDER, G. M., *Assistant Surgeon.*—To proceed to Way Cross, Georgia, for special duty, September 15, 1888.

GEDDINGS, H. D., *Assistant Surgeon*—To proceed to Camp Perry, Florida, for special duty, September 15, 1888.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL ARTICLES.

THE DIAGNOSTIC SIGNIFICANCE OF THE MITRAL PRESYSTOLIC MURMUR.[1]

BY FRANK DONALDSON, M D.,
CLINICAL PROFESSOR OF DISEASES OF CHEST AND THROAT, UNIVERSITY OF MARYLAND.

THE characteristics of the typical mitral presystolic murmur are well known and ought to be easily recognized. It is a loud, long sound, rough and vibrating in quality, commonly with a well-marked thrill. It is audible over a fixed and limited position—the mitral area—a circle of about an inch around the point where the apex touches the thoracic wall; the direction of the sound being toward the apex. Its maximal intensity is to the right of the apex beyond where the blood current enters the ventricle. It may be heard indistinctly above the third rib and, very exceptionally, in other directions. Its rhythm is at the end of the long pause immediately preceding and abruptly ending at, and with, the first sound. The rhythm of the presystolic murmur, when the pulsations are slow, is easily recognized by feeling the carotid pulse while auscultating, because the pause before the first sound is much longer than that which follows it. But when the beats are more rapid the distinction cannot be drawn, for the increased pace is gained at the expense of the period of rest, and one pause may be as short as the other (Fagge). The designation presystolic is sufficiently appropriate, since the murmur immediately precedes the ventricular systole. These important facts show that it is found during the diastole of the ventricle. The closure of the sigmoid valves, the filling of the ventricles, and the contraction of the auricle, take place during this period of the heart's revolution. With the murmur we often hear pronounced accentuation of the first sound at the apex, and of the second sound over the pulmonary artery, and, also. when it has existed for some time, a reduplication of the second sound.

The blood in the lesser circulation rushes on through the distribution of the pulmonary arteries into the elastic pulmonary veins, thence directly onward through the auricle into the ventricle, continuing its flow until the ventricle, as well as the auricle, is nearly full, when suddenly the auricle contracts on its contents and completes the distention of the ventricle previous to its systole.

Ludwig and Hess showed that the mechanism of the closure of the left auricular-ventricular orifice does not reside in the valve alone; the surrounding muscles of the ventricle have an active share not merely in floating up the valve curtains, but in reducing the size of the aperture which these valves have to close. The papillary muscles keep the curtains tight during the contraction of the ventricle. The whole action of the heart is screw-like, six or seven distinct layers of muscular fibres crossing one another. The base muscles do their share of the work of closure, the valves promptly complete it. When the muscles of the base are enfeebled, the valve curtains are insufficient to close the orifice (MacAlister).

It is a mistake to suppose that the presystolic murmur is always the same. Usually it is the most prolonged of cardiac bruits. It may be very short; so short, indeed, as to be with difficulty separable from the natural first sound. Occasionally it appears like a tone or accentuation of the first sound. In this case the first sound becomes so sharp and clear that it may easily be mistaken for the second sound, which becomes inaudible at the heart's apex, and, unless careful attention be paid to the rhythm, there is danger that the murmur may be mistaken for the normal sound, instead of an abbreviated presystolic bruit.

It is a very variable sound both as to its length, its loudness, and its quality. It is heard at some times and not at others. It may, and indeed often does, follow immediately the second sound, and continue up to the culmination of the first sound, with which it suddenly ceases. It is generally more intense at the ending than at the beginning. Traube says that, if the action of the heart be retarded by digitalis, this murmur ends before the first sound. Flint states that only in one of his cases did the murmur cease before reaching the first sound. It often commences in the middle of the diastole with the auricular systole, and runs up to the first sound. Again, it lessens in volume at the middle, and, rising, ascends to its first intensity.

It sometimes becomes altogether inaudible in the middle of the long pause, and then reappears. In some cases there is an entire absence of a murmur, but instead we hear an accentuated clicking first sound.

[1] Read before the Association of American Physicians, September 18, 1888.

The name of post-diastolic is given, very inappropriately, to the murmur heard immediately following the closure of the sigmoid valves. This sound, though rough, is not blubbering and vibrating. It is generally indicative of pronounced stenosis. The diastole of the ventricle begins with the closure of the sigmoid valves. A bruit that immediately follows the second sound, which, it is admitted, is found at this precise period of the cardiac rhythm, ought to be designated diastolic without prefix of "post." These two murmurs, the presystolic and post diastolic, may be present independently of one another, and when found in the same patient may coalesce, or they may be separated by an appreciable interval.

c and *d*. Irregular presystolic.
(After Gairdner.)

Although much has been written of late about the presystolic murmur, yet all who have had much experience in consultations in cardiac cases will confirm the statement of Broadbent, that it is not infrequently, even now, entirely overlooked and often mistaken for the mitral systolic murmur, the differential diagnosis of which has been clearly established. Formerly it was supposed that the presystolic murmur was rarely found, but closer observation has shown that it is of frequent occurrence, especially among women and children. Flint observed it in sixteen out of thirty-nine cases of mitral disease. Its grave prognostic significance alone justifies the attention that has been given to it.

In this paper, I shall only detain the Association by a brief study of the factors entering into the production of this interesting murmur when of organic origin.

There must be two factors in the production of "fluid veins," whether they are obstructive or regurgitant: the lesion, and the propelling force, together with the other well-known influences, modifying blood pressure. For the generation of sonorous fluid veins, we must have the passage of a jet of blood forced through a narrow constriction into a wider cavity or part of a vessel.

It is acknowledged that mitral stenosis is the lesion in a very large majority of cases in which a presystolic murmur is heard. Many prominent authorities believe that this lesion is invariable. The constriction is frequently found at post-mortems in cases in which there had been no presystolic murmur detected during life.

The mitral valves and the auricular-ventricular orifice are specially liable, in early life, to valvulitis from acute or subacute rheumatism and other causes, such as scarlet fever, measles, or chorea. These leave formations of connective tissue which narrow the orifice itself in the annular forms or by diaphragmatic partitions with buttonhole orifices, or the leaflets adhere together and produce funnel-shaped constrictions. In some instances the valves lose completely their natural formation. These new conditions are most favorable to the production of murmurs, which are due to oscillations in the blood itself. The current of blood passes through a small opening into a wider cavity, and is divided up into a number of jets, forming fluid veins. The rapidity and force of the current must cause variations in the intensity of the sounds.

The obstructive lesion of the mitral orifice, it must be borne in mind, is of very gradual formation, of months or of years. It commences often insidiously. The auricular-ventricular orifice is so large that it can bear some lessening of its size without seriously interrupting the proper filling of the left ventricle. Thus stenosis may be sufficient to produce the vibratory sonorous murmur, without any marked subjective symptoms.

While admitting that stenosis of the mitral orifice is, in a very large proportion of cases, the pathological lesion met with where this murmur is found, yet there are numerous cases reported in which the mitral orifices were not altered in size, but in which other obstructive and narrowing conditions were found inside the ventricle—such as shortened chordæ tendineæ, thickenings and rugosities about the leaflets of the valves or in the walls of the ventricle, to account for the production of the characteristic prolonged, blubbering, presystolic murmur. Wherever and whenever we find physical conditions to produce "fluid veins" with vibratory phenomena, we can have the same sound. We need not recall Flint's three cases in which aortic insufficiency, as demonstrated at post-mortems, produced functional murmurs with the characteristics of the mitral presystolic murmur. Dr. Bramwell has published such a case, and Dr. Guitéras reported three. Sansom speaks also of cases somewhat similar to Flint's. Osler has had a well-marked instance.

The writer has never clinically met with such a case, but he has heard aortic diastolic murmurs where there were marked accentuation and shortening of the first sound, similar to the effects met with in cases of mitral stenosis. While it is true that such cases have been reported by the most competent auscultators, they are in fact but rarely met with. There is, however, no *a priori* reason why they could not exist. Aortic regurgitation murmurs are diastolic in time, and if, as Flint claims, the leaflets of the mitral divide the reflow current in the same manner as in the production of the murmur at the auricular-ventricular orifice, the sounds may be formed and a prolonged murmur of presystolic rhythm with the blubbering vibrations may be heard. Dr. Guitéras maintains that this functional presystolic mitral murmur is more frequently heard than Dr. Flint supposed. Balfour, Nixon and Sansom, and others think differently. There can be no doubt that the diastolic aortic murmur can be conducted to the apex by the solid walls of the hypertrophied ventricle, the current of blood itself as well as by the sternum and walls of the chest. The infrequency of these functional mitral murmurs, when there is an aortic insufficiency, is difficult to explain.

Dr. Balthazar Foster suggests an explanation of how this murmur is heard best at the apex: That different valves are affected in different cases, and that, if the left sigmoid near the mitral is affected, the blood falls directly back into the ventricle and the bruit is heard best at apex; whereas, if the right or posterior sigmoid valve is diseased, the regurgitant blood impinges on the septima and the bruit is carried down the right side of the heart. Dr. Guitéras maintains that these propagated murmurs are in fact mitral obstructive murmurs, and that they are more apt to develop when the posterior aortic segment is affected, because in such cases the recurrent stream is brought directly against the anterior leaflet of the mitral valve.

Dr. Bramwell (*Diseases of the Heart*) refers to a case of rupture of the posterior coronary segment of the aortic valves in which no presystolic murmur was audible. There must be some unusual physical condition which has not yet been appreciated.

There is also a murmur which Barlow, Leaming, Flint, and Donaldson have designated as intraventricular, which, when there is much hypertrophy of the left ventricle, seems to occupy the first portion of the systole. This resembles the qualities of the presystolic, and, when the heart is beating rapidly, may be confounded with it. Of course, in diagnosticating mitral stenosis, everything is taken into consideration, together with the murmur.

Let us inquire from what sources the necessary force of the blood-current is derived. Dr. Gairdner taught that it is produced by the systole of the left auricle, and he accordingly named the adventitious sound the "auriculo-ventricular murmur." This could not possibly apply to the sound which exists before the contraction of the auricle, which, in health, occupies one-fifth of a second of time, and immediately precedes the systole of the ventricle. The feeble force of the auricle in health was shown by Chauveau, who, by prolonged irritation, exhausted its contractility, and found that the ventricle continued to act effectively, and kept up the circulation. Ludwig confirmed this result by introducing a tube through the auricle. In fact, the auricle may be regarded as the dilated termination of the pulmonary veins, acting as a reservoir to supply the ventricle, and to regulate the blood-pressure in it. The auricular cavities are never completely obliterated during contraction, though this does not appear to be the case with the auricular appendages.

We may ascribe the production of the presystolic murmur, in beginning obstruction of the mitral orifice, to the force of the left auricle. Temporary compensation is promptly established in the force of the circulation. It seems that there is a reserved force, as in involuntary muscles, which is called forth in the emergency.

We further admit that, as the result of obstruction at the mitral orifice, impeding the influx of blood into the left ventricle during the diastole, the left auricle, having extra work to perform, does become first dilated and subsequently hypertrophied. Indeed, percussion, in rare instances, reveals abnormal bulging over the auricle, and frequently the pulsation of the auricle is perceptible about the fourth rib. The walls of the left auricle, which are normally about one and a half lines in thickness, may be increased to as much as a quarter of an inch, with proportionate augmentation in strength. It may be that the prolongation of this bruit is due to this hypertrophy, but it is almost incredible when we know that it is the longest, as well as the most irregular and vibrating, of all cardiac murmurs. We question whether it is a force sufficient by itself to overcome the resistance caused by advanced mitral constriction, and to give us the acoustic characteristics of the presystolic murmur.

It must be borne in mind that the auricular systole does not occur until the very last portion of the diastole, and the murmur often begins after the second sound, and includes the so-called "post-diastolic." These phenomena occur previous to the auricular systole. We readily admit that its influence is shown in reinforcing the intensity of these murmurs.

In mitral stenosis the auricular portion of the cardiagrams is of longer duration, and its tracing higher, because the left auricle is dilated, and contracts with force, emptying itself with difficulty; it often shows a series of wavelets, giving it a serrated appearance corresponding to the purring thrill felt

by the hand. Ott, Hess, and Galabin attribute the late closure of the pulmonary valves to the diminished elasticity of the artery in consequence of long-continued high pressure.

FIG. 3.

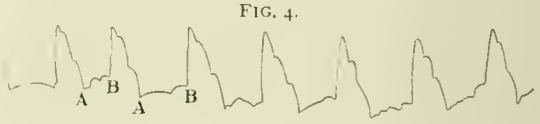
A B. Auricular systole. D. Aortic closure.
B C. Ventricular systole. E. Pulmonary closure.
E F. Ventricular diastole.

The cardiagram of the normal heart (see Landois's *Physiology*) proves that the aortic valves close a little before the pulmonic valves. They close, however, so near together that only a single sound is heard. In mitral stenosis (stage of non-compensation) the aortic valve closes sooner, and the pulmonic valves later than normal. This is because the left ventricle contains less blood, and the right more than normally. There results what is called a reduplicated second sound, which is an increase of a physiological condition. All conditions which cause the aortic valves to close rapidly (diminished amount of blood in the left ventricle), and the pulmonary valves to close later (congestion of the right ventricle)—both of which exist in mitral stenosis, favor the production of a reduplicated second sound, which occurs in one-third of the cases of mitral stenosis.

If mitral contraction occurs at a very early period of life, whether as a primary affection, or secondary to a corresponding narrowing of the tricuspid, other parts of the circulatory system become accommodated to it, and the patient may reach adult life before the lesion produces any symptoms—the post-mortem revealing the fact of the organic defect. Dr. Wilkes reports cases in which resulting hypertrophy of the right side in children was so great as to cause bulging of the chest, and in which the pulmonary artery partook of the hypertrophy, and became thicker than the aorta. On the other hand, cases occur in which, owing to mitral stenosis early in life, so small a quantity of blood is thrown into the left heart that there is imperfect nutrition of the whole body, which accommodates itself to the defect. Hypertrophy of the right ventricle and the left auricle compensates so thoroughly for the deficiency, that there may be no subjective symptoms, and no bruit, perhaps, beyond an imperfect first sound.

Dr. Gairdner did not ascribe the production of the presystolic murmur wholly to the muscular contraction of the auricle. Dr. Wilkes held that the murmur might anticipate the auricular systole, and that it might occur not only at that time, but also during the heart's diastole and pause. Dr. Galabin came to a like conclusion from the evidence afforded by the cardiograph. Dr. Sansom claims that the causation of the presystolic murmur may be independent of the auricle; he states "that in many cases he had observed that though there had been a prolonged presystolic murmur commencing in the long pause almost immediately after the second sound, cardiographic evidence has shown the auricular systole to occupy its normal position just anterior to the commencing contraction of the ventricle." He cites a case in which a murmur occupied at one time a portion and at another almost the whole, of the long pause, and the autopsy showed that the auricular systole could have had no share in producing such a murmur, for not only was the left auricle so dilated that its walls could have exerted no appreciable muscular power, but it was lined by a closely adherent, old, laminated blood-clot. It thus appears

FIG. 4.



Sansom's case, showing mitral stenosis, while auricular systole is in normal position. A B. Auricular systole.

that the post-diastolic murmur, as well as the presystolic, may be caused in the diastole, and be due to the entrance of the blood independently of the auricular systole, it being urged through the stenosed aperture, owing to the tension under which it has been retained in the elastic and distended auricle and pulmonary veins.

We feel justified in concluding that the systole of the left auricle is a factor of greater or less force in the production of this mitral direct murmur, but it is not the only one, and the others may produce it independently of the auricular systole.

Negative pressure. Let us see whether any negative pressure is brought to bear upon the left auricle and pulmonary veins to assist in getting the current into the left ventricle. Is there any suction action of the left ventricle of the heart? Until the publication, in 1878, of Goltz and Gaule's experiments, the majority of physiologists attached little or no importance to any suction action of the heart, although in all times there have been zealous advocates of the doctrine that diastolic suction was an important factor in the circulation. Goltz and Gaule, by the use of ingeniously constructed maximum and minimum manometers, determined the maximum and minimum pressures in the left and in the right ventricle. They found with natural respi-

ration, in the left ventricle of a dog, a negative pressure of 52 mm. of mercury. In the right ventricle there existed, in another case, a negative pressure of 17.2 mm. of mercury.

In accordance with the generally accepted ideas, they at first were inclined to attribute this negative pressure to the expansion of the chest during inspiration. To their great astonishment, however, they found, after the chest was opened, and independently of respiration, a negative pressure in the left ventricle of 23.5 mm. of mercury. This latter negative pressure, therefore, cannot be due to the elastic traction of the lungs. They attribute it to the elastic resilience of the ventricle following the systole, like that after compression of an elastic balloon. They say: "The adherents of the doctrine, according to which the heart acts as a suction-pump, will find their boldest expectations surpassed when they hear that the suction force of the left heart of a large dog, at the beginning of the diastole, is equal to a column of water 320 mm. (23.5 mm. of mercury), and that this force in a healthy man is probably even much higher." (Goltz und Gaule: "Ueber die Druckverhaltnisse im Innern des Herzens," *Pflüger's Archiv*, 1878, Bd. 17, S. 100.)

In 1879, Moens published an article ("Die erste Wellengipfel in dem absteigenden Schenkelder Pulscurve," *Pflüger's Archiv*, Bd. 20, S. 517, 1879), in which he attempted to show that the negative pressure found by Goltz and Gaule existed, not during the diastole, but during the systole. In order to make clear how a negative pressure might be produced at this period of the heart's action, he takes an elastic tube open at one end and connected at the other by means of a stopcock with a pressure-bottle. If the stopcock be suddenly closed while the fluid is flowing from the bottle through the tube, there is a negative pressure produced in the tube, beginning near the stopcock. Likewise, in the left ventricle, he argues that, as the blood is shot out by the ventricular contraction into the aorta, a negative pressure is produced in the ventricle. His chief inference, that the negative pressure is present during the systole and not during the diastole, was because a minimum manometer, passed down the jugular vein into the superior vena cava, failed to register negative pressure, as would be the case if the right ventricle exerted diastolic suction. He regards this experiment as proving that the negative pressure is not during the diastole, otherwise there would be a suction force exerted on the blood in the right auricle and vena cava superior. If the negative pressure is not during the diastole, it must be during the systole.

It will be observed that Moens does not actually demonstrate that the negative pressure is during systole. He infers it indirectly. On the other hand, he seems to have overlooked the fact that Goltz and Gaule found a negative pressure in the right auricle of 11.2 mm. mercury (this might have been due to inspiration), the negative pressure in the right ventricle, in the same case, being 17.2 mm. mercury. Moens is quoted by Martin and Donaldson, Jr., as having shown that the negative pressure exerts no suction force on the blood in the auricles.

In consequence of the doubt which Moens's work raised as to the period at which negative pressure existed in the ventricles, de Jager, in 1883 ("Ueber die Saugkraft des Herzens," *Pflüger's Archiv*, Bd. 30, S. 491), published experiments on this question, and came to conclusions in opposition to Moens's and in confirmation of Goltz and Gaule's. De Jager determined that the pressure at the beginning of the aorta never becomes negative, as it should be in case the negative pressure in the ventricle were due to the suction of the column of blood poured out from the ventricle. He also found that with the chest open, so that the action of inspiration on the aspiration of blood into the right heart was removed, the pressure in the right auricle becomes negative. He found negative pressures in the right auricle of 2 mm. to 6 mm. mercury. He does not believe that the auricles themselves are capable of exerting any suction force, and he, therefore, concludes that this negative pressure in the right auricle can be interpreted only as evidence of a suction exerted by it, which, of course, can occur only during diastole. The same conditions would, of course, obtain for the left cavities of the heart, as the experiments were made with the chest open. De Jager, therefore, concludes that a strong diastolic suction force is exerted by the ventricles.

As regards the causes of this suction force he mentions several possibilities, without coming to a decision. These possibilities are:

1. The elastic force developed during the systole, as in the compression of a rubber balloon.

2. The suction force on the exterior of the heart resulting from the negative pressure in the thorax (or the elastic traction of the lungs). This, of course, can be only one element, as negative intraventricular pressure is found after the thorax is opened.

3. Shortening of the large arteries coming from the heart.

Brucke inclines, as do Goltz and Gaule, to consider these factors as the essential ones.

Gruenhagen holds that Goltz and Gaule and de Jager have established the fact of a diastolic suction action of the heart.

The experiments of Martin and Donaldson, Jr., however, on the mammalian heart, at the Johns Hopkins University, are opposed to the existence of any suction action of the heart. Their experiments are exact, and, it would seem, quite conclusive

against the suction theory. It is difficult, however, at present, to reconcile them with Goltz's, Gaule's, and de Jager's experiments. They have the merit of putting the matter to a direct test, whereas the other experiments do not actually demonstrate a suction action, but leave it as an inference. They say:

"The negative pressure proved by Goltz and Gaule to occur in the ventricles for a brief period at the end of the systole, had already been shown by Moens not to affect the auricles, and, therefore, to be without effect in making the heart a suction pump as far as the venous system was concerned.

"Once the 'aspiration of the thorax' has been eliminated, the right auricle of the mammalian heart will not receive blood unless supplied to it under a decided, if small, positive pressure. While the heart in the closed thoracic cavity may, and probably does, act as a suction pump, this is not due directly to an active expanding force of the heart, but is the secondary result of the pneumatic conditions prevailing within the normal closed chest cavity."

If a suction action exists, it is evidently a factor not to be neglected in the study of mitral stenosis. All that increases the suction action, increases the force with which the blood passes through the narrowed mitral orifice and doubtless increases the murmur. De Jager found that when the action of the heart became feeble—as after long exposure, or by cooling, or by loss of blood—then only a slight negative pressure, or none, was produced in the ventricles. We may, therefore, infer that all circumstances which enfeeble the action of the left ventricle diminish correspondingly the force of suction, and, therefore, the murmur. Such circumstances are failure of the heart's force from any cause, among which may be noted atrophy of the left ventricle in pure mitral stenosis. In general, whether the left ventricle is atrophied or not, the small amount of blood which it receives through the narrowed mitral orifice during non-compensation must be attended with a weaker systole, and, consequently, diminished suction and lessened murmur. All this line of argumentation, of course, is not pertinent, if we accept the doctrine that no suction force is exerted by the ventricles.

Let us further inquire whether any other force is connected with the passage of the blood through the left ventricle. We hear of the blood's passive flow through the mitral orifice. Has it no power? The right ventricle, which propels its contents with a strong wave through the pulmonary arteries and with comparative ease, owing to the absence of tonus or resistance, and of vasomotor influence to contend against, forces the blood into the pulmonary veins and through the left auricle into the ventricle. If it meets with any obstruction, the backward pressure would, of itself, add to the onward blood pressure in the pulmonary veins, although the right ventricle promptly exerts its reserved compensatory force. If the obstruction continues, the extra work of the right ventricle gradually produces permanent hypertrophy which keeps up the compensation. When this is broken, there results the disastrous backward flow of venous blood with all its unpleasant consequences upon the lungs, liver, and other internal organs. This occurs, notwithstanding the protection afforded to the process of intra-pulmonary respiration, as shown in the safety-valve construction of the tricuspid valve (King), of the pulmonary semilunar valves (Flint, Jr.), and of the obstruction safety-valve principle of the pulmonary valve (Guitéras). The increased tension at the pulmonary valves gives accentuation of the second sound. Nature further provides a relief to the lungs by the increased capacity of the right cavities by from one-tenth to one-third over the corresponding cavities of the left side.

The right ventricle becomes very gradually hypertrophied. In some cases the enormously thickened walls completely cover the left ventricle and prevent our hearing the second sound at the apex and a very feeble impulse is noticed. The left ventricle, owing to the insufficient supply of blood through the auricular-ventricular orifice, is often not only not hypertrophied, but actually materially lessened in size—indeed, in a state of atrophy, unless there is also insufficiency of the mitral orifice as a complication. This additional lesion may cause hypertrophy of the left ventricle. May not the powerful right ventricle, by the blood pressure it causes in the pulmonary veins, be a prominent factor in causing variations in the length and intensity of the post-diastolic and the presystolic murmurs in mitral stenosis?

If this hypertrophy be very marked, may it not be the propelling force producing the long sound commencing immediately after the systole and occupying the whole of the diastole? If the force be feeble, it may only produce the post-diastolic and cause the deficiency in the middle of the distance between the second and first sound. When the patient is in the recumbent position and the heart is quiet the murmur is often inaudible; on changing the position it may be heard. Active exercise increases in marked degree the intensity of the murmur. When dilatation succeeds, hypertrophy of right ventricle and tricuspid insufficiency take place—the forces are not powerful enough to cause the murmur. The auricular systole, if dilatation has not made the walls too feeble, may give rise to the presystolic. The increased power of the hypertrophied left auricle and right ventricle certainly would cause the fluid veins to be audible vibrations in obstructive mitral disease. As the muscular power leaves the excessively enfeebled patient, the sound utterly disappears. Indeed, it is very remarkable how the murmur sometimes dis-

appears, temporarily or permanently, the condition of valve being unaltered.

To sum up (says Dr. Galabin, in his elaborate and able paper on, "Interpretation of Cardiographic Tracings," *Guy's Hosp. Reports*) the inferences suggested by a general review of all the tracings, it appears that the evidence of the cardiograph is in favor of the view that two totally distinct murmurs may be caused by mitral contractions: first, the auriculo-systolic bruit, which may either run up to the first sound or be separated from it by a short interval; and, secondly, a diastolic bruit, due to the venous flow through the narrow and roughened orifice, which in rare cases may be blowing in quality and separated from the succeeding systole by a long pause; and that, thirdly, these two may be merged together into a compound murmur somewhat rough from its commencement, but much intensified in loudness and harshness toward its conclusion.

Marey, in some experiments by means of which he reproduced the various sounds and murmurs of the heart, the auricle of which was not contractile, introduced a plug perforated by a hole between the auricle and ventricle, and then found that a diastolic murmur was produced, but only when the auricular pressure exceeded a certain point. Hence, he concludes that the murmur of mitral stenosis may be either diastolic or auriculo-systolic according to circumstances.

How far is our estimate of the pressure in the pulmonary veins justified by experimental research? From this source we possess but little positive knowledge. Beutner seems to be the only authority who has published any actual measurement of the blood pressure in the pulmonary veins. He found a positive pressure of 10 mm. of mercury in the pulmonary vein of a cat. In the pulmonary artery of a cat he found a pressure of 17.6 mm. mercury. These pressures were, of course, measured with the thorax open, so that we cannot attach absolute value to them. They indicate however, that, relatively to the pressure in the pulmonary artery, the pressure in the pulmonary vein is high, the pressure in the veins being more than one-half that in the artery. The pressure in the pulmonary vein, according to Beutner's measurement, is, moreover, absolutely a high one when compared with the very low pressure in the veins emptying into the right auricle. The pressure which Beutner found in the pulmonary artery is much lower than has been found by subsequent observers. The accepted belief is that the pressure in the pulmonary artery is one-third of that in the aorta; Goltz and Gaule regard it as two-fifths of the aortic pressure. If the ratio which Beutner found between the pressure in the pulmonary vein and that in the pulmonary artery holds true, then we may conclude that the pressure in the pulmonary vein is even higher than his observations indicate.

Inasmuch as actual measurement of the pressure in the pulmonary vein can be made only when the thorax on one side is open, the question arises: What influence upon this pressure has the elastic resilience of the lungs under the normal conditions of respiration? If the walls of the pulmonary artery and those of the pulmonary veins were of the same thickness, then, inasmuch as both vessels were subjected to the same intra-thoracic pressure, it is evident that changes in the intra-thoracic pressure, corresponding to the different phases of respiration, would not influence the blood pressure. The walls of the pulmonary veins, however, are thinner than those of the pulmonary artery, therefore the aspiration of the thorax must tend to lower the pressure in the pulmonary veins more than in the pulmonary arteries. It is impossible to say how great is this influence of the elasticity of the lungs upon the pressure in the pulmonary veins.

The feeble tonus of the vessels in the pulmonary circulation is of the utmost importance, as changes in pressure in the pulmonary veins are quickly manifested in the pulmonary arteries and *vice versa*. This circumstance justifies us in assuming that change of pressure in the pulmonary artery is attended by corresponding changes of pressure in the pulmonary veins, so that changes in the force of contraction of the right heart exert a much more direct influence upon the circulation of blood in the pulmonary veins than in the left heart and the systemic veins.

Cohnheim says: "The blood in the pulmonary veins is, under physiological conditions, not like that of the systemic veins under negative pressure when it enters the heart, but is under a positive pressure which is only a little less than that of the blood in the pulmonary artery." (*Vorlesungen, über allgemeine Pathologie*, Bd. 1, S. 28, Berlin, 1882.) This statement of Cohnheim does not seem to rest upon actual measurement, but to be based upon the slight resistance offered to the blood in the passage from the pulmonary artery to the pulmonary vein, and upon Beutner's measurement with open thorax. He found the pressure in the pulmonary vein more than half that in the pulmonary artery. As no means have been found which enable us to measure the pressure in the pulmonary veins under natural conditions, we are left to such inferences as the above.

PERSONAL OBSERVATIONS ON SKIN DISEASES IN THE NEGRO.[1]

By ROBERT B. MORISON, M.D.,
of Baltimore.

The study of skin diseases in the negro offers some points of interest which it may perhaps be well to

[1] Read before the American Dermatological Association at the Congress of American Physicians and Surgeons in Washington, 1888.

note in order that the attention of those among us who come into contact with this race may be called more particularly to the difference of the lesions as compared to the white race.

A difference in the symptoms and general appearances would, from the nature of the race, suggest itself before experience had taught one the fact. In a dispensary such as the one here quoted from, where fifty per cent. of the skin cases are black or modifications of black, an opportunity is offered for close observation of certain peculiarities which deviate from the ordinary or orthodox symptoms seen in the whites. It may be due to this race that the American dermatologist is so often quoted as saying there is a difference between skin diseases in America and in Europe. The negro race does present a modification of such diseases, thereby rendering the total average of skin symptoms somewhat different to the European stereotyped forms, but when considering the white race the specialist, from my own observation, meets the same diseases here as there, leaving out of the question those which are rarely, if ever, seen in this country.

There is, however, something in the appearance of skin diseases in the black race which might confuse an European specialist who was unaccustomed to seeing them, for they seem to be less liable to skin diseases of a severe type than the whites. They suffer in the aggregrate as often, but far less severely. Their skins are less sensitive to heat, poisons, irritants, nervous lesions—disease of the nerves being a theoretical method of explaining unknown causes—to constitutional or to general influences.

My attention being attracted by such differences, notes were begun by which a more careful comparison could be made over a series of years and a certain number of cases. In the record made on the dispensary books the color of the patient was noted, whether dark or light—that is, whether true black or mulatto, and they have thus been kept for three years, making a sufficient number to show by percentage and histories wherein the differences have presented themselves to me.

It is hardly necessary to state that the normal skin of the black race is histologically more coarse and thick than that of the white. It is composed of more dense fibrous tissue, the glands are larger as are also the nerves and vessels running into the papillary layer. The epidermis is thicker and slightly yellowish in color, thereby adding somewhat to the general color of the skin. The blackness of the pigment granules determines the color of the skin, there being no appreciable difference in the thickness of the pigment layer between the true black and the mulatto. There are fewer elastic fibres in the negro skin and more subcutaneous adipose tissue than in the white. The nerves, though larger, are less sensitive both to external and internal agencies. These histological differences may help to explain the modified symptoms which their skin diseases present.

I have tabulated, for the purposes of comparison, 500 cases of each race—the black and the white—and shall run over each disease as it comes up alphabetically. These cases were taken from the last three years of the dermatological clinic of the Baltimore Polyclinic and represent all the cases without exception up to 500 which have been recorded within that time.

The table of the blacks is divided into those who are black or true negroes and those who are mulattoes. I consider this an important division, as most generally the nearer the color approaches to white the less difference there is in the lesions.

The first disease on the list is *Acne*. Acne in the black is a rare disease. Out of my 500 cases only 9 are acne and they all were mulattoes. The white list shows 39, which is four times as many. Out of all the cases of the negro seen in private or public practice and of all the negroes purposely noticed in passing, it has been rare to discover an acne in the black. I have had only one case in private practice.

It appears in a mild punctate form, does not become indurate, and is easily cured by local applications. Itching accompanies it, according to the statement of the patients. No cases of rosacea, of rhinophyma, or coachman's nose, were seen.

The diagnosis is easy, differing from the punctate form of the whites only in the color of the surrounding skin and in the absence of redness in the papules.

Ainhum is a disease of the negro race and the two cases reported were both in black negroes who were sailors. One of them had previously lost the little toe of the left foot, he being now troubled with the disease in the little toe of the right foot. There was no history of self-mutilation. They seemed both above the average negro in intellect.

Chancre presents no differences excepting in the amount of induration, which is greater in the negro. One of those reported here and one of those reported in the white list were upon the upper lip of a female.

Chilblain is a common disease in the negro. It is less intense in the inflammation than in the white, but there is more itching and it is more chronic. In this record of ten cases there is no difference between the frequency of it in the black and in mulattoes. It seldom is so troublesome as to call for a physician's advice, but there are few negroes who will not say when asked, as I have found, that they are martyrs to chilblain.

Chloasma is a common disease in negro women. Few think it necessary to undergo treatment for it, but I have often noticed it when they come for some other trouble. Its appearance is that of a loss of pigment. In the black woman there is a yellowish spot on a dark back ground. Treatment is consequently reversed: we must produce pigment not abstract it.

Elephantiasis Arabum in the negro in this country usually follows syphilis, as in the two cases here observed. One of these was diseased in both vulvæ, which were finally removed by the knife. An interesting arrangement of the pigment in the histological specimens made from this case was reported previously by the author in The Medical News of April 23, 1887.

Erythema multiforme appears in small or large spots without redness, but with burning and itching which so much overshadow the other symptoms that doubtless many cases are overlooked. There has been such violent scratching as to produce a confusion in diagnosis. The cases here reported were in their incipiency, on the back of the hands and arms of two black females who washed for a living. The patches were slightly indurated raised above the surrounding skin, different in size, whitish upon their surface, and rendered pale upon pressure. In places there was evidence of scratching and rubbing, so that some of the patches were obscured.

Erythema nodosum is represented by two mulatto women and was situated upon the legs below the knees. The nodes were raised, copper-reddish, large, indurated, painful, and itching. They disappeared promptly under tonic treatment. The pain in these cases was less than in the whites, but the itching greater.

Eczema. Acute eczema is much less common and much less severe in the negro than in the white race. Out of 500 cases there were recorded 96, which is about 19 per cent. This is a much smaller percentage than is usual, for we see out of the 500 whites there are 160 acute eczemas, which is about 30 per cent. of the whole, the usual percentage in dispensaries. Looking at the record more closely, we notice that there are fewer cases among the true negro than the mulatto—40, or less than half, being dark. The majority of cases reported among the dark females are due to washing and are localized upon the hands.

I have no case of acute universal eczema recorded among the dark male or female. There are favorite situations for it to appear in this class, such as the instep or heel, the back of the hand, the neck, the knee-joint, and armpit. It appears in spots, dry and scaly, with a grayish-white, dirty-looking, thin crust covering them. They differ in size, from a ten-cent

piece to twice the size of one's hand. They itch constantly, but not intensely. They have the appearance of spots of dust upon a black coat, which may be brushed off. E. rubrum, papulosum, or vesiculosum universale I have not seen among them. The babies, however, do sometimes have a modified form of milk-crust, which approaches nearly to an ordinary moist eczema.

Among the mulattoes there is little difference between them and the whites in their symptoms. Their babies suffer from milk-crust just as frequently, and they themselves pass through an attack of acute eczema in the same way. They seem, however, more amenable to treatment, and less liable to intense itching than the whites.

In chronic eczema we find that the black negro outnumbers the mulatto. Of the 20 black females, 15 have washerwoman's eczema of the hands, the other 5 being spots upon the head or neck. The men have had theirs produced by oyster shucking or other occupations. These eczemas take on a form of keratosis, which nothing but change of occupation will cure.

Chronic eczema in the mulatto does not differ from that of the whites, other than that the itching is less acute.

Favus is rare in the negro. The short wool which covers the head, and which, even in babies, is, according to their custom, most often kept closely shorn, accounts for this fact. The parasite does not get a chance to grow. It is easily got rid of by treatment.

Furunculosis is a disease which is apparently infrequent in the negro, although the smallness of the number in this record is probably due to the fact that such cases are turned over to the surgeon.

Herpes facialis is a common disease among negro babies; so common that it is rarely thought necessary to consult a physician. It is, to a great extent, produced by the so-called "sugar-teat" which pickaninnies are allowed to suck constantly. The "sugar-teat" is a piece of fat bacon dipped into brown sugar or molasses, and wrapped in a piece of old linen cloth. This form of herpes takes the place of milk-crust in the negro, and is the only form of simple herpes here recorded.

In *herpes zoster* the pain preceding the eruption in the black is less severe, and less prolonged than in the white. There is decided itching rather than pain or burning, and when the vesicles appear they are white, on a black, somewhat indurated ground, containing the usual quality and quantity of serum. They sometimes leave—as in one of the cases here reported—pits, with loss of pigment, which last the rest of life. Slight keloidal growths sometimes follow in the wake of the largest vesicles.

The symptoms of *impetigo contagiosa* are indistinct, and not so characteristic as in the whites. The eruption is not profuse; there is little or no coalescing of pustules. There is considerably more itching, and the crusts formed after scratching are more yellow. Upon their removal they disclose a slightly reddish, glossy surface, which soon heals, leaving for a while a whitish spot. It is not very contagious, and it may be confounded with herpes in diagnosis.

Keloid. Negroes are much more prone to keloid than the whites. Two of the cases here reported were the result of smallpox, the keloidal growths surrounding the pits, making a network of hypertrophied eschars resembling the surface of a raised map. Such a result is not uncommon after smallpox in the negro. The third case reported followed piercing of the ears for ear-rings, and the size of the growth was gradually increasing. All these cases were in the black or true negro. Keloid in the mulatto is almost as rare as in the white race, and it does not grow with such rapidity as in the black.

Lupus appears to be uncommon in the negro. In view of the fact that this disease is now called tuberculous, it seems rather incongruous. The negro is supposed to be especially susceptible to tuberculosis. He lives in a meaner and far less healthy hygienic condition than his white neighbor; the moral tone and promiscuous intermingling of the sexes are not conducive to strength of body or cleanliness of the skin, and yet a disease like lupus, which is apparently the outcome of such poor surroundings, is rarely seen among them. One of the cases recorded was that of a black girl, nineteen years old, whose cheeks, nose, chin, and lips were diseased. The mucous membrane of the nose and pharynx was also affected. Spooning and cauterization resulted, as might have been foretold, in the formation of a keloid half an inch wide, occupying the outer edge of disease upon the cheeks. Progress in this direction was stopped, while the rest of the surface within the keloidal circle has from time to time broken out afresh.

By the application of mercurial plasters and the use of electrolysis the keloid has been diminished to one-third its former size. There is a curious-looking white line an eighth of an inch in width stretching along the outer border of the keloid and the tubercles of the diseased portion heal by leaving a whitish spot behind. The patient is a large, robust, otherwise fine-looking young woman without any symptoms of tuberculosis elsewhere.

Lymphadenitis. Universal enlargement of the glands is very common in the mulatto, not so much so in the black. It is more common in both than in the white race. The lymphatic glands and vessels are histologically larger and are easily affected by an inflammation. Being liable to glandular enlargement from slight causes other than syphilitic such enlargement does not mate-

rially assist in making a diagnosis of specific or of syphilitic disease. The cervical, inguinal, and other superficial lymphatic glands of young healthy negro children are often quite prominent and remain so during life. Suppuration is slow, while absorption of an enlarged gland by any means tried is seldom successful.

In the case of *molluscum contagiosum* observed the disease was upon the scrotum and penis, resembling the same disease in the white excepting that the contents of the small tumors were darker in color and mixed with pigment granules. Whitish spots remained for a while after the removal and healing of the tumors.

Pediculi. For the same reason that favus is rare—that is, because the head is so closely shorn, do we seldom see head-lice in negro children or men. The lesions produced by body-lice are slight and oftentimes unnoticed by the one bitten. The black man is somewhat impervious to the louse bite as he is to bed-bugs and mosquitoes. The poison of these venomous insects seems to be lost on the ebony color and texture of their skins.

Pruritus. Under this head I place all the troubles of the skin in the negro in which there is itching but no visible eruption. Apparently they have some of the diseases which white people have only in this form. It is very common to hear them complain of what they call an "eetching in the blood." When uncovered there is nothing to be seen but a rough black skin which feels hard and dry. The surface has lost its gloss and its elasticity is lessened. This condition of the skin I have only seen in the black, not in the mulatto. It is most often localized in such places as the front of the arms and legs and sides of the abdomen. The itching is constant, but not severe enough to cause traumatic scratching. The troublesome places are rubbed with the hand, seldom scratched. It does not fly from spot to spot, does not interfere with the occupation, and is most worrying at night. The treatment, which consists of hygienic measures combined with friction, is efficacious and seems to point to the cause as lying in an extra accumulation of effete epidermic cells.

In *psoriasis* the spots are covered with a more yellowish, less shiny crust than in the white. When punctate the crust is thicker than usual and is easily rubbed off. It then leaves a deep red, bleeding surface, the blood oozing freely from the minute vessels. As in other diseases of this race in which there is a sufficiently thick amount of epidermis removed, a white spot remains for a while after healing. In the orbicular form—as in one of the cases reported—many of the larger spots could still be seen after many years. It is not a common disease of the black and is easily cured. I have seen no relapses, nor had there been previous attacks as far as could be found out.

Scabies. Most of the cases of scabies which come to my dispensary are either imported by emigrants or caught from them. As there is little intercourse between blacks and whites there is little chance of transferring the itch mite from one to the other. The four females reported here thought they caught it from washing the soiled clothes of white people. The two men had just returned from oyster-dredging on the Chesapeake Bay, where whites and blacks are mixed promiscuously and where ignorant foreigners are enticed before they know what a terrible life is before them.

The lesions produced by the itch mite in the negro are modified when compared to the whites. There is less inflammation, less excoriation, and the number of burrows fewer and shorter than in the white.

Seborrhœa capitis is a common disease of negro women, and is so common that they very seldom consult a physician for it. If, however, the heads of black women who present themselves for other troubles be looked at, it will be seen, according to my experience, that about fifty per cent. of them have a pityriasis with a collection of yellowish-looking crusts upon the scalp, with a line marking the limit of trouble at the edge of the hair growth. Want of cleanliness is the cause, and it is in such heads that pediculi are found in the negro women.

Syphilis. This disease in the negro offers many striking points of difference when compared with it in the whites, but time will hardly allow of more than the noting of a few salient points at present. It is a subject worth an especial study at some future day.

The time of incubation, or the time between the exposure and the appearance of the chancre, is generally less than in the white. The chancre is larger, more indurated, less painful, more apt to produce phimosis—if in the proper situation—and remains longer. The inguinal glands become more enlarged and are more prone to suppuration. The secondary eruption is most often macular, sometimes papular or tubercular, rarely orbicular or ulcerous. The eruption may easily be overlooked, as there is no redness. The spots are slightly lighter in color and sometimes resemble closely the lesions in herpes tonsurans maculosus. Accompanying the eruption the patients complain of an itching and usually there are signs of scratching present. The mucous membrane of mouth, nose, and throat is usually diseased, and the lymphatic glands universally enlarged.

The tertiary stage is more sure to follow, as the negro is subject to nodes, gummata, chronic ulcers, and the various other syphilitic sequelæ. In summing up its usual course in the negro I should say the disease was more prompt in its first stage, less violent in its second, and more obstinately lasting in its third.

Tinea tonsurans will be seen, from this record, to be common with the negro, as it numbers over eight per cent. of all. The disease, whether in ring form or spots, differs from that in the whites in not having a surrounding red color. The scales appear more white upon the pigmented surface. There is slight itching and it seems to be more easily conveyed from one negro to another, or, at any rate, it runs through a family of them more promptly. Treatment is, nevertheless, sure, quick, and satisfactory.

Urticaria in the black negro is a mild disease. The wheals are not very distinct, not much raised, there is no redness in their periphery, their centres are lighter in color than the rest of the skin. There are some burning and itching, but the linear stripes, so easily produced in whites by the nail, were not visible in the cases here reported.

Verruca.—Warts are common among the blacks. They are usually large papillomata, which must be energetically treated to be got rid of. They seem less frequent than fibroma in this race.

There is only one more disease which I wish to mention, and that is *dermatitis venenata*. It will be seen by the chart that there are no cases reported of it in the negro. I have not yet seen a case of what is called poison oak in this race. Several times I have asked country negroes if they have ever seen colored persons poisoned with poison oak.

The answer has been, "Yes, sah; lots of them." When asked if there was any eruption, they said: "No, sah; der isn't any ruption, but der's an awful eetching in dee blood."

Now, from what I have seen of negroes, I do not doubt that many times the itching is the only symptom which indicates any trouble of the black skin.

Not to carry this simple *résumé* too far, I wish only to remark that it seems to me probable that the pigmentation of the skin is the prime factor in causing the diseases of the skin in this race to differ from those of the white.

Whether any practical result in treatment may be obtained by following out and confirming this supposition must be left to a larger experience and to still closer observation.

HYPNOTISM AS A THERAPEUTIC AGENT.

By G. J. PRESTON, M.D.,
of Baltimore.

Hypnotism, using the term to embrace the various states known as mesmerism, braidism, magnetism, etc., has passed through a great many phases. Omitting, for the sake of brevity, its application by the religionists many centuries ago, we find Mesmer using it as a therapeutic agent. In 1779 he published his book, *Mémoire sur la découvêrte du magnétisme animal*, in which there were many absurd theories and unsubstantiated facts. Shortly after this the Société Royale de Médecine made a report on the subject, condemning it in very strong terms. Mesmer, however, had a number of followers, one of the most illustrious of whom was Puységur, who continued to investigate the subject in the half light in which his master, Mesmer, had worked.

Without mentioning the names of many who, during the next half century, were enthusiastically studying hypnotism, we pass to Braid, of Manchester, who, in 1841, definitely formulated the doctrine of suggestion. He repudiated entirely the "magnetic fluid" theory of Mesmer and his school, and, while he wandered a little into the then popular doctrine of phrenology, in the main his investigations were scientific and correct. In 1848, Grimes, of New England, and, in 1850, Dr. Dods, also an American, were active promulgators of this science. Almost all these men were physicians, and hypnotism was constantly employed for therapeutic purposes. Mesmer reports numbers of cases cured by this means. Unfortunately, there was so much of error in his conception of the subject of hypnotism, and his enthusiasm, amounting to a sort of fanaticism, was so great that it led him to apply his newly discovered remedy to every class of cases. Still he reports cures, of the verity of which there can be no doubt.

Braid treated many cases of hysterical paralysis, contractures, and the like, by what was really suggestion. Not understanding thoroughly the nature of suggestion, he was accustomed to practise a sort of massage upon the affected limb, while the patient was hypnotized, thus, of course, making a suggestion, which can be done as well by a simple affirmation of the hypnotizer. At this same time Dr. Esdaile, an English surgeon in the hospital of Calcutta, was employing hypnotism very generally. He wrote to Braid that in six years he had done more than six hundred capital operations while the patients were under the influence of the magnetic sleep. So much for hypnotism in the hands of its early advocates.

While interest in the subject flagged very greatly, it was never entirely lost, and from the early periods of the discovery of the science, if it may be so called, until the present, there have not been wanting faithful students of its phenomena. The revival of hypnotism which took place in France a few years ago, like most revivals, has been carried on with very intemperate zeal. Statements have been made as to the wonderful power of suggestion, and so-called facts put on record, that are quite worthy the day when hypnotism was regarded as a mystic art, containing something of the supernatural. One need only recall the recent experiments of M. Luys, of suggestion at a distance—as, for example, obtaining the intoxicating effects of alcohol by means of a small phial held near the hypnotized subject. Such

a fact as this, for it is a fact well attested by many observers of M. Luys's experiments, can only be explained by suggestion. M. Luys was, in all probability, himself deceived, for his subjects most certainly have had suggested to them the effects that were expected from the various drugs employed. Moreover, few or none of the many enthusiasts have been able to obtain any like results.

Before taking up the special therapeutics of hypnotism, it is necessary to speak of a very important difference between the two great schools of hypnotism, the one at Nancy, the other at Salpêtrière. M. Bernheim, of the Nancy school, has been experimenting for years with hypnotism, and has used many thousand subjects, and he comes to the conclusion that it is possible to hypnotize nearly every individual, if one will only patiently repeat the attempts from time to time. He thinks that hysteria has nothing to do with hypnotism, and, as proof of this assertion, great numbers of his experiments have been made upon men. In other words, his doctrine is that hypnotism, in its simple, uncomplicated state, must be studied only in the healthy subject. M. Charcot, and the school of the Salpêtrière, on the other hand, have shown the close relationship between hysteria and the hypnotic state, and hold that all persons in whom the hypnotic state can be brought about are hysterical, or come under the general term hysteria, the limits of which are very wide. They attest, as evidence, that many patients brought to the Salpêtrière with supposed organic affections, are stated by relatives and physicians to be absolutely free from hysteria, and yet careful observation detects undoubted signs of hysteria ; the affection is treated accordingly, and cured. In addition, many cases of very well-marked hysteria have been described in men, and there are at the Salpêtrière now several men with hysterical hemianæsthesia.

It is very evident that the decision of this question, which requires more careful investigation, will have a very important bearing upon the subject of hypnotism. If, to obtain hypnotism in its most perfect form, the subject must be hysterical, then the application of this remedy is necessarily limited. Moreover, as a direct consequence of this position, it follows that the only conditions in which hypnotism can be of any service are purely affairs of the imagination, purely hysterical.

One of the earliest uses of hypnotism was to produce a state of insensibility, so that surgical operations could be performed without pain. The cases reported by Esdaile, mentioned above, and numerous instances related by other observers, show what an important part hypnotism would have played had it not been for the discovery of anæsthetics. Of course, after this discovery, the application of this agent fell into disuse, for several reasons, the most important being that not all persons were hypnotizable. Of late years, however, it has been employed for this purpose, especially at Nancy, and it has also been resorted to in accouchement.

As a means of confirming diagnosis, hypnotism is very valuable. Cases of paralysis, and often hysterical paralysis, counterfeiting most perfectly the organic affection, can be cleared up most wonderfully, oftentimes, by hypnotizing the patient. The same is true of contractions and of that very curious and interesting condition, hystero-epilepsy. It is a mistake to believe that this latter affection is confined to France; while it is probably seen in its highest perfection in Paris, it undoubtedly occurs in all other countries, notably in America. After having seen *la grande hystérie* at the Salpêtrière, any one who has seen much practice in the United States can recall such cases. Sometimes it is extremely difficult to make an exact diagnosis in this class of cases, for the first stage of the affection is very like ordinary epilepsy, but careful observation will always bring out the hysterical element.

Hypnotism offers a means of cure in those cases, or at least a means of preventing the attack. A great many hystero-epileptics know when the crisis is approaching, and if they are hypnotized and allowed to sleep for some hours the attack is generally averted. Unfortunately, it is not always possible to bring them under this influence at this time. Often there seems to be a sort of exaltation which effectually prevents the use of hypnotism. The patient will try to enter into this condition, for he dreads the crisis of hysteria, but will often say "it is impossible for me to sleep." Still it is possible, in a large number of cases, thus to intercept the attacks, which will, when treated in this manner, grow more and more rare.

Cases of monoplegia, contractures, and the like are very amenable to hypnotism. The treatment of this class of cases is that by suggestion. Just how far it is possible to go in this direction, we do not as yet know. If it is possible to produce vesication, and this has been repeatedly done on very susceptible subjects, one can hardly say where the limits should be fixed.

One very important point that the study of hypnotism has brought out and emphasized, is the potency of suggestion. Some light is let in upon the influence that the charlatan possesses over the people in general, and the faith in patent medicines and in homœopathy meets an easy solution. Doubtless most of the slight aches and pains that the general practitioner is called upon to treat are partly imaginary, and all that is necessary for cure is a certain amount of faith on the part of the patient, begotten by judicious suggestion by the medical man. At first sight, this seems to be a sort of chicanery, but it is impossible to deny its efficacy, and it is much safer for the doctor to

acknowledge, to himself at least, that it is not his simple remedy which has wrought the cure, but his suggestion to the patient.

One needs no better example of the power of suggestion than the many cures brought about by the *faith-cure*. In this case religious fanaticism is called upon to produce an effect upon the mind of the credulous patient, and if the malady is an imaginary one the relief is instantaneous. It was thought by some of the advocates of hypnotism, that it would prove an important agent in the treatment of certain forms of mental disease, especially paranoia; but such expectations have not been realized. In the first place, it is extremely difficult to hypnotize the insane; and, in the second place, the delusion has become so fixed, at least when the patient is in an asylum, that it is practically impossible to dislodge it. However, several very interesting cures have been reported, particularly those of M. Voisin in his wards at the Salpêtrière. These cases were evidently what might be called hysterical mania. Doubtless it would be quite possible to treat successfully certain cases of beginning paranoia before the delusion has become permanently fixed, and while it is merely an insistent idea.

It is possible in a short paper only to indicate the therapeutics of hypnotism, which are capable of very considerable elaboration. That hypnotism has its uses no one who has followed the careful and systematic work that has been expended upon it during the past few years can deny. On the other hand, it has certainly not met the extravagant anticipations that were raised a few years ago, when it was first employed as a therapeutic agent. Future investigation is needed to fix exactly its place in the category of remedial agents.

A word of warning must be given, as is necessary in the case of all therapeutic agents. Without doubt, harm can be done by the injudicious use of hypnotism. Already a number of cases of confirmed hysteria and even of complete mental derangement have been recorded in France, the results of the employment of hypnotism by persons unfit to undertake such experiments. Like other remedies, it should be used only to counteract some abnormal state, and its use as a parlor amusement cannot be too highly condemned.

Paris, September 17, 1888.

MEDICAL PROGRESS.

Methyl Chloride as a Local Anæsthetic.—According to Bailly, if a stream of chloride of methyl is poured upon some dry cotton, held in silk, a temperature of —9° to —67° is produced, which persists for a quarter of an hour to an hour. Passed by the forceps over the skin, it produces temporary analgesia sufficient for a number of minor surgical operations, and may be used to relieve certain painful conditions, such as peripheral neuralgias; in muscular rheumatism, particularly in lumbago and torticollis, have striking results been obtained. Gastralgias, hepatic colic, even a case of tetanus, were favorably influenced by the remedy, which the writer designates "stypazi."—*Deutsche med. Wochenschrift*, September 6, 1888.

Capsules Analgesiques.—

R.—Menthol,
Antifebrin . . āā 3j.
Sacchari lactis . . . q. s.—M.

Divide in capsules No. 24.

The dose is one or two capsules.—*Revue de Thérapeutique.*

Helleborein as a Local Anæsthetic.—Vittorio and Eloidio (*Allg. med. Centralzeitung*) have found that three or four drops (gr. $\frac{1}{40}$th to gr. $\frac{1}{30}$th) of a watery solution of helleborein, instilled into the conjunctival sac of the eye of rabbits or dogs, in about ten minutes produce complete anæsthesia of the cornea for half an hour, the other contiguous portions of the eye retaining their sensibility. Though helleborein may possess some advantages over cocaine, the extraordinary toxicity of the former will stand in the way of its frequent use. Permanent changes and unpleasant complications, such as manifestations of irritation in the eye, which are, for instance, to be feared from erythrophlæin, have not yet been observed from the use of helleborein.—*Münchener med. Wochenschrift*, September 11, 1888.

Hot-air Inhalations in Phthisis.—Gratifying results have recently been obtained in treating phthisical patients with inhalations of hot air, by Weigert, an American resident in Berlin. He found that tubercle bacilli outside the body die at a temperature of 41° C., and are adversely affected by one of 38°, and had constructed an apparatus for the inhalation of heated air, and commenced to make trials on phthisical patients in the early stage recommended to him by other medical men, he himself not being in practice. At first a temperature of from 40° to 60° C. was employed, the air for inhalation being quite dry. This temperature was gradually raised as high as 80° C. The patients bore this hot dry air exceedingly well, and continued to inhale it for three or four hours a day during a month, the only unpleasant effects produced being hyperæmia and dryness of the mucous membrane. The general effects are represented as having been remarkable, patients who had been falling away picking up strength and becoming quite robust, the physical examination showing at the same time that the dulness and râles had perceptibly decreased. The bacilli in the sputum, which had been very numerous, rapidly diminished in number, and finally disappeared altogether. These observations were confirmed by several other medical men. Dr. Halter, of Lengerich, Westphalia, seems to have gone even further than Dr. Weigert, he having himself inhaled, and caused patients also to inhale, dry air heated to 190° C., with satisfactory results.—*Lancet*, Sept. 29, 1888.

Sand-bags for Hemoptysis.—In a case of tubercular hemoptysis, the hemorrhage coming from the left apex, Betz, of Heilbronn (*Memorabilien*), attained prompt

results from the application of a two-pound sand-bag over the left apex, after he had observed that the respiration was greatly quickened, 33 to 35 per minute, and particularly that there was greater expansion in the left subclavicular region than in the right. The pressure of the weight reduced the number of respirations and aided the breathing. The hemoptysis ceased within twenty-four hours.—*Münchener medicin. Wochenschr.*, Sept. 11, 1888.

Treatment of Laryngeal Phthisis.—A solution of menthol, twenty parts, in one hundred parts of olive oil is much used by BEEHAG, with good results. By means of a syringe, prepared for the purpose, he applies it directly to the mucosa of the larynx, guided by the laryngoscope. At the moment of inspiration, the patient inspires deeply and particles of the medicament are carried into the finer bronchi. The cooling and anæsthetic effects of the menthol are at once developed, and the plan is devoid of any disagreeable effects.—*L' Union Médicale*, September, 1888.

To Keep Hypodermatic Syringes Clean.—Hypodermatic syringes, the canulæ of which have become obstructed, may be cleared by holding the needle for a moment over a flame; the foreign matter is at once expelled or destroyed. Should the wire in the canula become rusted, the former can be removed by dipping the latter in oil and holding it over a flame. It is well to introduce oil into the needle and then to heat the latter; rusting is thereby prevented. When about to use the needle, alcohol should be passed through it.—*Münchener medicin. Wochenschr.*, September 11, 1888.

Eczema of Anus and Genitals.—LUSTGARTEN advises hot sitz-baths, rendered very soapy, and, subsequently, the application of the following pomade.

R.—Oleate of cocaine	. . .	1 part.
Olive oil	. . . . .	2 parts.
Lanolin	. . . . .	10 " —M.

Apply twice daily to affected parts.—*Le Progrès Médical.*

Amaurosis from Dental Caries.—RÉVA (*Revista de Ciencias Med.*) reports a case of complete amaurosis, in a woman, aged thirty, upon the side of a carious second molar teeth of the upper jaw. Upon the removal of the diseased tooth, in the root of which a fragment of a wooden dental drill was found, sight returned.—*Medicin. Chirurg. Rundschau*, August 1; from *St. Petersb. med. Wochenschr.*, No. 21, 1888.

The Treatment of Ingrowing Toe-nail.—HOFMANN (*München. med. Wochenschr.*, No. 32, 1888) recommends the following procedure: The wound and the part are thoroughly cleansed and disinfected with sublimate solution; several drops of a solution of ferric chloride are poured upon the sore spot and the nail elevated; the part is then permitted to dry. This process is repeated on the second and third days. In a few days the hard crust which has formed is removed with the forceps. The bleeding which results is checked by the use of the iron solution. In three or four days the crust is again removed; and this is repeated until the surface of the skin is smooth. On the second or third day, already, the nail, softened and made friable by the iron solution, may, with some care, be painlessly removed with a small scissors or blunt knife. To prevent recurrence, bits of cork should be placed under the margin of the nail.—*Therapeutische Monatshefte*, Sept. 1888.

Rumination in Man.—A case of rumination in man has been observed by a physician of Odessa, occurring in a man of twenty-two years. The food was regurgitated about fifteen minutes after eating, and the chewing continued for some time, often for several hours. The patient, who was married, had been addicted to excessive sexual intercourse for three years, to which fact the regurgitation was attributed. It seemed to be a case of marked sympathy between the genital, gastric, and œsophageal functions.—*Revue Générale de Clinique et de Thérapeutique*, September 20, 1888.

Treatment of Ascites.—Although not a new device, the treatment of ascites by faradization is again brought forward by MURET, who reports good results in some of his own cases. He applies the current directly to the abdominal walls, daily, for several months, and finds that muscular contraction induces greater activity in the lymph channels and consequently absorption of the fluid. —*Revue de Médecine*, September, 1888.

The Administration of Creasote.—KEFERSTEIN recommends the following formulæ as useful for the administration of creasote:

R.—Creasoti	. . . .	1.3 parts.
Spts. vini. rectif.	. . .	25 "

Sig.—A tablespoonful three to five times daily.—*Therapeutische Monatshefte*, September, 1888.

Alcohol and Cirrhosis of the Liver.—M. Alison, after an exhaustive consideration of the effects of alcohol on the economy and its special action on the liver, believes that the business of the individual, outside of the causes commonly attributed to cirrhosis, plays an important *rôle* in its development. Field laborers are rarely attacked by it, and it is more rare in persons given to manual labor than in those who lead sedentary lives. He advises physical training as an effective therapeutic means.—*Archives Générales de Médecine*, September, 1888.

The Treatment of the Atonic Leg Ulcer.—Appenrodt recommends the treatment of atonic ulcers of the lower extremity by massage. For some days before manipulation is commenced, the sore is treated antiseptically and the entire leg made aseptic, for otherwise abscesses and furuncles would result from infectious matters being forced into the lymph channels. At first, gentle massage is performed below the knee and gradually advanced upward. The manipulation drives the lymph from the excoriated surfaces—an evidence of success. Lanolin is used to anoint the skin. Before and after the massage, the skin is thoroughly cleansed and disinfected. The ulcer and the surrounding inflammatory area are covered with gauze spread with lanolin, over which are placed tissue-paper and a bandage. The addition of disinfectants to the lanolin is not only unnecessary, but in most cases harmful. Only when the skin is not susceptible may iodoform gauze be used, because this often gives rise to erythema. Impermeable coverings are to be avoided. Swelling and hypersecretion disappear and granulations soon show themselves. Rarely is it necessary to add starch or zinc oxide to the lanolin to overcome any eczema. The massage must be continued after the ulcer has healed and the limb be judiciously used.—*Therapeutische Monatshefte*, September, 1888.

Administration of Morphine.—It is pointed out in *Les Nouveaux Remèdes* that morphine should never be given in cherry-laurel water, or in any solution containing hydrocyanic acid, however small the quantity. The precipitate formed of morphine and the acid is a most deadly poison. It forms slowly, and the patient is liable to take a toxic dose when the contents of the bottle are nearly exhausted.

The Treatment of Retro-pharyngeal Abscesses.—Burckhardt, of Stuttgart, in three cases, has successfully opened retro-pharyngeal abscesses by incisions into the neck. The skin and platysma, at the level of the larynx, are divided by an incision parallel with the anterior border of the sterno-mastoid muscle, the cervical vessels pushed outward and dressing forceps introduced between the latter and the larynx toward the abscess. The advantages of this method consist in the possibility of anæsthesia, ready drainage, and antiseptic treatment of the cavity.—*Deutsche med. Wochenschrift*, September 13, 1888.

Rupture of the Spleen.—M. Barrallier, who has made a study of this accident, concludes that it is most liable to occur in the earlier stages of malarial poisoning, when the spleen is suddenly inflamed and the seat of great vascular engorgement. The lesion, which is commonly fatal, has a sudden onset, and is preceded by no special symptoms. He designates it as a pernicious splenic fever.—*Archiv. Gén. de Méd.*, Sept. 1888.

For Itching.—To relieve the itching of hemorrhoidal affections, pruritus ani, pruritus senilis, etc., wash the part with lukewarm water and good soap; then rub in lanolin in the following combination:

℞.—Lanolin puriss. . . . 30 parts.
Vaselini,
Olei olivæ . . . āā 20 parts.

When the itching about the anus is severe, cocaine may be added thus:

℞.—Cocainæ hydrochlorat. . $\frac{1}{10}$ to $\frac{1}{5}$ part.
Lanolin puriss. . . . 30 parts.
Vaselini,
Olei olivæ. . . . . āā 20 "

The addition of ten per cent. of flowers of sulphur has proved useful.—*Therapeutische Monatshefte*, September, 1888.

Antiseptic Obstetric Dressing without Injection.—In view of the fact that intra-uterine injections are by no means devoid of danger, Roulin practises and recommends that just previous to labor the external genitals be thoroughly cleansed with a solution of chloral, 1 : 100. After the birth of the child the parts are again washed and the vulva covered with several layers of lint sterilized and impregnated with salol. Over this is placed a cotton wad, wet in a solution of chloral of the same strength as that before mentioned, and wrung out nearly dry. The dressings are changed every six hours. Eight cases have been treated in this way with excellent results. The originator admits that in cases of retained placenta and the like, injections would be required, but ordinarily this plan answers admirably and is wholly free from danger.—*L'Union Médicale*, September 27, 1888.

Bandaging the Extremities for Pulmonary Hemorrhage.—Seitz (*Archiv für klinische Medicin.*), as the result of experimental investigations, recommends bandaging the extremities for hemorrhage from the lungs; first the upper extremities, at or about the middle of the arm, then the lower at the middle of the thigh or immediately below the knee, using silk bands about three-quarters of an inch wide; or, in case of necessity, strips of any sort. By imprisoning the blood, the tension of the left ventricle is diminished, and contraction of the vessels in the area not included occurs. The half hour during which the bandages are retained suffices for the formation of a thrombus at the site of hemorrhage. The method was used in the time of Hippocrates.—*Deutsche medicin. Wochenschr.*, September 20, 1888.

For Hysterical Hyperæsthesiæ, Gastralgiæ, Vomiting, and Spasmodic Conditions.—Ewald (*Digestive Disorders*, vol. ii.) recommends the following:

℞.—Morphinæ hydrochlorat. . gr. iij.
Cocainæ hydrochlorat. . gr. iv–viij.
Tinct. belladonnæ . . ʒ j–ijss.
Aquæ amygdal. amar. . ʒ vj.—M.

Sig.—Ten to fifteen drops hourly.—*Therapeutische Monatshefte*, September, 1888.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, OCTOBER 20, 1888.

THE CASE OF FREDERICK THE NOBLE.

THE arraignment of Sir Morell Mackenzie by the German physicians associated with him in the medical management of the unfortunate Frederick the Third, and principally by Gerhardt, von Bergmann, and Landgraf, has received from Mackenzie a scathing rejoinder, which contains a distinct accusation that von Bergmann, in futile endeavors to replace a tracheal canula, made a false passage in front of the trachea, which was the immediate cause of precipitating the inevitably fatal result.

We have refrained from commenting upon the report of the German physicians, although in our possession several months, until we should have read the report of Mackenzie. In general terms, we may state that the questions raised in this unseemly controversy are largely questions of veracity;—questions which cannot be decided here, where Mackenzie and his chief opponents have always been held in equally excellent repute. We decline to enter into the details further than is necessary to present a strictly clinical aspect of the case itself as gathered from the two reports.

There are three important clinical points involved, which are of great scientific and therapeutic interest. All the others seem foreign to the main features of the case, being contingencies and complications which might occur under various conditions, or might not occur at all; and we shall not discuss them. These three points may be put in the form of questions.

1st. Was it at all probable that a benign growth was practically transformed into malignancy by the applications made with the electric cautery, before a fragment of the growth had been removed for microscopic examination, or by the manipulations subsequent?

2d. Is it probable that thyrotomy and eradication or radical destruction of the growth *in situ*, at the time that preparations had been made for the purpose, would have been more successful than the plan adopted?

3d. Was unilateral or complete excision of the larynx justifiable at any period of the malady, and if so, at what particular period?

First. A thorough and painstaking collective investigation, now perhaps completed, by Dr. Felix Semon, of London, has been so far published as to show great improbability that intralaryngeal manipulation has ever converted a benign tumor into a malign one; and that it is quite likely that the ultimately malign growths were malign originally, even in the few instances in which the transformation was believed to have taken place. In view of the conclusions drawn from this collective investigation of several thousand benign neoplasms submitted to intralaryngeal manipulations the most diverse, it is strange that so well informed a laryngologist as Sir Morell Mackenzie could have done more than hint at the remote possibility of such an occurrence: the more so as his own manipulations were by no means free from the same implication. Even those laryngologists who had hitherto held this view the most strongly, have corrected their previous opinions. This question is a very important one; for if the answer should be affirmative as to more than an insignificant percentage, the inference would follow that repeated efforts at intralaryngeal procedures for the eradication of benign neoplasms would have to be superseded by procedures for eradication by external access. In the instance under discussion, the fragments removed by Mackenzie and pronounced benign by Virchow, must have been the very surfaces most likely to undergo the transformation alluded to. We, unhesitatingly, answer the first question in the negative.

Secondly. At an early period in its history, a neoplasm, as yet insignificant in its visible dimensions, occupies a portion of the larynx more frequently the special seat of malign growths than of benign ones. It exists in the person of a man in his prime and apparently in the best of general good health. The

patient's age and a partial family history of cancer render the case at least suspicious. It must be closely watched. Failure to control the development of this neoplasm by intralaryngeal attack, instituted under either the hope or the conviction that it was benign, leads to the opinion that it is not benign; and intralaryngeal interference is thereupon suspended. This is the situation when thyrotomy is proposed.

The operation of thyrotomy to afford complete access to the neoplasm for the purpose of eradicating it in a few minutes, provided it appeared that it was limited to a small portion of the interior of the larynx, was, in our opinion, a very proper proceeding under the circumstances—in the light of the subsequent clinical history probably the very best, whether the tumor should prove to be benign or malignant. If the latter, the importance of having had the proposed operation performed at the earliest moment practicable, cannot be successfully contested.

Thyrotomy, in itself, is not a dangerous operation. Performed at a time of election, it is really less dangerous than tracheotomy performed in an emergency. A healthy subject is rarely confined to his room for more than two or three days after the operation; and he is often able to leave his house in from a week to ten days. If, however, a large and vascular neoplasm occupies the interior of the larynx, its extirpation may be attended with copious hemorrhage, and inflict such injuries to the tissues as may compromise the result. As far as may be judged from all the reports, no such complication was to be anticipated; and the probabilities are, therefore, strong that the immediate result of this operation would have been a good one, although the voice would have been impaired. It could hardly have been worse than the plan adopted. It might have been salvation. Should the tumor have proved to be benign, a permanent cure would have been in immediate prospect. Should it have proved to be malign, the prospect of recurrence would have remained for some time in doubt; probably for a long time, provided that the whole of the morbid growth had been removed with a sufficiently extensive zone of healthy tissues. Should it have turned out that the growth was not only malign, but that it extended beyond the field visible on laryngoscopic inspection, the question of resort to radical measures by excision of the larynx, in whole or in part, would have had to be settled at once, instead of being postponed to a period which, under symptomatic and expectant treatment, would render the prospects of recovery still more problematical. In a case of malign growth, the sooner a decision is reached in this respect the better.

In estimating the probabilities of death from the operation of thyrotomy in carcinoma of the larynx, or in gauging the prospects of recurrence, a great deal depends upon the stage of the disease at which the operation is performed. Each case must be made a study in its own behalf. Statistical computations are often misleading. Sir Morell Mackenzie gives a list of twenty-two thyrotomies for carcinoma, in which there are only two cures.

We have not the data at hand to determine the stage of disease at which these operations were undertaken; but our belief is that not one of them was undertaken at a period so promising for success as the case in question at the time the operation was contemplated;—hence the inference that in this instance another case would probably have been added to the series of cures, rather than to the series of deaths. We notice, however, that Mackenzie has failed to include two cases of cure, one of three, and the other of twenty years' standing, both mentioned on page 20 of the pamphlet he criticises, and from pages 19 and 21 of which he makes citations at the very head of his table. The first case alluded to was one of von Bergmann's, which, he states, he vainly requested Mackenzie to examine. The other is one of the elder Solis-Cohen's, performed in February, 1868, the subject of which is still living. This case was reported in The Medical News of December 3, 1887, and was reproduced in the *Revue Mensuelle de Laryngologie*, etc., 1882, No. 2. In another instance in the thyrotomy table, of which we have cognizance, recurrence did not take place in three months, as recorded, and did not take place in the larynx at all. An independent epithelioma became developed in the cutaneous cicatrix.

To our mind, the minute size of the original growth in the Emperor's case, and still more the facts that Mackenzie states that he destroyed it so utterly that by August 13th the last slight wound of his electric cautery had healed, and that the growth thus destroyed never returned, are proofs incontrovertible that this same growth, which required three months for its eradication by intralaryngeal procedures, could have been removed in a few minutes, just as radically, by thyrotomy, on that

memorable 21st of May, when everything was ready for that purpose. In this connection we cannot refrain from expressing our surprise that the two slight cauterizations, described by Mackenzie, accomplished so much. It adds another unique feature to this remarkable case.

It should be remembered, however, that the growth pronounced benign by Virchow, and destroyed by Mackenzie, may have been really benign; and that the malignant neoplasm existed beneath it and out of sight; and, in further support of Mackenzie's position, it should also be remembered that Virchow distinctly stated that his studies in this connection had failed to reveal a single example of coexistence of benign and malignant growth.

The light now shed on the case enables us to answer the second question in the affirmative.

The *third* question is much harder to answer; and here our judgment leans much further toward the views maintained by Mackenzie. That life is in imminent immediate peril in every case of complete excision of the larynx, there is but little doubt. There is but little less doubt that it is nearly as practically imperilled in unilateral laryngectomy. Under both conditions, however, the stage of the disease is of immense importance. The better selection of cases is rendering both operations more and more promising of success. Few patients die from the immediate effects of either operation; but a large number perish within two weeks from pneumonia. A great many perish from recurrence at a period anterior to that which they have a prospect of reaching under expectant treatment. A few are cured.[1]

The choice of the two alternatives: inevitable death at a period varying say between one and three years from the beginning of the malady; and a forlorn chance of recovery should the immediate and the immediately proximate risks be successfully surmounted, must in great measure be left to an intelligent patient himself. There are occasions under pressure of which a man might well prefer a certainty of life sufficiently long to provide for his family, or to attend to some matters of great humanitarian importance, rather than run the risk of almost immediate death with a bare chance of ultimate recovery. There may be circumstances under which a physician might be debarred from communicating such a decision to others; and be compelled to bear the entire responsibilities that may ensue in consequence. The decision once made, every day of delay lessens the chance of success, and thus, in a very short time, the result of a decision not to submit to any radical operation becomes irretrievable.

A careful review of both stories has led us to the opinion that, thyrotomy having been abandoned at the commencement, a radical operation upon the larynx was justifiable up to the period at which Landgraf is said to have noted extension of the morbid process and its commencing encroachments upon the hitherto sound side, and to have urged a consultation in consequence; but after that period the radical operation was no longer justifiable.

Our answer to the third question is, that, if the patient were willing, a radical operation was probably justifiable during a portion of his sojourn in Great Britain, and that after his removal to San Remo the time for such measures had passed.

[1] Park's case, 1885, "reported cured in six months" in Mackenzie's table, remains a CURE, and is still alive (1888) without recurrence.

The Trustees of the Hoagland Laboratory, in Brooklyn, announce the completion of the Laboratory and its equipment for practical work. Special facilities are offered to those who desire to prosecute original research. For this purpose private laboratories have been provided, and arrangements are now being made for the purchase of a library which shall contain all the literature necessary for reference in the departments of bacteriology, physiology, and pathology.

Owing to the absence in the South of Dr. George M. Sternberg, the Director, in the further prosecution of his investigation into the cause of yellow fever under orders from the President of the United States, the course of lectures on bacteriology, already announced, will be postponed until his return. The Trustees further announce that the services of George T. Kemp, Ph.D. John Hopkins University, have been obtained as Associate in bacteriology and physiology, and that, with his assistance and under the direction of Dr. Sternberg, practical instruction in bacteriology will be given during the Winter and Spring.

Dr. William T. Lusk has been elected President of the New York State Medical Association.

Dr. Osler does not leave Philadelphia to enter upon his duties as physician to the Johns Hopkins Hospital until next May.

DR. JOHN N. MACKENZIE has been elected Clinical Professor of Diseases of the Throat and Nose in the Medical Faculty of the University of Maryland, *vice* Dr. Frank Donaldson, resigned.

ZUCKERANDL, formerly of Grätz, has been made Professor of Anatomy at the University of Vienna; von Ebner, also formerly of Grätz, Professor of Histology; and Puschmann, Professor of the History of Medicine.

SOCIETY PROCEEDINGS.

ASSOCIATION OF AMERICAN PHYSICIANS.

Third Annual Meeting,
Held at Washington, September 18, 19, and 20, 1888.

(Specially reported for THE MEDICAL NEWS.)

(Concluded from page 429)

SEPTEMBER 20TH.—MORNING SESSION.

DR. GEORGE L. PEABODY, of New York, presented the pathological specimens from the case in which there was

A PIN IMBEDDED IN A WOMAN'S HEART.

The patient died at the New York Hospital the 26th of last May. She was under observation only a few hours. On admission she was suffering greatly from dyspnœa and was unable to give a circumstantial account of her illness. For some time previously she had passed less urine than normal, and her feet had been swollen. She suffered from constipation, vertigo, spots before the eyes. Her appetite was poor, bowels regular. Temperature 100.8°, respiration 44, pulse 130. The specimen of urine was of a yellow color, acid in reaction, and of specific gravity 1.020, with albumen, epithelial casts, and pus cells. Her chest contained a large amount of fluid; moist râles both behind and in front. No murmur. Heart-sounds very feeble. Œdema of feet and legs. She was given acetate of potash and infusion of digitalis, and passed a fairly comfortable night. The next morning she seemed to be doing fairly well, when she suddenly experienced great precordial pain, distress, and intense dyspnœa. She was given morphia subcutaneously, but she continued to suffer until death came to her relief in half an hour.

At the post-mortem a black, eroded pin, the top of the head of which was free in the left ventricle, was seen piercing one of the papillary muscles attached to the anterior segment of the mitral valves, and penetrating the wall of the ventricle obliquely to the depth of a little more than an inch. The point of the pin was distant one-fifth of an inch from the external surface of the heart. There was no evidence of any recent inflammation in this neighborhood, but the endocardium about the protruding head of the pin was greatly thickened and snow-white, and firmly adherent to the edge of the head. A most careful examination failed to reveal the route by which the pin had travelled to its present location, and it is interesting that it should have remained for a long time free in the cavity of the ventricle without producing thrombosis. The pin had evidently been in its present situation a long time, and, in all probability, had entered the body by the mouth.

ON THE RELATION BETWEEN TROPHIC LESIONS AND DISEASES OF THE NERVOUS SYSTEM.

DR. E. C. SEGUIN, of New York, opened the discussion on this subject. He said that he excluded from consideration vasomotor disorders, and diffused or quantitative nutritional changes, partly because he considers them to be a distinct subject, and partly because their study would be beyond the scope of a short paper. He divided the so-called "trophic lesions" into two great classes. In one the lesions are probably mostly due to the action of extraneous causes, and are preventable. The second class embraces lesions which seem to be directly due to the nervous disease, and which are its necessary and unpreventable results. He endeavored to show that lesions of the second class, which alone merit the name of *trophic lesions*, occur in organs and tissues which are anatomically continuous, and whose life (or preservation of structure and function) is associated or interdependent. He concluded that disease of the nervous system produces true trophic lesions when it interferes with the associated or interdependent life of continuous tissues. This proposition he offered only as a partial and preliminary answer to the question under discussion.

DR. H. C. WOOD, of Philadelphia, as co-referee, presented the following conclusions: 1. It is physiologically proven that the nervous system directly affects general nutrition. 2. Various lesions are the immediate result of previous nervous disease. 3. In various cases the lesions are not preceded by circulatory disturbances. 4. No known vasomotor condition is capable of causing any of these lesions. 5. Therefore, it is absurd to attribute changes to preceding vasomotor changes.

DR. W. M. ORD, of London, said that he felt very much honored at being asked to speak on this important subject, but before he said a word he would beg to tender the Association his gratification at the very high tone and character of the discussions on the papers he had previously heard in this room.

As regards the two papers he had heard read, they had certainly stood in strong contrast with one another: the one critical, the other appealed strongly to the imagination and fascinated one by its strong and logical character of thought and imagery. He would try to prove at the start how, from disturbances of nutrition, there is a starting-point in the nervous system of the local hepatic disturbances. He did not think Dr. Seguin denied that the changes in chronic rheumatism are of a histological character. He would quote two cases bearing upon this point which he saw recently before leaving London, having had them under observation for more than a year. The first was a case of chronic hypertrophic cervical pachymeningitis, which presented a very typical form of that disease. This patient, a young man, at the time of his admission showed very little change in the skin and none in the joints. He was kept in bed, treated, and recovered to a large extent his motor power, and completely his sensation. There was a steady wasting of the tissue around the second and third digits, a distinct and marked change in the joints. The joints of the thumbs and fingers became somewhat tender, and finally loose. All the physical signs of progressive chronic arthritis developed in conjunction with dystrophy

of skin and muscle without any local irritating cause. The next case was an old man, who, for many years, lost power and wasted in the upper extremities. This man had a wasting of the skin, and a very remarkable change in the joints. They were considerably swollen, were constantly dislocated and as constantly put back in place. The whole muscles of the upper extremities were wasted. He sat up in bed with great difficulty. These two cases illustrate very well the primary affection of the nervous system in determining dystrophy of the joints.

Early in his endeavors to analyze pseudo-arthritis he was brought face to face with a class of cases which interested him very much. As a woman approaches the climacteric period one sees a painful swelling of the small joints of the fingers and toes. Examining this with great care the one thing always present was disorder of the catamenial function, and chiefly such a disorder as consisted in menorrhagia. He had seen cases in which, as the climacteric began to develop, the joint affections returned with intensified severity; but the day before he left London he saw two cases: one was a lady of sixty years, who had troubles of this kind during the climacteric period, and had a large uterine fibroid. Here was an unusually persistent type of the subacute form of this disease long after the cessation of the catamenia. People who suffer in this way are, in all cases, very excitable, anæmic, and sensitive women. It appeared to him that, as affections of the nerves or spinal cord may bring about neurotic dystrophies in joints, so local irritation may produce, in a reflex way, affections of joints more or less parallel to the affection determined by nerve disease. In the same way he has great reason to believe that continued prostatic irritation will produce affection in the joints of the leg. Gonorrhœal rheumatism may itself not be the result of a microbe, but the work of the nervous system. Acute rheumatism might be traceable to similar causes. It seemed to him that acute rheumatism is often developed under conditions which would indicate affections of the nervous system—such affections as would bring about, in a reflex way, the irritation of the joint. It occurs certainly after parturition. It occurs almost invariably in people who are very anæmic, or have lost large quantities of blood, and whose nervous system is brought into a state of over-expansiveness.

Dr. M. Allen Starr, of New York, said that he had very little to add to the discussion. It seemed to him that the departure of Dr. Seguin marks a decided advance toward a certain amount of clearness in the study of trophic disturbances. The point he made, that trophic disturbances must be distinctly separated from nutritive disturbances, has not been appreciated, and it seemed to him to be a very important one, and one that threw considerable light on the subject.

There is a class of nutritive disturbances that has not been mentioned yet, which has been described by Dr. Osler as cerebral palsies, viz., that class of atrophies which follows hemiplegia in children. In adults it does not appear to be followed by any amount of atrophy on the paralyzed side. It is important to separate vasomotor from trophic disturbances. Trophic disturbances follow very closely on vasomotor disturbances, and it is not strange that the two should be confounded.

Dr. H. P. Bowditch, of Boston, agreed entirely with Dr. Seguin that any attempt to explain the mechanism of trophic changes must be speculative in our present knowledge. We have to recognize in muscular tissues two distinct metabolic processes, one having its cause in the nitrogenous and the other in the non-nitrogenous metabolism. These are distinct inasmuch as it has been shown that the nitrogenous metabolism is not connected with muscular activity, while the non-nitrogenous is. When the muscular activity is kept within physiological limits urea excretion remains the same. Nitrogenous metabolism of the body is essential for muscular activity. It is essential for muscular activity that an abundant stream of nitrogen should flow into the body and out again. So the nitrogenous metabolism of the muscles goes on quite independently of its functional activity. If we limit the term trophic to the nitrogenous metabolism of the muscle and let the non-nitrogenous metabolism go as the functional activity, we would simplify matters a good deal.

Dr. Pye Smith, of London, said that he had listened with great pleasure to the two admirable papers read before the meeting. He confessed that both from a physiological and clinical standpoint his judgment would be entirely on the side taken by Dr. Wood with such eloquence and zeal. He did not quite agree with Dr. Wood in imputing a logical error to those who resort to the supposition of traumatism and vasomotor disturbances to explain the phenomenon in question. He would quote the case reported by Hilton of a patient with an ulcer in the hand which got worse and worse in spite of all endeavors to cure it, when it was discovered that a minute exostosis was pressing on the ulnar nerve, and when the exostosis was removed the ulcer healed rapidly. Gangrene caused by an embolus obstructing an artery is a well-known fact. He still thought there are cases of gangrene quite inexplicable on such an hypothesis. They had all seen those strange cases of skin eruption come on rapidly following lesions of the cord. His own experience is that these trophic cutaneous lesions are bullous or herpetic in character. He thought they must admit from such strong evidence that trophic nerves have a true position not only in physiology but in medicine.

Dr. Ferrier, of London, was of the opinion that there can be no question of the direct influence of the nervous system on the nutrition of the tissues altogether apart from vasomotor changes, and agencies operating *ab-extra*. This is shown, among other things, by the structural modifications which are observed in the glands on stimulation of their secretory nerves; and by the degeneration which ensues in muscles which are separated from the cells of the anterior cornua, or when these latter are destroyed.

This degeneration he holds to be the direct result of the severance of the muscles from their trophic centres, and is not due to secondary inflammatory changes, inasmuch as it occurs under conditions which entirely obviate the initiation and propagation of irritation. But he believes with Dr. Seguin that the great majority of the trophic disturbances which so commonly occur in connection with injuries of nerves, such as panophthalmitis from lesion of the fifth, and the herpetic and other cutaneous disorders from lesion of common sensory nerves, are not due to the withdrawal of trophic influence, but are the results of secondary inflammation or injurious agents operating from without. They are observed more especially in connection with partial lesions of nerves and those most calculated to excite irritation.

He should, however, expect to find (although he is

not aware that the subject has been fully investigated) that section of all the sensory nerves of any given region would induce degeneration of the nerve endings and their annexes, precisely analogous in character to the degeneration which occurs in muscles when the motor nerves are divided, or the anterior cornua destroyed.

But the point is whether these and similar facts are to be regarded as proofs of the existence of a special system of trophic nerves and trophic nerve centres, distinct from those which minister to the general functions of motion (secretion) and sensation, or whether the maintenance of the nutrition of the tissues is merely a different aspect of the general functional activity of sensory and motor nerves.

He has, on the principle "entia non sub multiplicanda," been more inclined to adopt the latter view, and to regard, with Sigmund Mayer, and Dr. Seguin, the muscles, nerves, and anterior cornua as forming together a functional and nutritive unity. In combination these structures exhibit what we call normal laws of reaction and nutrition; but when separated they are reduced, each to its own independent vitality, and exhibit the changes which we are accustomed to call those of degeneration, characterized by the retrogression of the more highly organized, and proliferation of the less highly organized structures.

The recent important researches of Gaskell have thrown new light on the structure and functions of the nervous system, more especially the nerves which innervate the walls of the bloodvessels and the hollow viscera.

There are two sets of nerves possessing diametrically opposite functions. One set, *katabolic*, excite activity and cause waste; the other set, *anabolic*, inhibit activity and promote repair. It may be that the inhibitory or anabolic influence is not, like the katabolic or motor, the direct result of nerve stimulation but only a question of interference of nerves alike in function. But if the facts cannot be so explained, then there would appear to be (in the case of the muscles of organic life at least) a system of nerves which would be properly called trophic.

Whether this differentiation of nerves obtains also among the muscles of animal life is a point which has not been, as yet, determined.

He is of the opinion that more light will be thrown on this subject by the researches on thermal or heat centres now being actively pursued, and on which Dr. H. C. Wood and Dr. Ott have given us valuable contributions.

The question is whether there are nerve centres which influence and regulate the production of animal heat, apart from those which are related to motion and sensation. Many facts have been adduced in favor of this proposition, but, he thinks, much will have to be done before we can regard it as proved.

The muscles are the chief foci of heat-production in the body. He should, therefore, argue that the centres of heat-production must be coextensive with those which minister to the nutrition of the muscles. He is, therefore, not readily inclined to believe that there can exist, anywhere in the nervous system, any one centre capable of maintaining (as a nerve centre must) afferent and efferent relations with the whole muscular system. So far as yet appears from experimental research, increased production of heat has been found in association with irritative lesions of nerve centres and tracts; but he is not aware that it has been proved satifactorily that increased heat-production and increased tissue-waste result from the removal of a centre whose functions could, with propriety, be termed inhibitory or anabolic. But he thinks that researches in this direction are those which are best calculated to throw light on the difficult problem at present under discussion.

MR. VICTOR HORSLEY, of London, begged to be allowed to communicate the results of experiments performed by Dr. Frederick Mott, of London, in the laboratory of the Brown Institution, since it seemed to him that Dr. Mott's observations were of the utmost importance, especially in view of the direction which the present discussion had taken.

The question appeared to him to present the following points. Destruction of what we regard as trophic centres or cutting of fibres leading from the same may presumably produce disturbances of nutrition in one of three ways or combination of these, viz.:

(1) True trophic disturbance.

(2) Loss of function.

(3) Vasomotor changes.

Vasomotor changes, he thought, were anyhow put out of the question by the fact that experimental removal of the superior cervical ganglion of the sympathetic produces practically no change. Dr. Mott's method of experimentation appeared to him to possess the especial merit of excluding not only this complication, but also that due to loss of function. His method was as follows: He ligatured, on one side, certain anterior roots in the cauda equina of monkeys, under strict antiseptic precautions, and then observed the condition of the femora on the two sides. Now the normal metabolic changes in bone are, of course, known since the days of Hunter to be a combination of absorption and restoration. Dr. Mott found that the trophic changes in the bones produced were destructive—*i. e.*, exaggeration of the normal process of absorption. The femur of the side on which the roots were ligatured was probably atrophied, and on microscopic investigation Dr. Mott discovered that the medullary surface of the interior of the bone was thickly covered with osteoclasts. Considering that the function of the bony skeleton is so essentially passive, especially in contradistinction to the example of muscle quoted by previous speakers, and considering the small influence which vasomotor changes could be imagined to bear on the nutrition of such a resistent tissue as bone, he thought that Dr. Mott's experiments definitely supplied proof for the first time of katabolic changes originated by lesion of efferent nerve fibres.

DR. SEGUIN, in closing, said that he had been very much pleased to find that his conclusion and subdivision of these lesions have not met with more contradiction than they had received. He claimed that true trophic lesions are the result of some mysterious connection between the nervous system and organs in other parts of the body. With respect to the very interesting experiments of Dr. Mott, he would say that there is nothing new in the essence of the experiments. He was very pleased to hear no actual refutation of his conclusions.

DR. FRANCIS T. MILES, of Baltimore, read a paper on

THE EFFECT OF CONCUSSION OF THE SPINE ON THE REFLEXES.

He called attention to some lesions of the spine of a traumatic origin which, while cutting off the influence of

the will destroyed the reflex actions. This is a subject, he said, very little brought to the attention of the profession. Dr. Hammond, in his work on the *Diseases of the Nervous System*, gives a case in which the reflexes were lost. In all the series of cases collected in the *Medical History of the War of the Rebellion* nothing is said of the loss of the reflexes from concussion.

Dr. R. T. Edes, of Washington, said that several cases of this kind came under his observation in the hospital in which, a number of weeks after the shock, there was very much exaggerated tendon reflex, a fact of much value in the present discussion. In one case, a male, he found him paralyzed and in a state of complete contracture. He had fallen on his back under the wheel of his wagon. On autopsy, the parts above the medulla oblongata were lost, but all down the cord there was that condition of sclerosis which is found associated with a state of exaggerated reflex.

Dr. Wm. Osler thought that as a result of concussion there may be an abolition of the reflexes which may persist for some length of time. Then, in addition to that, there may be a complete abolition of the reflexes from a central myelitis and a destruction of the integrity of the gray matter. He had a case of that kind recently in Philadelphia. The cases to which Dr. Edes referred they had all seen.

Dr. H. C. Wood had seen a number of cases in which the traumatism ended in a subacute myelitis involving the whole cord. Then again, he had seen cases in which the traumatism ended in chronic lateral inflammation. For instance, a woman gets hurt, may be badly frightened into hysteria, the cord gets badly shaken, a minute hemorrhage perhaps occurs through it, and she gets a myelitis. We may have various lesions following traumatism, as from a blow on the head.

Dr. M. Allen Starr said that it seemed to him that in those cases of concussion in which the reflexes are arrested and in which there is no injury post-mortem to the part of the cord that governs the reflexes, there is the explanation on the theory of inhibitory impulses coming from a higher region and transmitted downward which arrest the reflexes. Such a condition exists in hemiplegia. No doubt in many of the cases of Dr. Mills the condition was one of irritation at a higher level and so arresting the reflex. He agreed with Dr. Edes that, if the patients lived long enough, the irritation would have ceased and they would have recovered with exaggerated reflexes.

Afternoon Session.

Demonstrations in Pathological Anatomy.

Dr. Wm. H. Welch, of Baltimore, demonstrated a series of

microscopical specimens of the thyroid gland after partial extirpation.

It is a well-known fact, he said, that the extirpation of both lobes of the thyroid gland in a dog is followed by characteristic symptoms and the death of the animal. The longest duration of life after the extirpation of the gland was nineteen days. The symptoms made their appearance usually within two or three days after the operation. The first symptoms were fibrillary twitchings of the muscles of the tongue. Similar tremors made their appearance in the other muscles of the body. Tetanic spasms of the muscles of the extremities were very commonly present. Trismus, difficulty in respiration, sometimes labored, and sometimes an alteration of the rhythm of respiration. Sometimes paroxysms of dyspnea. The animal very soon became apathetic, lay down most of the time, could only be roused by noise, but very readily by touching him. In many cases there was observed pallor of the gums of a scorbutic character. Ulceration of the cornea and inflammation of the conjunctiva were frequently present. The hair fell out, the skin itched, and a thickening of the skin was quite noticeable about the cheeks and forehead. A tendency to walk backward and difficult deglutition had been observed. The extirpation of both lobes of the thyroid gland is, therefore, followed by a characteristic group of symptoms and death of the animal.

Last year Prof. Münck, of Berlin, isolated the two lobes of the thyroid gland in a dog by tying off all their vascular and nervous connections, left them *in situ*, and sewed up the wound. The experiments of Münck induced Dr. Halstead to undertake another series of experiments.

A word as regards the normal anatomy of the thyroid gland. After isolation of a single lobe of the thyroid gland according to Münck's method, interesting changes are observed in the remaining lobe. The first noticed is an enlargement of the epithelium. This is accompanied with dilatation of the capillaries. For forty, fifty, or eighty days the change goes on until finally the structure of the gland is so altered as to be no longer recognized as the former thyroid gland.

Dr. T. Mitchell Prudden, of New York, then demonstrated some

sections of atrophied thyroid gland from a case of myxœdema,

described by Dr. Henry Hun in *The American Journal of the Medical Sciences* for July, 1888. Attention was especially called to the large amount of lymphatic tissue which was present in and near the small remnants of glandular structure of the thyroid.

Dr. A. Jacobi then read a paper on the

pathology of the thymus gland.

It has been, he said, the alleged hypertrophy of the thymus gland that has attracted most attention. It is not a very uncommon thing to find a thymus gland weighing twenty-three grammes. He has seen a few cases of sudden death in an infant and absolutely no assignable cause of death except a large thymus gland. If we find a thymus gland of the thickness of more than one centimetre, it is quite natural that the slightest change in the circulation of such a gland should so interfere with the neighboring part as to bring on sudden death. Medullary sarcoma has been first described by Astley Cooper. There is a case of hemorrhagic sarcoma, undoubtedly a sarcoma of the thymus gland with round cells. Virchow mentions a case of sarcoma of the thymus and supposes it can reach the pleura and pericardium in such cases.

Now, it being a fact that the literature of the thymus is very scanty and there being very few observations of disease of the thymus in our literature, it occurred to him thirty years ago that it would be worth while to look

after the thymus in every post-mortem and notice what has occurred. He had, therefore, gathered a certain number of cases in which the thymus was affected, either primarily or secondarily, together with other diseases.

A number of thymus glands have been examined and he had some positive results in regard to tuberculosis, syphilis, diphtheria, etc. Evidently the thymus is an organ in more constant change than any other organ in the human body. He has met with cases in which the thymus was reduced to a very small size by being pressed upon by a tubercular tumor of the neighboring parts. In infants who are tubercular, tuberculosis of the thymus is not very rare. It is found in small tubercular deposits of a miliary kind. There is no doubt that syphilis in the thymus gland is found in two forms as in other organs. It is found as an increase of connective tissue as in liver, spleen, and kidneys in other diseases. It is further found as gummata. There is nothing very characteristic about the changes of diphtheria. They are the least conclusive of all.

DR. GEORGE M. STERNBERG then read a paper on his

RECENT RESEARCHES RELATING TO THE ETIOLOGY OF YELLOW FEVER.

He said he would make a demonstration of the methods of research and give in a general way the result of his investigation up to the present time. As to the specific etiological agent, he had not arrived at any definite result, yet he has done a good deal to make the way clear for other observers, and hoped they may yet arrive at definite conclusions in this respect. To make an analysis of the bacteria found in the intestine of a single individual would require at least six months. He had made ten autopsies in Havana. His general plan of procedure was as follows: As soon as notified that he could make an autopsy, he went to the hospital and made it as promptly as possible. He took blood from the heart, material from the liver, spleen, kidney, and the bladder through its walls, and the stomach and intestines. From the kidney and liver he got organisms in a certain proportion of cases. In six he had a negative result from the liver and four from the kidney. In the majority of cases, from the urine drawn from the bladder he had a negative result. In two out of ten cases he got organisms. In no case did he get the organism which Freire has described, either from the blood, tissues, or alimentary canal. In five cases in which he took considerable pieces of liver and kidney and immersed them in a one per cent. solution of bichloride of mercury, wrapped them up afterward in a piece of muslin saturated with bichloride of mercury several thicknesses, put these pieces away in a laboratory for forty-eight hours, then taking off the wrapping and cutting into the organ, in every case he obtained organisms. In no case did he get the micrococcus of Freire.

In his cultures he found an organism which was altogether different from any heretofore described by reason of the mode of its growth in gelatine. In the first case from the intestine and stomach he got numerous colonies of an organism which, put in twenty per cent. gelatine, gave him colonies of a peculiar form, and he supposed he had a microörganism. In the next two cases he got different colonies.

In Executive Session the following were elected

OFFICERS FOR THE ENSUING YEAR:

President.—Dr. Francis Minot, of Boston.

Vice-Presidents.—Drs. R. Palmer Howard, of Montreal, and S. C. Busey, of Washington.

Recorder.—Dr. I. Minis Hays, of Philadelphia.

Secretary.—Dr. Henry Hun, of Albany.

Treasurer.—Dr. W. W. Johnston, of Washington.

Councillor.—Dr. George L. Peabody, of New York.

The following were

ELECTED TO MEMBERSHIP:

Drs. Morris J. Lewis, of Philadelphia; D. W. Prentiss, of Washington; Norman Bridge and J. N. Danforth, of Chicago; Charles L. Dana, of New York; and Harold C. Ernst, of Boston.

Adjourned.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN NEUROLOGY.

W. R. BIRDSALL, M.D., CHAIRMAN.

Stated Meeting, October 12, 1888.

DR. CHRISTIAN A. HERTER read a paper on

THE THERAPEUTIC USES OF HYPNOTISM.

His object, he said, was to direct attention to the important therapeutic uses of this agent and to the best methods of employing it. The employment of hypnotism is attended with difficulty on account of the prejudices existing against it in the minds of the profession, as well as the public at large. It is, indeed, a subject that is still *sub judice*, and hence it is necessary to qualify any conclusions that may at present be arrived at concerning it. Hypnosis resembles ordinary sleep, with the element of "suggestion" from the operator added. Suggestion is effective, however, in the waking state also, as shown in the so-called Christian science and faith-cure, as well as to some extent as regards homœopathy.

Dr. Herter spoke at some length of the researches of Lieboldt, and described the six degrees into which he had divided hypnotic trance. This was at variance with the well-known division of Charcot, into catalepsy, lethargy, and somnambulism. Charcot's cases, he thought, should not be taken as a basis of conclusions because they were, as a rule, trained subjects. He had never seen the neuro-muscular excitability, so much spoken of, occur spontaneously, although he had found that it could be readily secured by suggestion.

He then described the proper method of producing hypnosis, as advocated by Lieboldt and Bernheim. The operator should first secure the patient's confidence, and then tell him to look him steadily in the eye and think of nothing but going to sleep. The process could be materially aided by suggestive remarks addressed to the patient, and by placing two fingers upon the face; the fingers being finally pressed gently upon the eyelids. In order to obtain good results it is necessary to watch the patient very closely, and to suit the words to the symptoms of sleep as they develop themselves. The *rationale* is very simple. Verbal suggestion in the

waking state makes the patient believe that he is falling asleep, and the method closely resembles the natural process. It had been found that men and women are about equally susceptible to hypnotism, the preponderance being only one per cent. in favor of the latter.

Dr. Herter next spoke of some of the conditions in which it had been employed as a therapeutic agent. He first referred to hysteria, which, he said, had been more written about than any other in this connection. Notwithstanding the literature that has accumulated concerning it, however, the special indications for resorting to hypnotism in it are still far from clear. It is probable that hypnotic suggestion might be of more or less service in all forms of hysteria; but, as a rule, the recovery, if secured, is not permanent. In old cases of contractures due to this cause, it is indeed often very difficult to get any appreciable result. The effect on hysterical amblyopia and amaurosis is extremely interesting, and in many cases a very marked improvement in vision has attended the persevering use of hypnotism. Of the motor paralyses, none is more benefited by hypnotism than abductor paralysis of the larynx. In hysterical convulsions the number and severity of the attacks are greatly diminished. He said that one need never be discouraged by failure to secure hypnosis at the first trial in any case of hysteria. The prospect of a cure would depend on various circumstances, and in many instances hypnotism would at all events serve as a useful adjunct to other treatment. Not much is to be hoped from it in hystero-epilepsy. He had personally employed it in two cases, but with no satisfactory results. In one of the cases profound stupor was induced, which resembled post-epileptic coma. The prospect was not encouraging in epilepsy either.

In several cases of chorea the effect on the movements was rapid and marked, and with perseverance a cure might sometimes be made in this affection. A number of daily sittings are generally required, and in some cases it is necessary to keep these up for months. Still, in any case of supposed cure there would always arise the question whether the disease had not simply run its course and ended spontaneously. There was the most ground for hope in those cases in which the movements were general, and the previous existence of rheumatism and endocarditis did not seem to render the chances of relief less favorable. In insanity the results from hypnotic suggestion have not, for the most part, been satisfactory. He had seen it tried quite extensively in the insane asylum at Zurich, Switzerland, but had never observed any benefit that was not evanescent. The largest number of experiments had been made in cases of paranoia, but the dissipation of the hallucinations sometimes effected was only temporary.

In delirium tremens its effect is often excellent, and quiet, restful sleep was sometimes secured by it in cases in which the same result could only have been obtained by the use of drugs in doses so large as to be dangerous. Alcoholism constitutes one of the most hopeful fields for its employment. The *séances* should be given twice daily for several months, and in many cases the patient becomes inspired by suggestion with disgust for drink. The same is true also of the opium, chloral, cocaine, and tobacco habits; but in all these cases surveillance in an asylum is, of course, an essential feature of the treatment.

Masturbation and other bad habits had been cured by hypnotism, and perhaps no more satisfactory results from its use had been observed in any other affection than incontinence of urine in children. Seiboldt had employed it in seventy-seven cases with a very large percentage of cures in those which remained under treatment for any length of time. The average age of the patients was seven years, and in two of these cases there was incontinence of feces in addition to the enuresis. The result obtained was the more gratifying from the fact that many of the cases had resisted all the ordinary methods of treatment. In various rheumatic affections Bernheim and others had reported fairly satisfactory results. Among these were lumbago and subacute, chronic, and gonorrhœal rheumatism. In chronic joint cases it was claimed that not only was the pain diminished, but that the nutrition of the joint was actually improved by the treatment. Dr. Herter thought that it was doubtful, however, whether any real effect upon the joint was produced. In neuralgias much benefit could be affected in recent cases, but if the trouble was chronic there was less chance of success. In some old cases of sciatica, however, good results had been claimed, and, at all events, the method was often of service in securing sleep, even if no permanent benefit could be looked for. In functional headaches it was of decided service, and in certain instances of migraine he had been successful in mitigating and cutting short the attack by its aid.

At first sight, it might seem that such an agency as this could have no effect upon a function like that of menstruation; but it had been practically demonstrated that in some cases not only the interval between the menstrual periods but the length of the periods themselves could be absolutely controlled by it. The number of individuals in which such results as these could be obtained was, however, comparatively rare.

As to the employment of hypnotism in surgery as a substitute for the ordinary anæsthetics the number of patients, with the exception, perhaps, of children, in whom it was available for major operations, is, no doubt, small, especially as the anticipation of having an operation performed is extremely apt to interfere with the success of hypnosis. On the whole, its employment in this field is not to be recommended, he thought, except in cases in which, for any reason, the use of anæsthetics was contraindicated. He had, however, seen a molar removed under its influence without the patient suffering any pain, or having any remembrance afterward of the extraction of the tooth.

Having spoken at some length of the use of hypnotism in parturition, Dr. Herter said that we are justified in arriving at the following conclusions regarding this subject:

(1) It induces sleep, and it is in no wise prejudicial to the efficiency of the uterine contractions.

(2) It has no tendency to produce post-partum hemorrhage, and is unattended by any other bad results.

(3) It is in no way comparable to chloroform in labor, and should only be used in those rare cases in which the usual anæsthetics are contraindicated.

In insomnia it can often be employed with good results, but it sometimes requires months of persevering treatment to effect a cure. In cases in which drugs have been resorted to it can be used in addition to the habitual remedy, the dose of the latter being gradually

diminished, and perhaps finally exchanged for a placebo. Among the other affections in which it has been tried are writer's cramp and paralysis agitans.

Among the objections which have been raised to the employment of hypnotism are the following:

(1) That it tends, in certain susceptible subjects, to produce temporary mental alienation; some individuals thus developing hallucinations during wakefulness.

(2) That some individuals fall asleep spontaneously, showing a tendency to auto-hypnotism. (This tendency, however, can always be antagonized by suggestion.)

(3) That some can readily be put to sleep by any one who chooses to do so. (This can also be antagonized by suggestion.)

In conclusion, Dr. Herter suggested the following general rules for those practising suggestive therapeutics:

(1) Never hypnotize any subject without first obtaining his or her formal consent.

(2) Always hypnotize in the presence of a third person.

(3) Never give any suggestions other than those which are necessary for the patient's improvement in health.

Public exhibitions of hypnotism, he thought, should be prohibited by law, and the use of this agency exclusively confined to the medical profession. One advantage connected with its employment in medicine is that it does not lose its effect by repetition. On the contrary, the subject becomes more and more readily influenced by it the oftener he tries it. From what had been said it could be seen, therefore, that suggestive therapeutics is not a delusion; and he had no doubt that, before many years, it will take a regular place in medical science. (At the conclusion of his paper, Dr. Herter exhibited on a female subject the method of inducing hypnosis.)

DR. BIRDSALL then read the

REPORT OF A CASE OF TREMOR TREATED BY HYPNOTIC SUGGESTION.

The patient was a young German, male, twenty-one years of age, who came to his service at the department for nervous diseases at the Manhattan Eye and Ear Hospital, suffering from tremor of the right forearm, which had made its appearance a short time previously, and which completely incapacitated him for his ordinary work. There were rapid flexion and extension of the arm, and the movements were so violent as to shake his entire body. A thorough examination failed to detect any organic disease of the nervous system or any other part of the body. His general health was unimpaired and his habits appeared to be exceptionally good. As he seemed to be rather an impressionable subject, it was determined to try the effect of hypnotism upon him. Hypnosis was readily induced, the arm becoming perfectly quiet under its influence, and he was told that when he awoke the tremor would not return. When he first came out of the trance there was no motion, but it soon came back to a slight extent. He was told, however, that it would stop altogether before long, and requested to return for a second treatment the following day. The treatment was repeated several times, and after the fifth *séance* the cure was complete. Later, when Dr. Birdsall had gone out of town for the summer, the patient returned to the hospital stating that the trouble had returned to a slight extent. It was again entirely cured by the same treatment, administered by the physician in charge, and some time after that the patient left town to reside in the South; since which he had been lost sight of.

This was, no doubt, a hysterical case, and to detect whether the young man was shamming or not the most severe tests were applied, both in reference to the tremor and the genuineness of the hypnosis. Dr. Birdsall said, in concluding his report of the case, that he believed that we are not justified in wholly discarding a method of treatment which has already shown itself so useful; though, of course he did not mean to contend that we should by any means attempt to treat all classes of cases by hypnotism, and thus place ourselves on a level with the faith-healers and Christian science people.

DR. OSGOOD MASON read a paper on

SIX CASES OF TREATMENT WITH ANIMAL MAGNETISM.

He said, in commencing, that as the term hypnotism is not altogether satisfactory, and as he had been in the habit of employing that of animal magnetism before the latter came into vogue, he still preferred to retain it, in the absence of any better designation. The first of his cases he had treated eighteen years ago, and was that of a female completely broken down in health from overwork and anxiety, who suffered especially from headache. The treatment by hypnotism was repeated ten or twelve times with great improvement to her health and comfort. The second case was that of a female, twenty-two years of age, suffering from hysterical paralysis and subject to hallucinations and violent screaming fits, and she also was greatly relieved. The third patient was an Irish girl of fifteen, who suffered from epileptic attacks. The bromides were first tried without any appreciable effect. Under treatment by hypnotism, however, there was marked improvement, although she did not remain very long under observation. The fourth patient was a lady of gouty diathesis, who suffered from chronic rheumatism and was in wretched health generally. She was treated twice a week for three months, at the end of which time she returned to England, where she had formerly lived, greatly improved. The fifth patient was a lady who suffered from a painful neuritis of a traumatic origin, and finally died from inanition. Her case was referred to simply on account of one peculiar effect produced by the hypnotic treatment. It was a remarkable fact that every time that the treatment was repeated her hand, which was usually cold and of a blue color, was temporarily restored to its normal condition. The sixth patient was a girl of fifteen, suffering from epileptic attacks, who came under observation August 31, 1885. Finding that medicinal treatment was entirely unsatisfactory, he tried hypnotism with very gratifying results. The *séances* were repeated twice a week, and the number of the attacks, which at first occurred from six to ten times a day, was soon reduced to one or two a week, and afterward to one or two a month. In about five months they disappeared altogether, when the treatment was discontinued. Three weeks after this was done, however, she had two attacks; in consequence of which the treatment was resumed, and kept up regularly for three months. Since then there had been no return of the trouble whatever.

The deductions which Dr. Mason said he had derived from these and other cases which he had observed were as follows:

(1) Animal magnetism is of decided value as a therapeutic agent.

(2) Sleep is not always necessary for the production of the greatest benefit.

(3) It has the effect of equalizing the circulation.

(4) It also regulates and equalizes nervous action.

Corollary: The equalization of the circulation is the result of the equalization of nervous action.

Mr. Corey, of Boston, Chairman of the Committee on Hypnotism of the American Society for Psychical Research, then read a paper on

THE THERAPEUTIC VALUE OF HYPNOTISM.

He spoke particularly of the results reported by M. Voisin in certain cases of insanity. He also referred to many of the affections spoken of in Dr. Herter's paper, and expressed the opinion that hypnotism would undoubtedly prove of great service in properly selected cases in medical practice. In the latter part of it he dwelt at some length upon the medico-legal aspect of the subject, and spoke of the danger that hypnotized individuals might be induced by the unscrupulous to commit criminal acts.

Dr. Kremer said that his experience with the method had been comparatively small. He had, however, tried it in six or eight cases of a neurasthenic or hysterical character. Three of these presented points of special interest, and he said he would relate them. The first was that of a young girl with hysterical aphonia, who readily succumbed to the hypnotic influence. He was, however, unable to make her speak while hypnotized, and three or four months afterward the aphonia got well spontaneously. It seemed to him that the effect of hypnotism on this patient was bad. It was a fact worthy of note that, on one occasion, he extirpated an ingrown toenail for her, while hypnotized, without her feeling any pain. The second case was one of paralysis with spastic contraction, so that the patient could not put the heel to the ground. Under the influence of hypnotism the spastic condition entirely disappeared, and the knee-jerk, which had been abnormally marked, diminished. Otherwise she might have been treated for lateral sclerosis. The third case was one of hysterical cough, in which there seemed to be a hyperæsthetic condition of the entire respiratory tract. Cocaine was employed for a considerable time, but noticing a tendency to cocaine poisoning, Dr. Kremer employed hypnotism. The cough was completely stopped, but the alleviation was only temporary. He thought that in this class of cases there were other remedies which would act as well as hypnotism, and that in cases of neurasthenia it had a general depressing effect. In one case he had had considerable difficulty in arousing the patient from the hypnotic sleep, and in several instances he had found that the treatment gave rise to headache and malaise. On the whole, his experience with the method had not been very favorable.

Dr. C. L. Dana mentioned the case of a child of a neurotic family, who was suffering from vomiting and intense headache, in which, after other remedies had proved inefficient, complete recovery was secured by hypnosis repeated twice. After referring to two other cases, he said that it was something of a coincidence that at the time when the convention of the "Christian Alliance," composed of those who believed in faith-healing, was treating the subject of suggestive therapeutics empirically, it should be discussed at the Academy of Medicine from a rational point of view. He said that five or six years ago, when the method of Bray was in vogue, he had studied hypnotism with considerable care, and he had known of one subject, a young girl of nervous temperament, who was affected with convulsive attacks in consequence of the treatment. While the methods of Bernheim and Lieboldt are much less objectionable, he did not think that the practical application of hypnotism was of very wide range. There are comparatively few individuals who are suitable subjects for treatment by it, and there are but few physicians who are willing to devote the time necessarily required by the method.

Dr. Dana thought the so-called faith-cure and Christian science should be prohibited by law, and expressed the opinion that it was better for a person to remain ill rather than to be cured by such agencies, which tend to produce paresis of the will and eventually to bring about a certain amount of volitional degradation.

Dr. Herter said, in reply to Dr. Kremer, that he had never had any difficulty in arousing a patient from the hypnotic sleep, although he had seen the method tried on more than one hundred subjects. The only exception was in an individual who had been in a spontaneous condition of trance previously. He did not think this a valid objection to hypnotism, and as to the headache and malaise referred to, he thought these could always be prevented by suggestion before allowing the patient to awaken. He had never noticed any depressing tendency about the treatment. He agreed with Dr. Dana entirely as to the bad effects of Bray's method with the bright light, which had been known to give rise to epilepsy and convulsions, but said that he did not know of any evil results from the method now employed. It is comparatively easy to hypnotize a considerable portion of people, although he thought that in the higher classes of society it is more difficult to get subjects sufficiently passive than it is in people of the middle and lower classes.

NEWS ITEMS.

The Philadelphia Polyclinic Course of Evening Lectures.—The second annual series (Part I.) of evening lectures on practical subjects will be given by the Faculty of the Philadelphia Polyclinic, at the college building, Broad and Lombard Streets, free to members of the profession and to medical students, and in the following order, beginning at 8 o'clock:

October 23d, Prof. Henry Leffmann, "The Recognition of Poisoning."

October 30th and November 6th, Prof. Thomas J. Mays, "Pulmonary Consumption Considered as a Neurosis."

November 13th, Prof. Charles K. Mills, "Visual Localization."

November 20th, Prof. J. Henry C. Simes, "Pseudo-sexual Disorders."

November 27th, Prof. S. Solis Cohen, "The Management of Fever, with especial reference to High Temperatures."

December 4th, Prof. H. Augustus Wilson, "The Preparation and Application of the Plaster-of-Paris Bandage."

December 11th, Prof. John B. Roberts, "Treatment of Leg Ulcers."

December 18th, Prof. Edward Jackson, "Failure of Sight in Old People."

Part II. will be announced hereafter.

Disinfection in Cases of Contagious Disease.—In a disinfecting establishment in Berlin, one may have disinfected by compressed steam any article capable of absorbing infectious matter. Two marks (fifty cents) are charged for calling for and delivering, including disinfection, of articles occupying the space of one-half cubic metre (0.65 cubic yard); and four marks (ten cents) for each additional one-tenth cubic metre (0.15 cubic yard). The articles are returned within forty-eight hours. From April 1 to December 31, 1887, "in only a small proportion of the cases of contagious diseases officially recorded was this means of disinfection used, and in many cases probably all articles which might be infected were not sent." During this time, some ten thousand cases of infectious disease were reported, and disinfection was employed in seventy-four thousand. The best results were seen in diphtheria (15.9 per cent.).

The police department of Berlin requires unequivocal disinfection in case of Asiatic cholera, of variola, of typhus and relapsing fevers, and in diphtheria, and disinfection when officially directed in case of scarlet fever, of epidemic dysentery, of measles, of whooping-cough, and of phthisis. Besides, disinfection of dwellings is obligatory in the affections mentioned, consisting of scrubbing with five per cent. solution of carbolic acid, and rubbing the walls with bread. Guttmann recommends spraying, with a suitable apparatus, the walls with a one per cent. solution of corrosive sublimate, and, subsequently, wetting the walls with a one per cent. solution of carbonate of sodium, to render the sublimate innocuous. The oxychloride of mercury is precipitated, which may be readily removed. Dr. Hanstein states that a one per cent. solution of corrosive sublimate may be unhesitatingly applied, alone or with a five per cent. solution of carbolic acid. Those engaged in the work have not suffered in the slightest, if they have worn masks. The disinfection of a moderately large room occupied two workmen three hours.—*Centralblatt für die gesammte Therapie*, Sept. 1888, from *Berliner klin. Wochenschr.* No. 22, 1888.

Bacteriological Investigations into the Water and Air of the City of Warsaw.—Following are the results of the investigations of Bujwid into the condition of water and air of the city of Warsaw. No pathogenic microörganisms are ordinarily found in the air; it therefore follows that disinfection of hospitals and operating rooms is of no practical value or significance. Certain microörganisms which may be found in the air Bujwid failed to find during investigations over a period of three years. Of those found in the air non-pathogenic, but one not yet known gives rise to suppuration in mice and rabbits; the rest are innocuous. The number of bacteria in the air is subject to great variations and depends largely upon the winds and conditions of habitation. After a rain or snow the number is smaller. Basement rooms and abodes contain the largest numbers. On an average, one hundred thousand times more bacteria are found in water than in air. Good water should not contain more than three hundred rod bacteria to the cubic centimetre (0.06 cubic inch). Different results were obtained from the examinations of water from various springs and running streams; above the city the water contained about three hundred bacteria, in the midst of the town over fifty thousand to the cubic centimetre. Bujwid found no pathogenic microörganisms whatever. After filtering this same water (sand filters have recently been introduced into Warsaw) the proportion of bacteria diminished from twenty to sixty. Spring water contains a still larger number of microörganisms. In the discussion which followed, Barzyci stated that in a village near the city of Rzeszow, having no spring, a peasant living by the creek was affected with typhoid. His linen was washed in the stream. Shortly, many of the inhabitants, who obtained their drinking water from the creek and who lived below the house in question, likewise sickened with typhoid; all living above escaped.—*Wiener medizin. Presse*, No. 34, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM OCTOBER 8 TO OCTOBER 15, 1888.

Meacham, Frank, *Major and Surgeon* (U. S. Army).—Died at Fort Douglass, Utah Territory, October 9, 1888, at twenty minutes past 1 P. M.

By direction of the Acting Secretary of War, Louis M. Maus, *Captain and Assistant Surgeon*, is relieved from duty at Fort Schuyler, New York, and will report in person to the commanding officer Fort Ponter, New York, for duty at that post.—Par. 10, *S. O. 236, A. G. O., Washington*, October 10, 1888.

By direction of the Acting Secretary of War, leave of absence for two months is granted William G. Spencer, *Captain and Assistant Surgeon* (U. S. Army).—Par. 11, *S. O. 236, A. G. O., Washington*, October 19, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING OCTOBER 13, 1888.

Bates, N. L., *Medical Inspector*.—Detached from the "Pensacola," and placed on waiting orders.

Farwell, W. G., *Surgeon*.—Ordered to U. S. Receiving Ship "Franklin."

Scott, H. B., *Passed Assistant Surgeon*.—Detached from the New York Navy Yard, and ordered to the Naval Hospital at Mare Island, California.

Magruder A. F., *Surgeon*.—Ordered to duty at headquarters of Marine Corps.

OSTEOPLASTIC RESECTION OF FOOT.

Extract from a Clinical Lecture
Delivered at the German Hospital, October 13, 1888.

BY FERDINAND H. GROSS, M.D.,
VISITING SURGEON TO THE GERMAN HOSPITAL.

BEFORE showing you an operation this morning, I propose to begin the surgical clinics of this hospital for the ensuing season, by making some remarks upon the case which is here brought before us.

The patient, Charles B., is a laborer thirty years of age, upon whom I performed, between three and four months ago, an osteoplastic resection of the foot. It was done for caries of the largest two tarsal bones, namely, the astragalus and os calcis.

In regard to the family history of this man, which is otherwise good, we learn of the unfavorable circumstance that his mother, who is still living, has had some kind of ulcers upon one of her legs for the past ten years; but that, aside from this, she enjoys fair health. Concerning himself the patient states that in his early childhood he had two sores on his right heel, which remained open for two years; but that his foot afterward gave him no trouble until 1885, when half a dozen sinuses formed about the heel bone, and that for these he had been treated for eighteen months in the hospital of a neighboring county. The patient has no recollection that his foot was ever injured by violence. Taking into account the additional fact that when he was admitted into this institution last January with two of the sinuses still existing, he was also suffering with an ulcer of the cornea, we cannot easily dismiss the belief that there is here a dyscrasia, some defect in the nutritive system, although his appearance now is excellent, and his general health quite good. The eye ulcer was quickly cured, when my colleague, Dr. Deaver, who was on duty at the time, operated upon the foot for necrosis and removed some dead bone. This was followed by marked improvement, but not by radical relief. At the time of my own operation on the 18th of June, a carious condition of the calcaneo-astragaloid joint was readily made out by the probe coming in contact with the rough dead surfaces of the two bones.

The operation to which recourse was had is one of modern device, and but few surgeons have as yet put it into practice. It has been performed but twice in this city, once by my friend, Dr. William B. Hopkins, of the Episcopal Hospital, and once when it was done upon the patient here presented.

This ingenious surgical procedure was originally planned and successfully carried out in 1871 by Wladimiroff, of Russia. Strange to say, it seems to have remained unknown to surgeons of other countries until nine years later, when Mikulicz, of Vienna, performed the same operation; without, however, being aware that it had been previously done by his Russian *confrère*. The operation now bears the names of both of these distinguished men, and is known as the "Wladimiroff-Mikulicz's osteoplastic resection of the foot."

The indications for the operation are, caries of the tarsal bone I have mentioned, and extensive and irreparable loss of tissues of the heel, whether such loss be the result of disease or traumatism. It has been resorted to most frequently for the former cause, but in a small proportion of those cases the disease subsequently extended to other bones, and in one gangrene occurred, making amputation necessary. Nevertheless, the result upon the whole has been very satisfactory.

You will notice from what remains of the foot, and more especially from its unusual position, that it bears some resemblance to talipes equinus, and Wladimiroff originally described his operation as an artificial production of that deformity. In the variety of club-foot to which reference is made, the heel is drawn up by the shortened muscles of the calf, and in extreme cases the weight of the body is carried upon the anterior termini of the metatarsal bones and plantar surface of the toes.

In carrying out the procedure under consideration, which consists of several separate and distinct steps, the aim is to bring the metatarsus into a continuous straight line with the leg by planting the anterior half of the foot in a vertical position upon the ends of the tibia and fibula. To do this in a satisfactory manner, it is necessary, on the one hand, to remove a thin section of the articular surfaces of those bones, as is done in Syme's amputation at the ankle-joint, and, on the other, to remove the posterior surfaces of the scaphoid and cuboid.

Having given you in a general way a conception of the operation and its purpose, it remains to explain the successive steps as they were carried out in this case.

After thorough etherization of the patient, the first step consisted of a posterior tibial neurectomy. For this purpose an incision was made over the course of the nerve behind and below the malleolus, extending forward as far as the tuberosity of the scaphoid. The nerve having been raised from the wound, a piece of it two inches in length was excised. Later on you will understand why this was done. The patient was then placed upon his abdomen with the foot projecting over a firm cushion on which his leg rested, and the sound limb held out of the way.

In the second step, an incision was made across the sole of the foot boldly dividing all the tissues down to the bones, beginning at the tubercle of the scaphoid and ending at a point about three-fourths of an inch behind the tubercular eminence of the base of the fifth metatarsal bone. To understand clearly the relative position of the operator to the patient, you must bear in mind that we are dealing with the right foot. The next incision was started from the upper end of the one made for

the excision of the posterior tibial nerve, the knife being guided through the tendo-Achillis a half inch above the os calcis and thence along the outer side of the foot until it entered the cut made through the sole, when all became continuous in one incision; thus mapping out the part to be removed.

In the third step were included disarticulation of the two diseased tarsal bones, ablation of the ends of the tibia and fibula and posterior surfaces of the scaphoid and cuboid. Disarticulation of the astragalus at the ankle-joint was accomplished from behind forward, whilst in front this bone and the os calcis were detached from below upward, the one from the scaphoid and the other from the cuboid. Here I show you the specimens, which have been preserved; this large mass contains the astragalus and os calcis, here you have the posterior surfaces of the scaphoid and cuboid, and here the section from the tibia and fibula. The two first-named have become united on one side by bony ankylosis. By removing a section from the specimen with the saw, the diseased condition of these bones is made apparent. To continue the description of the operation, the next thing to be done was to remove the remaining band of the Esmarch apparatus which had been applied early, and secure all bleeding points by catgut ligatures. One of the terminal branches of the posterior tibial artery was severed near its origin while some abnormally hardened tissues were being dissected from the bone. The two plantars must be divided a little further down, but the blood-supply to the foot depends mainly on the integrity of the dorsalis pedis.

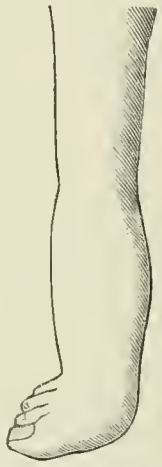
The large gap was next closed by bringing the foot into its new position; and in order to procure the best possible fixation between the tarsal bones and those of the leg, two sterilized bone pegs, three inches in length and three-sixteenths of an inch in diameter (which were kindly supplied by Dr. Hopkins), were sunk into holes drilled two inches deep into the tibia. Corresponding holes having been drilled, one into the scaphoid and another into the cuboid, each an inch deep, the foot was impaled upon the end of the tibia by means of the projecting pegs. During this stage of the procedure the ends of the retrenched posterior tibial nerve were brought together by two fine nerve-sutures, the tendon of the peroneus longus, which had been shortened by the excision of a considerable piece, was reunited by strong catgut, and the tendo-Achillis was stitched fast to the divided plantar fascia. Several strands of large sized catgut were placed in the wound to facilitate drainage, and, finally, the edges of the skin were approximated by a number of interrupted sutures.

The operation was performed under thorough antiseptic precautions, and during its progress the wounded parts were repeatedly douched by a solution of bichloride of mercury from the irrigator which you see suspended over the operating table.

The limb was secured to an anterior splint of heavy surgical felting, consisting of leg and foot pieces riveted to a long iron bar curved over the ankle region in such a manner as to leave an interval between the pieces of felting at that place. The wound was well covered by antiseptic materials, and the limb suspended at a comfortable height above the bedding by means of rings on the anterior splint. In this position it was an easy matter to apply the subsequent dressings.

The greatest elevation of temperature was reached on the third day after the operation, when the thermometer indicated 101.2° F., but on the following morning it had fallen to 99° F., and thereafter remained within favorable range. The dressings were, as a rule, renewed every three days, the wound always having a favorable appearance, and during the entire healing process there were no deep suppurating tracts communicating with bone. As you see the patient to-day everything looks well.

At the end of ten weeks union was sufficiently firm to justify, under the influence of ether, the forcible turning up of the toes, which for a long time had been held rather immovable from false ankylosis.



With a supporting bandage at the seat of union and by the aid of crutches, with which he expects soon to dispense, he is now practising locomotion about the wards of the hospital.

TRAUMATIC ANEURISM OF THE LEFT BRACHIAL ARTERY.

Failure of direct and indirect pressure; ligation of the artery immediately above tumor; return of pulsation on the tenth day; ligation immediately below tumor; failure to arrest pulsation; incision and partial excision of sac; recovery.

By RUDOLPH MATAS, M.D.,
VISITING SURGEON CHARITY HOSPITAL, ETC., NEW ORLEANS, LA.

Notwithstanding the fact that in these latter days the integrity of the brachial artery has ceased to be endangered by the practice of venesection, still, traumatic aneurisms of this vessel are sufficiently common and amenable to ordinary treatment to merit for the records of such cases no other than a commonplace interest. The exceptional features presented by this case, as indicated by the heading, are sufficiently instructive and interesting, it is hoped, to commend this report to the attention of the reader.

The patient, Manuel H., colored, laborer, native of Louisiana, æt. twenty-six, was admitted into Ward 2, Charity Hospital, April 30, 1888. The

history given by patient was, to the effect, that two months before admission he was accidentally shot with a rifle, the whole load, consisting of fine bird shot, being distributed in the scapular, posterior acromial, and humeral regions of the left side, the gun having been fired at a distance of about fifteen feet from the patient. Two weeks after the shooting and when he believed himself completely recovered from the effects of the injury, he noticed a swelling on the inner and posterior aspect of the arm, nearly midway between the bend of the elbow and the lower border of the armpit. This swelling "throbbed" and rapidly increased till it attained its present dimensions.

Condition on admission.—Patient is a robust, tall, and very muscular negro, to all appearance perfectly healthy, outside of the local trouble for which he seeks relief, and without any history of hereditary or acquired taint. On stripping the patient, the left arm presents a marked contrast to the opposite member; it is decidedly larger as shown by the most superficial inspection, presenting an elongated, fusiform swelling which pulsates. On closer inspection it is also noticed that the skin over the scapular, acromial, and posterior humeral regions is closely sprinkled with small dark cicatricial dots which indicate the points of entrance of the small shot; an opinion which is confirmed by the ready detection, by palpation, of the shot as they lie, for the most part, encysted, subcutaneously, at the very point of entrance. It is found that the prominence of the tumor begins, above, about three inches from the lower border of the pectoralis major and terminates below at a point one and one-half inches from the bend of the elbow. The circumference of the affected arm at the most prominent part of the tumor is fourteen and five-eighths inches that of the healthy arm at the same point being twelve inches.

Inspection reveals pulsation which is confirmed by palpation. A marked thrill is also detected in the most prominent and apparently thinnest part of tumor; a decided purring murmur is heard on auscultation, and it is noticed that the pulsation is diffused, characteristically expansive, and synchronous with the radial beat. Pulsation, thrill, and all the active phenomena manifested by the tumor are immediately arrested by pressure over the axillary lower third, or subclavian, above clavicle. Pressure on axillary, sufficient to arrest radial pulsation, causes marked diminution in size of tumor, but this reduction is best marked after application of the Esmarch bandage, under which the circumference of the arm is quickly reduced to twelve and six-eighths inches.

Diagnosis is, plainly, traumatic aneurism of the brachial artery.

Treatment.—In view of the readiness with which the circulation in the tumor was controlled by pressure, the Esmarch was applied; but this had to be removed ten minutes after application owing to the intolerable pain and almost agony that it produced. The patient protested so emphatically against this method of treatment (Reid's method) that it was not repeated.

The next day, April 1, the patient was put to bed, the diet was reduced, veratrum viride, potass. iod., and ergot were administered, and the Massachusetts General Hospital compressor was carefully adjusted to the brachial, just above the aneurism. At the same time, the forearm was tightly flexed on the arm. The patient bore the compressor, screwed sufficiently tight to arrest the radial pulsation, for forty minutes, when the pain became intolerable and the pressure had to be diminished. The compressor was subsequently applied, only lightly enough, however, to slacken the circulation in the tumor and weaken the radial pulsation.

April 22. The compressor has been alternately compressed and relaxed but kept on the artery all day and all night under the supervision of Mr. Sherck, the *interne* of the service. The patient gives evidence of having passed a wretched and sleepless night owing to pain from the compression. On removing the compressor, the tumor pulsates most vigorously and the arm measures now fifteen inches in circumference, showing an increase of three-eighths inch since the beginning of treatment.

23d. The compressor has been kept moderately adjusted, the forearm flexed on the arm and the arm on shoulder; the arm being kept in this position of forced flexion by a well-adjusted bandage which fixes it to head. The patient, who is anxious to get well and is willing to do all in his power to facilitate a cure, has stood with fortitude the ordeal imposed upon him, though an occasional hypodermatic injection of morphia has been required to help him, especially at night-time. The tumor, in the meantime, has not been in the least affected by the therapeutic measures thus far instituted. It pulsates more vigorously than ever, the arm has gained one-eighth inch more in circumference, and the sac is apparently becoming much thinner on the inner aspect of the arm where it threatens to rupture. In view of the unfavorable outlook, it was decided to ligate the brachial in its upper third, just below the superior profunda and immediately *above* tumor. This was done under careful antiseptic precautions, and without difficulty; the artery being ligated with a Kocher's catgut No. 9 (juniper oil), the ligatures cut short, and the incision closed without drains.

Immediately after ligation the pulsation and all the active phenomena in the aneurism were arrested. The tumor became hard, the radial pulse imperceptible. The arm shrank one and one-half inches at maximum circumference of tumor.

30th. Dressing removed, union by first intention throughout wound. Tumor does not pulsate, but has shrunk very little since day of operation.

May 2. In examining the case, my attention was directed to a slight localized pulsation in the tumor, by one of the students in attendance. This pulsation became more marked the next day and progressively continued until it was almost as pronounced, and the tumor as painful, as when patient was first seen.

6th. I decided to ligate the distal end of artery *immediately below tumor* at bend of elbow, and in case of failure to control the pulsation thereby, to apply the Esmarch and lay open the sac and seek for the intermediary nutrient branches.

Operation.—A catgut ligature (Kocher's, 9) was applied to the brachial at the bend of the elbow without the slightest perceptible effect on the pulsation or size of the aneurism. The Esmarch was then applied and an incision was made along the whole length of the tumor extending from the primitive incision for the ligation of the brachial, close to the lower border of the axilla, to the bend of the elbow, about six and one-half inches. The sac was at once exposed, and, with the hope of extirpating it, a close though rapid dissection was begun which succeeded in isolating both ends of the sac and the major portion of its anterior and internal aspect; it was found impossible, owing to intimate connection of the sac with the important and deeper structures of the arm, especially with the biceps and brachialis anticus, to continue the dissection toward the humerus.

The dissection and isolation of the sac were therefore stopped and a large incision made throughout its whole length; at the same time an elliptical piece of sac, representing its exposed portion, was excised, and the clot which was partially laminated, but mostly passive, in its central parts, was turned out in larger quantities, the whole cavity being constantly and thoroughly irrigated with a 1 : 2000 acid sublimate solution (Laplace's). By this means three orifices were readily detected at the bottom of the sac, two of these being large enough to admit readily a No. 8 gum catheter; the middle orifice only offering some resistance to the catheterization.

The gum catheter was first passed into the orifice nearest the axilla and it readily passed upward inside of the artery until it stopped at the point where the first ligature had been applied sixteen days previously, proving clearly that that was the proximal axillary end of the aneurism. A catgut ligature was once more applied while the catheter was *in situ*, the catheter, which served as a perfect guide, being withdrawn as the ligature was tightened. The introduction of the catheter into the lower orifice led at once to the bend of the elbow, where it was arrested at the point where the ligature had just been applied. It remained now to close the third or middle orifice, which was smaller and apparently had no connection with the two preceding; this orifice I presumed to be the orifice of a much dilated inferior profunda. This orifice was completely sealed by passing four fine interrupted silk sutures (for want of fine catgut) through its lips. The Esmarch constrictor was then relaxed and I was considerably surprised to notice a decided flow of blood from the other two orifices notwithstanding the fact that the vessels with which they communicated had been apparently controlled by previous ligature at the proximal and distal extremities of the sac; this showed plainly that there must be some important collaterals which communicated with the vessels between the points of ligature and the internal or aneurismal orifices. In view of this I immediately stitched the lips of the orifices with *fine* sublimated silk, by which means the openings were sealed completely and not a drop of blood entered the sac henceforth. A strip of acid sublimated gauze (Laplace's) was then left in the sac instead of a drain and deep interrupted sublimated silk and catgut sutures applied.

In addition to the usual antiseptic dressing the whole arm was wrapped up in cotton wadding and hot bottles were kept to the forearm and hand.

7th. Patient has passed a restless night and suffered great pain at site of wound. Temperature 102° F.

In view of this, dressings were removed under antiseptic precautions, and the cause of the trouble discovered to be an intense erythema and *complete* vesication of the edges of the wound, owing to the overzealous application of the too strong and caustic 1 : 500 acid sublimate gauze. The trouble could have been obviated by using a weaker gauze, or previously protecting the skin with a layer of Lister's protective or iodoform gauze.[1] A milder gauze (1 : 1000) was substituted and the wound dressed otherwise as usual. From that date onward the wound gave no further trouble; it granulated without further suppuration and the patient was discharged completely cured and with only a linear cicatrix to indicate the site of the aneurism, May 21, 1888.

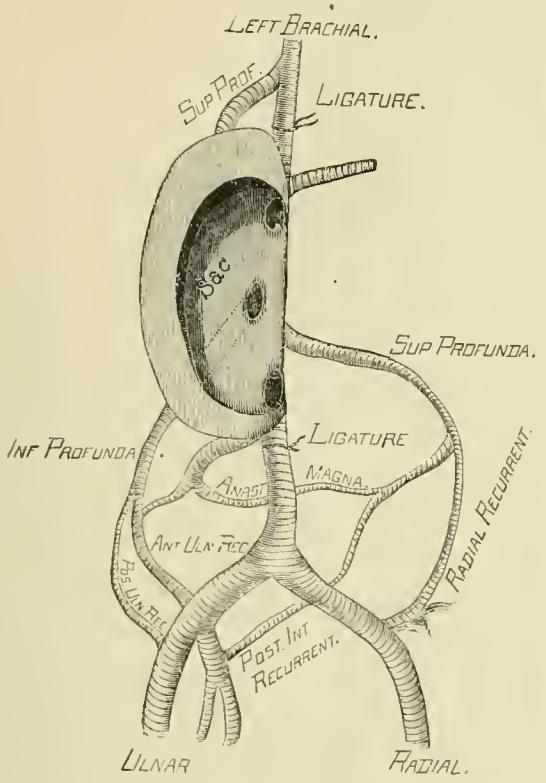
Remarks.—An eminent authority[2] has written: "Deligation of the brachial, or of the lower part of the axillary artery for aneurism is so very generally successful and is so slight an operation that but a small number of cases are published." It is to the fact that the case under consideration proved so marked an exception to the general rule thus stated that it owes its main interest. It will be noticed that (1) after the failure of the various measures that had been instituted to diminish the circulation in the sac, (2) the brachial was ligated at what might be called the point of election in the upper third of the arm, just below the origin of the superior profunda and immediately above the sac; that (3) apparent cure followed the deligation of the artery at this point, (Anel's operation); that (4) pulsation returned on the tenth day, and with it all the other aneurismal symptoms; (5) that four days after the return of the aneurismal symptoms a ligature was applied to the brachial at the distal end of the sac; (6) that notwithstanding this ligature the tumor still pulsated and its size remained totally unaffected; (7) that after incising at the same sitting and clearing the sac (old operation) the orifices of three arteries of supply were readily discovered and the inefficiency of the ligatures easily explained, as will be readily understood by referring to the accompanying diagram; (8) the ease and the thoroughness with which the bleeding orifices of the nutrient vessels were sealed by the method employed, viz., *suture;* (9) lastly, the rapid recovery of the patient and the equally prompt healing of the wound in spite of the extensive traumatism inflicted.

Tripier, an excellent authority, states in a valua-

[1] Vide article on "Corrosive Sublimate" by Dr. F. W. Parham, New Orleans Medical and Surgical Journal, June, 1888.

[2] Barwell, Ashhurst's Encyclopædia of Surgery, 1883.

ble contribution on the pathology of the brachial artery[1] that "in all cases of circumscribed traumatic



Schematic representation of the collateral circulation in the case of M. H.

aneurism we should always try indirect digital compression if it is possible to apply it. If it does not succeed, then we must chose between the ancient method and that of Anel. The ancient method is of more *difficult execution*, but it is incomparably more certain in its results, as it more positively guards against relapses and hemorrhages. It is certain, however, that by Anel's method some very good results have been obtained; but in a certain number of cases it has failed and the surgeon has had to appeal to the ancient method. Several instances of this sort have been recorded. The most complete and instructive [thus far, 1869] having been that of Brodie, who in 1820, in a case of brachial aneurism resulting from an unfortunate venesection, applied a ligature to the brachial about seven centimetres above the tumor. The aneurism returned about five months after; a second ligature about three centimetres above the aneurism was now applied [and the sac opened.—R. M.]; the tourniquet was removed and hemorrhage followed from the sac. A fresh ligature was now placed immediately below the sac; the tourniquet was again removed, and another gush of blood followed from the sac; then a fourth ligature was placed *immediately* above the tumor and this did finally control the hemorrhage."

This was certainly an obstinate case; but energetic as were the procedures adopted by Brodie they would have failed with the aneurism now reported, as, in this instance, the ligature immediately *above* and *below* the sac completely failed to check the circulation in the tumor. It is plain that no other method would have succeeded but that which was adopted, *i. e.*, the free opening of the sac and *the closure of the orifices of supply in the sac itself.* It is in accomplishing this last result that we have an opportunity of observing the advantages gained by the improved technique of the present day.

It is doubtless greatly due to the difficulties formerly experienced in attempting to secure the nutrient orifices in the sac that Tripier and the majority of contemporary writers who appreciate the thoroughness and great merits of the Antyllian operation for aneurisms of the extremities, still regard it as of "more difficult execution." In the light of my recent experience, I feel convinced, however, that this is one of the difficulties of the operation which is most easily surmounted. It will be remembered that Boyer, Günther, and other older surgeons already recommended the introduction of bougies or catheters into the aneurismal openings in order more readily to isolate and secure the proximal and distal ends of the artery. By this means they succeeded readily enough in securing the distal and proximal end of the tumor, but only beyond the limits of the sac, so that the intermediary branches, which, as in the case here recorded, are sometimes so troublesome, were not intercepted by the ligature and continued to bleed in spite of it. In order to secure these collaterals, which communicate with the main vessel between its immediate extra-aneurismal portion and its proper opening, or mouth, in the sac, the method recently suggested and practised by Annandale offers great and positive technical advantage.[1] This method consists "in introducing a bougie of suitable size into the openings from the side of the sac, in making a small incision through the wall of the sac on each side of the bougie, and in passing an aneurism needle through these round the vessel, the ligature being tightened as the bougie is carefully withdrawn."

In the present instance the bougies were only used to apply ligatures outside of the sac; the bleeding orifices within the sac having been thoroughly sealed by a few fine sutures. This procedure served me so satisfactorily, that I cannot but heartily recommend it to those who may be placed in similar circumstances.

[1] Article "Brachiale," Dechambre's Dictionnaire Encyclopedique des Sciences Médicales.

[1] Vide Edinburgh Medical Journal, February, 1886; also, Editorial, in The Medical News, May 29, 1886.

In addition to this important detail, we might add that the complete ischæmia of the limb which is solely obtainable by the Esmarch bandage, which so readily adapts the parts to the difficult and delicate dissections sometimes required in the practice of this operation; also the introduction of the animal ligature, which has so thoroughly revolutionized the practice or, at least, the principles of arterial deligation to such a degree indeed that, in future, the so-called spontaneous or idiopathic aneurisms will, in many cases, be treated with the ligature in as close a proximity as the purely traumatic. Again, the superiority of the antiseptic practice which totally suppresses or greatly minimizes the risks of suppuration, risks that were so unavoidable and disastrous in the older days; and, finally, that greatest and grandest of the advantages of the modern surgeon —anæsthesia—which allows the operator to cut with a calm and deliberation that were denied his ancestors, are all circumstances which are conspiring to return to the "old" operation the prestige which has been necessarily denied it for so many years.

AN ENVIRONMENT EXPERIMENT REPEATED 1888.[1]

By E. L. TRUDEAU, M.D.,
of Saranac Lake, N. Y.

In a paper read before this Association at its last session some experimental evidence was adduced which tended to show that, at the first step of artificial tubercular infection, the pathogenic properties of the tubercle bacillus and the natural resistance of the tissues are so closely balanced that infection may often be prevented and always hastened by the nature of the environment in which inoculated animals are placed.

In order to complete this research, a confirmation of the evidence already obtained as to the favorable influence of a good environment over the course of the disease has been sought for, while two points relating to the experiment in which the rabbits were allowed to run wild and failed to become infected, have seemed to merit further study. The first relates to the quantity of virus made use of, and the second to the permanency of the beneficial influence exercised by favorable surroundings. Whether the animals would have escaped equally well had the amount of bacillus-bearing fluid injected been larger, and whether their apparent recovery was permanent or only temporary, are questions to which an answer has been sought by a repetition of the former experiment with such variations only, as would tend to throw light on these points.

On June 10, 1887, six full-grown, healthy rabbits, were inoculated in the right lung with a quantity of a pure culture of the tubercle bacillus, as nearly as could be estimated, at least twice as large as that made use of in the experiment of 1886. They were at once turned loose on the same island and supplied with an abundance of food throughout the entire summer. After being permitted thus to run at large for four months, three of them were killed, while the remaining three were placed in a box and spent the following four months in confinement in a sandy pit, on a moderately restricted diet. At the expiration of four months they too were killed and their organs examined.

Lot No. 1.—Killed as soon as removed from a favorable environment. In the first rabbit no lesion whatever, was observed; in the second extensive and advancing tuberculosis of both lungs, with caseation at many points in the injected lung, was noted; while in the third, a thoroughly localized lesion, consisting of a small fibrous cyst, containing hard putty-like material and attached to the costal pleura at the site of inoculation, was the only disease present. In the centre of this fibro-calcareous nodule a few bacilli with spores were demonstrated by staining. All the organs were sound and the animal was loaded with fat.

Lot No. 2.—Killed four months after removal from favorable to less favorable surroundings. In the first animal examined, a small localized cavity in the middle lobe of the right lung marked the site of injection. The connective tissue forming the walls of this little excavation was so thick as to make it resemble a cystic tumor, in the centre of which were a few drops of a turbid fluid. The lung tissue in the immediate vicinity was normal and no enlarged bronchial glands were detected. The other organs were all healthy and the general nutrition excellent. The fluid from the cavity stained and examined under the microscope showed a few bacili, most of them full of spores, and from a portion transferred to blood serum, a pure culture of the tubercle bacillus was readily obtained. In the second rabbit all the organs were perfectly normal, in the third the following lesions were noted. The right pleura, especially on its mediastinal aspect, was studded with small growths, some of them nearly as large as a split pea, of extreme toughness and light yellowish color; on section they were found composed of a fibrous capsule of varying thickness containing material of the consistency and color of dried putty and partly calcareous. Under the microscope a few bacilli were made out in these nodules, and plants from the same source on blood serum resulted in a pure culture of the tubercle bacillus. The lungs were perfectly free from disease, the other organs were sound and the animal was in good condition.

A comparison of the experiments of 1886 and 1887, made under precisely the same conditions,

[1] Read before the American Climatological Association, September 19, 1888.

except that in the latter double the quantity of virus was injected, gives the following results. In 1886, for five rabbits, one death occurred from progressive tuberculosis, and four entirely escaped infection. In 1887, out of six animals, one at the autopsy showed advancing diffuse pulmonary tuberculosis, two failed to become infected, and three (or one-half) presented localized and arrested primary lesions. The beneficial influence produced by a good environment on the course of the tubercular affection, as evinced by the arrested lesions of the last rabbit, seems to have been maintained for four months in spite of their removal to less favorable surroundings.

The dormant virulence of the germs and the dangers which still threatened are shown by the readiness with which these microbes and their spores spang into activity when planted on a suitable culture medium.

From a comparison of the two experiments it would appear that the amount of virus which enters the economy at one time is an important factor in determining infection, and the influence of a favorable environment is emphasized, not only by the entire freedom from disease presented by two of the rabbits, but by a careful study of the arrested lesions of their mates. The lungs of these animals bore testimony to the effectual efforts of nature to localize the mischief and in none of them were secondary lesions present. In two a fibrous sac contained all that remained of the necrotic tissues and the bacilli, and formed an efficient barrier between these still dangerous elements and the healthy parts by which they were surrounded; in the third the injection passing between the upper and middle lobes had evidently entered the pleural cavity alone and acted on a much larger surface; the calcified and fibrous nodules which studded the pleural surfaces marking the numerous foci which had been successfully localized.

The absence of any fresh outbreak of tubercular disease noted at the autopsies of the animals placed for the last four months in less favorable surroundings, is evidence that the conservative reaction of the tissues against the bacilli tended ultimately to bring about complete recovery. The danger of relapse could not, however, be said to have passed, for the encapsulated bacilli grew readily when released and planted on a suitable culture medium.

The autopsy room constantly demonstrates that infection is often arrested when the primary lesions are restricted, while death almost invariably follows when they become more advanced. Vibert recently, while making 131 autopsies at the Paris Morgue on persons who had come to their death by violence while apparently in good health, noted in twenty-five—that is, in more than nineteen per cent., the presence of some slight tubercular lesion. In seventeen of the twenty-five a few calcareous and fibrous nodules remained as the only evidence of an unsuspected and arrested tubercular process, but in none were the pathological changes in the lung extensive. Recovery often follows the operations now undertaken for tubercular peritonitis, though it is evident that all the infectious material cannot be removed. Dogs when injected subcutaneously with a moderate amount of a culture of tubercle bacilli, develop only localized foci, show no deterioration of health, and finally recover completely, but their resistance to the disease can be overcome by the inoculation of larger quantities of the virus. Koch, for a long time, failed to infect rats, but finally succeeded by repeated introduction of more liberal amounts of the culture.

The doctrine of the unity of tubercular virus may be said to derive support from a consideration of the proof offered by both experiments taken collectively, for although the amount of virus injected proved a most important factor in determining infection, whether the animals escaped entirely or died of progressive tuberculosis, whether purely localized disease not incompatible with life or widely differing generalized and progressive pathological processes were induced, seemed to depend not on any variation in the nature of virulence of the virus injected, which was the same in all cases, but in an increased or diminished degree of resistance induced in the tissues through the influence exercised on the vitality of the animal by extremes of environment.

All attempts at the direct destruction of the tubercle bacillus in living beings by germicides have so far proved fruitless, while the records of the autopsies made by Vibert, Councilman, and others, as well as the evidence offered by the present research, furnish proof that the tissues themselves can, under certain conditions, either limit the destructive action of this microbe or even entirely rid themselves of its presence. The best promise of success in the management of tubercular affections for the present, therefore, lies not so much in the search for specific germicidal methods of treatment as in a careful study of all those measures which tend to increase the vital resistance of the infected individual. One of the principal objects of this Association is the study of those conditions of light, air, and habitation best adapted to bring about in the human subject affected with tuberculosis, arrested lesions such as have been described above. That it is possible artificially to produce this result on animals by these simple means alone should be an incentive to a thorough discussion of those climatic and hygienic conditions which go to make up a favorable environment.

THE ABORTIVE TREATMENT OF SYPHILIS.

By J. WILLIAM WHITE, M.D.,
CLINICAL PROFESSOR OF GENITO-URINARY SURGERY IN THE UNIVERSITY OF PENNSYLVANIA; SURGEON TO THE PHILADELPHIA AND GERMAN HOSPITALS.

The essential nature of syphilis has not, as yet, been definitely determined. It seems probable, in the light of modern pathology, that it will be found to depend upon a specific microbe, but that microbe has not yet been isolated or cultivated, or distinctly demonstrated in any way, either clinically, experimentally, or microscopically. The treatment of syphilis cannot, therefore, be based scientifically upon anything but clinical experience. Such experience, however, points so unequivocally to the employment of some form of mercury throughout almost the entire course of the disease, that as regards this main point there are practically no differences of opinion among living syphilographers. Whether we assume that syphilis has to be classed with the exanthemata as a specific eruptive fever, in which case the mercurial may be regarded as a specific antidote to the syphilitic virus; or believe that the phenomena of the disease are due to the entrance into the economy and the multiplication therein of a certain protoplasmic mass—the so-called syphilitic cell—in which case the effects of the drug may be attributed to its action in promoting destructive metamorphosis; or whether, confessing ignorance, we simply appeal to the history of the therapeutics of syphilis and select the drug which we know to have been of the greatest value, we are equally led to employ some form of mercury. There is also but little difference of opinion as to the general method of its employment. Whether given as an antidote, an alterative, a "tonic," or empirically, small doses administered over long periods, with the idea of producing in each case the full physiological effects of the remedy while avoiding its toxic action, represent the views of the vast majority of specialists.

When, however, we approach the subject of the proper period at which to begin its administration we meet at once with a wide divergence of opinion. Mr. Jonathan Hutchinson, unquestionably one of the ablest of living syphilographers, has recently reiterated, under the above attractive caption, the views which he long ago expressed regarding the early administration of mercury in syphilis, claiming that by the prompt employment of the drug in cases of chancre, and its subsequent continuous use, the secondary stage of the disease may be suppressed or rendered "abortive."[1] His general propositions will undoubtedly meet with universal acceptance. When he states that in cases in which the induration of the sore is well characterized and considerable, it always yields quickly and definitely to the influence of mercury; that we never see sores remain typically hard while the patient is under that influence; that in cases in which high temperatures have been observed in syphilis, they always promptly subsided under the use of mercury; and that when the patient receives no treatment until his eruption is well out, mercurial medication will usually, in the most definite manner, cause the eruption to disappear, every one having experience in the treatment of this disease must undoubtedly agree with him. The probable truth of the view which he has always so warmly advocated, that syphilis is due to a specific particulate virus, or, in the language of to-day, to a living microbe, and that, therefore, it is quite within reason to speak of the "specific" or "antidotal" action of mercury, will also be generally, though not universally, admitted. But when we come to consider his advocacy of the administration of mercury, immediately upon the appearance of induration in the chancre, we meet with a serious practical difficulty which, it seems to me, Mr. Hutchinson hardly estimates at its full value. There is a widespread belief among syphilographers, that while there is a strong probability that an indurated sore will prove infecting, and that a soft suppurating sore will not, there are exceptions to both these rules, and that "there is really no absolute proof of the infecting nature of any given sore, but the fact of infection itself." Mr. Hutchinson, it is true, says that ever since the recognition of the facts that some chancres are not infecting, and that the phenomenon of induration is the most valuable one by which to diagnosticate the true chancre, we have been in the habit of waiting until the character of the sore declares itself before beginning to use the specific, and adds, that many, and especially those of the French school, have advocated delay until constitutional symptoms in the form of eruption appear, but with this remark apparently dismisses this aspect of the subject.

I have always regarded his work and teachings with such admiration and respect that I have been led once more to consider the matter carefully, having for years taught and practised on the theory above mentioned, namely, that, all things considered, it was wisest to postpone the use of mercury until there was evidence of constitutional infection. Every surgeon whose work has brought him in contact with large numbers of cases of venereal sores, must recognize the fact rather unaccountably ignored by Mr. Hutchinson, but unquestionably familiar to

[1] The Lancet, January 31, p. 174. Mr. Hutchinson, among other conclusions, stated his belief: "That it is impossible to begin the administration of mercury too soon, and that it should be resorted to without loss of time in all cases in which a chancre shows a tendency to indurate; that many cases of indurated chancre, treated early by mercury, never show any of the characteristic symptoms of the secondary stage.

him, that between the typical soft suppurating local sore and the distinctly indurated chancre there are large numbers of doubtful ulcers which partake of the characteristics of both: local sores with deceptive inflammatory hardening and true chancres with equally deceptive inflammatory softening, suppuration, and even loss of substance.

Nearly every specialist who has written upon the subject has recognized and been influenced by this well-known fact. Mauriac, in his excellent paper on the diagnosis of chancre, after describing the cartilaginous, elastic, sharply circumscribed resistance met with at the base of a true chancre, says that when we find it we may "suspect very strongly that we are dealing with a syphilitic growth, although even those symptoms cannot be considered as infallible." Diday prefers to wait until secondary symptoms make their appearance before instituting mercurial medication, believing, with Zeissel and Sigmund, that the subsequent course of the case is either uninfluenced, or is actually rendered milder by this delay. Bumstead and Taylor assert very positively that no course of mercury administered for a chancre, however thorough, or prolonged, is likely to prevent the subsequent evolutions of general manifestations. Some eminent authorities maintain the contrary, but their opinion has not been confirmed by our own experience. In the very many attempts that we have made to subdue the disease during the existence of the initial lesion, and prior to the appearance of general manifestations, we have always failed. Moreover, although the use of mercury retards the appearance, and probably ameliorates the severity of the secondary symptoms, yet it is a fact attested by many observers, ourselves included, that those cases ultimately do best in which the specific treatment is deferred until the secondary stage. Keyes says "general treatment should be commenced as soon as the diagnosis of syphilis is positive. To be positive on such an important point requires more evidence than is furnished by the simple physical characters of the sore, be they ever so positive. Diagnosis sufficiently accurate to commence treatment upon can only be made by confrontation—establishing the syphilitic disease in the person from whom the chancre was derived—or by waiting until some positive corroborative signs of secondary lesions appear. When the diagnosis is sure, there is no need of further delay."

Van Harlingen, in the *International Cyclopædia of Surgery*, says, "as regards the period at which the administration of mercury should begin, it is now agreed by most syphilographers that nothing is gained by its too early administration. Given on or shortly after the appearance of the initial lesion, its effect is to delay and render irregular the definite generalized lesions, without preventing their eventual appearance. An element of confusion is thus introduced into the orderly evolution of the various manifestations, and occasionally the delay in their appearance gives rise to false hopes of a permanent cure, often rudely dispelled by an unexpected outbreak, or perhaps by the transmission of the disease to an innocent person."

Fournier, perhaps the most eminent living syphilographer, has recorded a case which bears most strongly upon the question under consideration. A female child, six years old, was said to have been infected with syphilis, during an attempt at rape. She had marked vulvitis, and upon the labia three grayish, shallow, indolent, indurated ulcers covered with a diphtheritic-looking membrane, and raised a little above the general surface. In both groins there were enlarged, multiple, lymphatic glands. He positively diagnosticated chancre, but, conforming to his custom in medico-legal cases, declined to testify for a few days. During this time, under a simple dressing, the symptoms disappeared, and the patient, who was carefully observed for several months, never showed any subsequent signs of infection. Fournier believes that the case demonstrates that small inflammatory lesions may so closely resemble chancres as to deceive the most experienced surgeon, and adds that in medico-legal cases the diagnosis should not be made upon the local lesions alone, but should depend upon the development of constitutional symptoms.

It would be easy to multiply evidence to this effect, and I could from my own case-books give many examples of cases in which, if compelled to give an opinion, based upon the appearance at a given time of the local sore, I should have made the diagnosis of syphilis, although delay has, fortunately for the patients, demonstrated the innocent character of their troubles. Mr. Hutchinson, to be sure, says, with characteristic candor, that he must admit that the gross total of cases of primary syphilis which has been under his care has not been so much as that which falls to the share of specialists, particularly those holding hospital appointments, and that more patients come to him in the secondary stages than in the primary. This probably accounts for his somewhat too sweeping recommendation as to the early employment of mercury.

The surgeon who is daily called upon to give an opinion in cases which involve the whole future of the individual, his relations to the other sex, his determination toward celibacy or matrimony, his matrimonial relations if he should be already married, the question of the influence of paternity, the institution of a course of treatment extending over years, the diagnosis of any obscure visceral troubles which he may develop later in life, the profoundly depressing mental effect which a knowledge of syphilitic infection usually has upon intelligent people—the surgeon, I say, who remembers

these facts and recalls the views which I have above cited, as to the possibility of error, should surely hesitate about beginning a course of treatment which will possibly obscure or render altogether impossible the diagnosis.

While I am not disposed in the least to agree with those who believe there is positive advantage in delay as regards the subsequent course of the case, yet I do not think, on the other hand, that the gain from the immediate treatment during the primary sore is sufficient to counterbalance the doubt and uncertainty which that treatment often throws about the future life of the patient. It has been my custom to advise my pupils never to begin constitutional treatment for syphilis, unless they were prepared to swear positively and to demonstrate that that disease existed, and certainly the cases are comparatively rare in which a careful surgeon would be willing to take this position during the existence of the primary sore alone. I have recognized both in my teachings and practice a few necessary exceptions to this rule, which may be included under the following heads:

1. Where confrontation is possible and the sore is distinctly a typical one.

2. Where with a similar sore its continued existence would destroy or imperil the conjugal relations of two people or possibly the happiness of an entire family.

3. Sores with characteristic induration, but with marked tendency to spread and involve important regions.

4. Sores in such conspicuous positions, as upon the lips or the nose, that their continuance would involve a general knowledge of the patient's condition.

With these exceptions I still believe, in spite of Mr. Hutchinson's teachings to the contrary, that it is the part of wisdom to wait until the development of glandular enlargement at some point removed from the initial lesion, and not, therefore, by any possibility a result of simple adenitis, demonstrates the constitutional character of the trouble. It is not necessary to wait for the syphilodermata. Treatment may be safely begun when, after a suspicious sore upon the genitals, consecutive enlargement of the epi-trochlear or post-cervical lymphatics takes place, and, beginning at this stage, I can cordially endorse all that Mr. Hutchinson claims for a mild continuous mercurial treatment as to its effects in suppressing or "aborting" subsequent symptoms. The argument which I have used as against the mercurial treatment of chancre applies with equal force to the local abortive measures which have from time to time been recommended. These include cauterization; excision; antiseptic measures; and various local applications of mercurial preparations by means of ointments, hypodermatic injections, or otherwise. Taking them in the order mentioned, their relative advantages and disadvantages seem to me to be as follows:

As to cauterization, it appears to me unquestionable that it can be of service in but a very small proportion of venereal sores as they usually come under the notice of the practitioner. The publication of certain cases, such as the well-known one of Mr. Hill, who cauterized the torn frænum within twelve hours after the accident, and in whose patient syphilis developed at the usual time, and that of Clerc in proof of the uselessness of immediate ablution, has had a marked effect in influencing professional opinion upon this matter. The teachings of Ricord and Sigmund, who believed that cauterization within five days after contagion certainly prevented infection, have long since been shown to be misleading, as in those days local sores were not clearly differentiated from infecting chancres.

Sores which appear within five days after intercourse are rarely or never syphilitic, and this fact at once throws out 99 per cent. of Ricord's and Sigmund's alleged successful cases. In the remainder, in which cauterization was immediately applied, as in Mr. Hill's case, to a tear or abrasion during coitus with a person known to be syphilitic, there is, of course no certainty that the disease would have developed even if no local treatment had been adopted. The opinions of syphilographers vary greatly in regard to the value of this form of treatment. Keyes peremptorily rejects it as useless and unphilosophical with the remark that no amount of cauterization nor any local treatment can prevent the development of general syphilis after the poison has once been absorbed much less after the chancre has appeared. Hill and Cooper think it wiser to assume that we cannot indicate any period at which syphilis is a local disease which can be extirpated by local treatment. Bumstead and Taylor believe that chancre is never a mere local lesion.

On the other hand, Mr. Hutchinson finds it difficult to believe that absorption of syphilitic virus is so rapid that there is no stage during which it remains limited to the seat of inoculation, and prefers to act as if this stage comprises the first week or ten days after contagion. Jullien remarks that, in spite of theoretical considerations as to the rapidity of absorption of the virus of syphilis, or of other contagious diseases, he still thinks we have no right to neglect whatever small chance may be offered by the employment of cauterization whenever the sore is seen during the first three days. Cornil says that we are not in possession of absolutely conclusive evidence upon this point, but that it is highly probable that the syphilitic virus inserted under the skin remains there a certain length of time without any other action than gradually to change the cells which are in immediate relation with it, and slowly

to prepare them for the hyperplasia which soon constitutes the chancre. Auspitz, Unna, and Kölliker believe that the initial indurated sore is not to be considered as a symptom of general infection. The experience of the latter authors in the excision of chancres has encouraged them to believe that, in a small proportion of cases, general contagion may in this way be prevented.

Familiar with these opposing views, and striving to find a safe general rule for practice and teaching, I have for a long time thought it best to assume that a sore seen within a few days after its appearance, and as yet unaccompanied by any enlargement of the inguinal glands, was still a localized lesion. If favorably situated—*i. e.*, upon the skin of the prepuce or of the genitals—I have advised its removal by excision, and in a large number of cases have practised it, picking up the sore and surrounding tissue with a pair of toothed forceps, and removing it by a single sweep of the knife, or by means of scissors curved on the flat, afterward dressing the wound with iodoform or boracic powder. When the patient refused this treatment, or when the sore was so situated that its removal would cause considerable pain, hemorrhage, or deformity, I have employed destructive cauterization with fuming nitric acid.

As regards protection from subsequent constitutional disease, my results have, on the whole, been unsatisfactory; but in a few cases—five, all told, with two more which are yet doubtful—I have succeeded in making my observations under unusually satisfactory circumstances. In these cases the patients came to me promptly upon the development of the sore, and sent to me, for examination, the women with whom they had had connection; evidence of syphilis being discovered in the latter, I excised the sores of the male patients, and cauterized the resulting wound with nitric acid. In three of these cases, microscopical examination by my friend, Dr. Simes, showed that the sores possessed the usual characteristics of hard chancres. In one of them slight glandular involvement had already shown itself; in the others it had not yet appeared. The shortest period intervening between the appearance of the sore and my inspection of it was twenty-four hours, the longest five days. In two of the five cases, including the one in which there was slight glandular involvement, no further symptoms have ever developed; in the remaining three the appearance of constitutional symptoms was delayed from three to five weeks beyond the usual time, just as is the case from the mercurial treatment of chancre. The other two cases which I have mentioned are now under observation, and I have, within a few hours, had the opportunity of observing another interesting case of tear of the frænum during a suspicious intercourse.

It is only fair to add that, during the time I have been making these observations, I have had several cases in which excision was not performed on account of the anatomical seat of the sore, which I yet believed to be almost certainly specific, but which healed, and disappeared without the development of the slightest constitutional trouble. In these latter cases, however, I had no opportunity for confirming my diagnosis by confrontation. In all cases (and these comprise the majority which come for treatment) in which a week or more has elapsed since the development of the sore, and in which involvement of the dorsal lymphatics of the penis, and the inguinal lymphatic glands is observable, I reject cauterization as a routine method of treatment, on account of its undoubted uselessness at that stage in preventing constitutional disease; the pain which it causes; the inflammatory action which follows it, and which often produces enough œdema and swelling to cause phimosis, and thus convert an open sore into a hidden one; the subsequent effusion of lymph, which simulates true induration and confuses the diagnosis; and, finally, the greater liability to the production of suppurative action in the ordinarily indolent bubo of syphilis.

It seems to me that by this plan of treatment I have given my patients whatever small chance there may be of avoiding constitutional disease, while at the same time exposing them to the minimum degree of local pain and disturbance. The so-called aseptic treatment of the initial lesion of syphilis seems to me a misnomer, so far as the essential character of the sore is concerned, unless it be meant to include only the thorough destructive cauterization of all portions of the infected tissue. Applied simply to superficial dressings placed over the chancre, it can refer only to the prevention of the development of pyogenic organisms upon the surface of the sore. As to the tendency of infecting chancres to suppuration is usually very slight, and their local significance is generally unimportant, we can hardly look here for advantages from the employment of aseptic or antiseptic methods which are at all commensurate with those obtained by the same methods in ordinary surgical conditions.

The method recently recommended by Dr. Edward Bronson, of New York, the local treatment by hypodermatic injection of mercurials beneath the base of the initial lesion and into the mass of the indurated lymphatic glands, is based almost exclusively on theoretical grounds. It appears to rest upon the view that mercury acts as an antidote when brought directly into contact with the syphilitic germs, and that this influence would probably be especially active if the drug were brought to bear directly upon the local lesions which are the foci of infection during primary syphilis. If we believe that the virus remains localized for a time after inoculation, and is not disseminated through the general system, and that mercury acts by its germicidal

influence, this treatment is not unphilosophical, but seems manifestly inferior to the more thorough plan of excising both the chancre and the enlarged lymphatics of the groin. The latter procedure would be less likely to result in local troubles, such as abscess or cellulitis, and would certainly be more effective.

My views upon the general subject of the abortive treatment of syphilis may accordingly be expressed as follows:

I. While it is unquestionably desirable to begin mercurial treatment at the earliest proper moment, and while that treatment undoubtedly either suppresses or renders milder the subsequent secondary manifestations, and while there is every reason to believe that in this way the liability to later or tertiary lesions is somewhat lessened, nevertheless the sum total of these advantages does not warrant the employment of mercury one moment before the diagnosis of constitutional disease is absolutely assured.

II. While in many cases that diagnosis can be made with a high degree of probability from the appearance of the primary sore alone, yet it cannot be said that all possibility of error is excluded until some general symptom, such as the enlargement of distant lymphatic glands, has shown itself.

III. The administration of mercury during the existence of the primary sore, unaccompanied by general symptoms, for the purpose of suppressing or "aborting" syphilis, is not, therefore, justifiable, unless by confrontation the diagnosis can be confirmed, or unless there are urgent and unquestionable reasons for securing rapid cicatrization of the chancre.

IV. It is proper to employ cauterization or excision according to the site of the chancre, in cases in which it is seen very soon after its appearance, and especially when it is known to have followed intercourse with a syphilitic person. The chances of preventing constitutional infection in this way, while very slight, may yet be considered sufficient in such cases to counterbalance the disadvantages of the method, such as pain, swelling, the production of phimosis or of suppurating bubo, and the obscuring of the diagnosis by the resulting inflammatory exudation.

V. Aseptic or antiseptic measures, while harmless, cannot be considered especially indicated in the local treatment of chancre, and can, in all probability, have no true abortive influence.

VI. The local use of mercurials, hypodermatically or by inunctions, is perhaps worth a trial, but it is probably inferior to the more radical methods, based essentially upon the same principles, namely, excision and cauterization.

1810 SOUTH RITTENHOUSE SQUARE.

MEDICAL PROGRESS.

The Prevention of Puerperal Fever.—DR. C. J. CULLINGWORTH, in his introductory address at St. Thomas's Hospital, at the opening of the session, showed by statistics that, by the use of antiseptic measures puerperal fever has been almost entirely banished, and it has come to be regarded as quite an unusual event for a patient's temperature during convalescence to exceed 100° F.

In the face of such results as these, it is surely time to give up talking about an autogenetic variety of puerperal fever. The precise character of the antiseptic measures to which these wonderful results are due, varied in different hospitals, and varied, too, in the same hospital from year to year. It would, therefore, serve no good purpose to attempt to describe them in detail. The object at which they all aimed was the same, namely, the exclusion of pathogenic microörganisms from the genital passages. As to the best methods of effecting this object, there is, no doubt, still some difference of opinion. The best authorities, however, are quite agreed:

1. That the fundamental rule in antiseptic midwifery, the neglect of which renders all other measures futile, is to insure perfect antiseptic cleanliness of the hands of the attendants, of any instruments or appliances that may be required, and of everything that is liable to be brought into contact with the genital passages.

2. That the most efficient antiseptic for this purpose at present known is corrosive sublimate.

3. That the best method of insuring antiseptic cleanliness of the hands is to wash them thoroughly with soap and warm water, using a nail-brush vigorously, and then to rinse them carefully, again with the help of a nail-brush, in a solution of corrosive sublimate, 1 in 1000.

4. That if the patient has been already examined without antiseptic precautions, the vagina ought to be irrigated with a germicide solution as a preliminary proceeding.

5. That if, for the foregoing or any other reason, sublimate irrigation be employed, care should be taken to avoid any of the solution lodging in the passages, lest the patient be mercurialized.

With regard to the desirability of sublimate irrigation as a routing practice before and after delivery, opinions vary. It cannot be denied that some of the most brilliant results hitherto obtained have been obtained by those who regularly practise sublimate irrigation. On the other hand, however, there is the experience of the hospitals of New York and Boston, where the crowning success was achieved after irrigation, as a routine practice, had been entirely abandoned. Moreover, it must not be forgotten that several cases have been recorded in which sublimate irrigation has resulted in fatal mercurial poisoning. For the ordinary douching of the vagina during the puerperal period, the simpler and non-poisonous antiseptic solutions are, in Dr. Cullingworth's opinion, quite as efficacious as the more powerful ones, and infinitely less dangerous; but as a disinfectant for the hands, instruments, and other appliances, corrosive sublimate is perfectly free from danger, and at present stands unrivalled.

The essential antiseptic measures are very simple, and their habitual employment is by no means burdensome. A pint of corrosive sublimate solution of the proper

strength (1 in 1000) can be prepared in a minute or two from a ten-grain powder, a dozen of which can be put in a little box, and carried in the pocket. In the powders supplied by his direction to the obstetric clerks in connection with the maternity department at St. Thomas's, the ten grains of corrosive sublimate are mixed with fifty grains of tartaric acid and a grain of cochineal. The tartaric acid increases the bulk of the powder and, what is more important, lessens the risk of a portion of the mercury being lost by precipitation, either from being formed into an insoluble albuminate, or from the alkalinity of the water, as in the case of London. The cochineal is, of course, merely a coloring agent to prevent the solution being mistaken for anything else.

A solution of corrosive sublimate does not, like solutions of potassium permanganate, lose its antiseptic property after being once used. It is, therefore, usually sufficient to prepare a supply on entering the lying-in room, to renew it when the labor is over, and afterward to prepare a fresh solution once a day. The solution should be placed in a small bowl on the washstand by the side of the washstand basin, and kept there, ready for immediate use, from the time the first internal examination is made to the end of the puerperal week.

The best antiseptic lubricant with which we are at present acquainted is a solution of corrosive sublimate in glycerin, 1 part to 1000, and this also can be easily carried about in a suitable and well-secured bottle.—*British Medical Journal*, October 6, 1888.

The Treatment of Phthisis with Calomel.—Dochmann, in the September *Therapeutische Monatshefte*, relates his experience with the use of calomel in phthisis. Administered in the first and at the beginning of the second stage, calomel improves the appetite, diminishes the cough and fever, and dispels the night sweats and the objective symptoms. At the end of the second and at the beginning of the third stage, it reduces the fever, checks or diminishes the diarrhœa, and improves the general condition. Whether calomel has a specific action upon the local changes in the lungs or influences the life and development of the tubercle bacilli or checks the progress of the destructive process, only more extensive observations can determine, The following formulæ may be used:

℞.—Hydrarg. chlorid. mitis . . grs. x.
Pepsini . . . . . 3j.
Tinct. opii . . . . . gtt. xxx.—M.
Ft. pulv.
Dein adde
Ext. phellandrii aquatic., q. s. ut ft. pil. No. 60.

℞.—Hydrarg. chlorid. mitis . . grs. x.
Pepsini . . . . . 3j.
Ergotine (Bonjean's) . . grs. ij.
Ext. glycyrrhizæ q. s. ut ft. pil. No. 60.

For hemoptysis:

℞.—Hydrarg. chlorid. mitis . . grs. x.
Pepsini . . . . . 3j.
Ext. hyoscyami . . . grs. ix.
Ext. phellandrii aquatic., q. s. ut ft. pil. No. 60.

On the first day the patient takes six pills (two at intervals of two hours), on the second day five, on the third day four, and from the fourth day he takes two pills, thrice daily, throughout the period of treatment. Every fifth or sixth day, the calomel is intermitted for two or three days, during which time iodide of potassium may be given. The size of the first dose depends upon the fever; should the fever increase, the dose of calomel is increased to twelve to fourteen pills a day.—*Wiener medizin. Presse*, No. 39, 1888.

Creasote in Phthisis.—Keferstein recommends the following formula:

℞.—Creasot. . . . . 1.3 parts.
Spirits of wine . . . 25 "
Cinnamon water . . 100 "
Syrup of cinnamon . . 25 " —M.

One commences by administering three teaspoonfuls during the day. Each week the dose is increased one teaspoonful.—*Gazette Médical de Paris.*

Use of Antipyrine in the Nasal Passages.—Dr. F. Whitehill Hinkel reports (*New York Medical Journal*, Oct. 20, 1888) four cases treated by antipyrine spray and summarizes his experience as follows:

1. A solution of antipyrine possesses hæmostatic properties when sprayed into the nose, though not superior to cocaine.

2. Antipyrine in about four per cent. solution may be used upon the nasal mucous membrane with temporary relief to occlusion from engorgement of the turbinates, and with sedative effects upon irritable states.

3. It is most effective where the element of irritation exceeds that of inflammation.

4. It presents an advantage over cocaine in not producing local numbness and dryness, and in the absence of the general stimulating properties of cocaine, causing sleeplessness, headache, etc. In cases such as hay fever, in which an agent of relief is used for long periods, antipyrine as a nasal spray is less likely than cocaine to produce constitutional disturbance or to lead to a "habit."

5. Antipyrine presents the disadvantage of causing more or less severe smarting, and being unequal to the relief of severe inflammation or severe occlusion of the nares.

6. Its antiseptic and stimulant properties will probably make it serviceable as an application to fresh wounds and to granulations and ulcerations in the nasal chambers.

7. Combined with cocaine, it increases the local action of the latter, enabling it to be used in weaker solution.

Ether for Pediculi Pubis.—In the *Monatshefte für praktische Dermatologie* it is proposed to destroy pediculi pubis by a single application of ether in spray. This procedure is less injurious to the skin than the application of chloroform, which likewise accomplishes the same object.—*Deutsche medicin. Wochenschr.*, September 20, 1888.

Calomel and Digitalis in Cirrhosis of the Liver with Ascites.—While calomel is used with general success as a diuretic in cardiac and renal diseases, opinions are divided as to its employment in cirrhosis of the liver. Upon the suggestion of Senator, Dr. Schwass (*Berlin. klin. Wochenschr.*, No. 38) has used calomel and digitalis for ascites following hepatic cirrhosis, with extraordinarily fortunate results. In the case of a forty-five year

old man, who had been in the hospital ten months, requiring puncture at least twice monthly to evacuate the fluid which collected in the peritoneal and right pleural cavities, the ascites disappeared upon energetic treatment with calomel in conjunction with repeated punctio abdominis, and the patient in a few weeks recovered to such a degree as to be able to leave the hospital. Temporary benefit was attained in the grave complications of cirrhosis with organic heart disease, nephritis, and tubercular peritonitis. The combination of calomel and digitalis possesses greater advantages. It often acts beneficially when one or the other alone fails. A further advantage is, that with the simultaneous administration of digitalis calomel is borne better and for a longer period—that is, its unpleasant secondary effects, ptyalism, stomatitis, and gastro-intestinal catarrh, either do not appear at all or appear only in a mild degree, or at a later stage than common. A grain and a half of calomel and three-quarters of a grain of digitalis are given every three hours for a week. It is an advantage if the cases are treated early. In advanced stages of the cirrhotic process permanent benefit can scarcely be expected. Based upon numerous observations Schwass makes the recommendation, in suitable cases of ascites from hepatic cirrhosis—that is, when no complication with grave disorder of some other organ exists, excepting affections of the heart, and when the disease has not yet entered upon the last stage, that an attempt be made with calomel and digitalis to prolong life, perhaps with a restoration to activity.—*Wiener medizin. Presse*, No. 40, 1888.

Ergotine in Enlarged Spleen.—Fania reports the case of a patient suffering from a greatly enlarged spleen, due to malaria, in which that organ resumed its normal size after the hypodermatic injection of ergotine.—*L'Union Médicale.*

Parotiditis.—

R.—Phenic acid	. . . . .	gr. viij.
Quininæ sulph.	. . . .	℥ss.
Acidi salicylici	. . . .	℥ss.
Rum	. . . . .	℥iv.—M.

One-eighth of this to be taken every hour or two in the very severe forms of parotiditis.

Tar-water for Hemorrhage.—Dr. Corneille de Saint Marc has found tar-water as useful in hemorrhage as hamamelis and other hemostatics. It is best given in quantities of an ounce to an ounce and a half in twenty-four hours, in hemorrhages from the lungs, nose, or uterus. The remedy is even said to be useful in advanced phthisis with severe hemoptysis.—*Deutsche medicin. Wochenschr.*, September 20, 1888.

The Preparations of Sozoiodol.—Dr. Langgaard (*Therap. Monatshefte*) reports the result of his experience with the preparations of sozoiodol. He used the soluble sodium salt and the free diiodo-paraphenol-sulphonic acid, for which he proposes the name sozoiodolic acid. It was shown that the acid or the sodium combination, in solutions of one-half to one per cent., retards the development of the micrococcus of suppuration. Two per cent. solutions entirely check the development. Experiments upon rabbits demonstrated that fifteen grains of sozoiodol-sodium have no toxic effect. In the antiseptic treatment of wounds, besides the free acid, the sodium, potassium, and aluminium combinations were principally used, which, on account of their non-toxic quality and absolute tastelessness, may be preferred to other antiseptics in common use. Of the sodium and aluminium combinations, which are readily soluble, or of the free acid two to three per cent. solutions in water may be employed. The same means may also be adapted to the impregnation of dressings, such as gauze and cotton. When a slow, prolonged action is desired, the sozoiodol-potassium commends itself for its slight solubility, sprinkled in a finely powdered state, either alone or with talc or sugar of milk, five to ten per cent. ointments of sozoiodol-sodium, potassium, aluminium, or zinc with lanolin; for insufflation, sozoiodol-potassium and sodium, alone or with sugar of milk, sozoiodol-zinc, ten per cent. with sugar of milk, sozoiodol-mercury, four to ten per cent.—*Wiener medizin. Wochenschr.*, No. 40, 1888.

Pleural Surgery.—T. Pridgin Teale expresses himself in the following remarks regarding operations which involve the pleura. He thinks "we are losing our fear of exposing the pleura and the lung, just as we have learnt, step by step, how to deal boldly and safely with the peritoneum.

"The evil of admission of air into the pleural cavity is not the mere exposure of the pleural surface to the air, is not that the lung collapses by the mere admission of the air, but that where there is a fairly healthy lung and pleura, the inrush of air reduces to a serious extent the mechanical power of the thoracic wall over the function of inspiration.

"That in cases in which this mechanical difficulty threatens the life or impedes the recovery of the patient, surgery must decide upon the best method of closing the wound to the inrush of air whilst allowing adequate drainage of any pus cavity to be carried on.

"That the region of the diaphragm is a situation in which abscess amenable to surgical treatment frequently occurs, such abscesses often commencing below the diaphragm, and tending to discharge through the diaphragm and through the lung.

"It seems probable that such abscesses can be more safely attacked through the lower angle of the thorax, provided there be dulness at the seat of puncture, than through the abdominal wall.

"As to washing out the cavity of a large pleural, or pulmonary, or hepatic abscess, it is probable that antiseptic washing is of value in the early period, whilst the cavity is offensive; but that, as soon as the secretion has become sweet, washing is not only unnecessary, but tends to disturb the comfort of the patient, and retard his progress. If drainage be effective, so that fluid does not lodge, the fluid, which is sweet when secreted, should escape from the cavity before it has time to deteriorate.

"As to the question of excision of portions of rib in treating empyema, on this point he is unable to speak from personal experience. The tendency of surgical opinion seems to be rather to reserve it for special and exceptional cases than to make it a general rule of practice."—*British Medical Journal*, Oct. 13, 1888.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, OCTOBER 27, 1888.

HÆMOGLOBINURIA.

NOTWITHSTANDING the enormous amount of clinical and pathological work which has been expended during the last ten years on the subject of paroxysmal hæmoglobinuria, and on the hæmoglobinæmia of which it is a symptom, we are yet ignorant of its essential cause. The action of cold, or of prolonged muscular effort, as exciting causes is, it is true, well understood; but why a small proportion of individuals should be subject to transient alterations in the blood so profound, from the action of insignificant causes, "chasing the royal blood, with fury, from his native residence," remains to this time wholly unexplained. Nor do we, in point of fact, possess any reasonable hypothesis concerning the causation of this condition, for the analogy of the hæmoglobinuria following the administration of certain drugs and the transfusion of blood, helps us not at all to the discovery of the essential nature of the *materies morbi* of the paroxysmal form.

Still further work must be done ere our knowledge of hæmoglobinuria shall have become complete. The direction of that work appears to lie in a closer, more exact, and more minute investigation of individual cases. An excellent example of such work is to be found in a recent valuable paper by PRIOR, of Bonn (*Munch. med. Woch.*, July 24 and 31 and August 7, 1888). The subject of the investigations upon which Prior's paper is based was a man forty-three years of age, without history of syphilis, but who, while under observation, developed pulmonary tuberculosis, of which he finally died. Twelve seizures were duly studied. Of these, eight began with a distinct chill, one with well-marked fever, three without decided prodromes. The exciting cause on five occasions was exposure to cold; on three, unusual bodily exertion; once, exertion and wetting; on three occasions there was no discoverable cause. Ten of the attacks were accompanied by fever, the rise of temperature reaching in the course of an hour 102° to 104° F. The duration of the febrile movement varied from one and a half to eight hours, the average being five hours. In two instances the hæmoglobinuria was unattended by rise in temperature. The reaction of the urine in all the attacks was acid. In this respect the case differs from instances recorded by Rosenbach and Fleischer, who noted neutral and alkaline reactions. In eight of the twelve paroxysms the coloring matter of the blood appeared as methæmoglobin, twice as a mixture of methæmoglobin and oxyhæmoglobin, and twice as oxyhæmoglobin alone. The hæmoglobin, as a rule, made its appearance in the urine about the time the temperature reached its maximum, the amount being greatest when the fever was most intense, or in the beginning of the crisis. The more intense the chill and the higher and more prolonged the fever, the more abundant and long continued the excretion of hæmoglobin. The average specific gravity of the urine was about 1017, ranging from 1012 to 1021: its amount was somewhat diminished on the day of the attack, and increased on the following day.

During the paroxysms the urea and other solid constituents of the urine were also diminished, being again increased somewhat upon the following day. The form of albumen present in the attack was chiefly serum-albumen; to a much smaller extent paraglobulin. The proportion of albumen was determined at that period when, upon spectroscopic examination, the hæmoglobin was found to have disappeared; it was never great, not exceeding 0.3 per cent. In about half the attacks the spleen and liver were tender upon pressure and appreciably enlarged, in some instances being recognizable upon palpation. In one attack only was the spleen alone enlarged; this enlargement of these organs persisted some little time after the subsidence of the attack. In rudimentary paroxysms, in which there was hæmoglobinæmia, as determined by the presence in the blood of phantom corpuscles and corpuscular débris, without the presence of hæmoglobin or albu-

men in the urine, there was a likewise demonstrable enlargement of the liver and spleen. In two paroxysms there was icterus. During the paroxysms the heart's action was frequent, 140–150; pulse small; respiration disturbed, dyspnœa occurring even in those attacks unattended by elevation of temperature. Among the nervous disturbances were dulness, creeping sensations of the surface, contracted pupils, unsteadiness in movement. Upon the occurrence of the sweating stage the pupils dilated. Headache and vomiting are also to be regarded as indications of disturbances of the general nervous system.

There can be little doubt that in paroxysmal hæmoglobinuria brought about by the action of cold or prolonged muscular effort, the symptoms are caused by some autogenous chemical substance, rapidly developed and acting as a poison; the action of this substance upon the blood is analogous to that of chlorate of potash, carbolic acid, or foreign blood introduced by transfusion. It not alone deprives the red corpuscles of their coloring matter as does glycerine, but it also destroys them. This substance and the hæmoglobin dissolved in the blood serum are in part disposed of in the liver and spleen, in part eliminated by the kidneys. What it is, remains to be determined.

THE SUPPRESSION OF SMALLPOX.

According to the official records, smallpox has entirely disappeared from Philadelphia after having prevailed to a moderate extent for about six months. During this period there were 364 cases and 80 deaths, which makes the death-rate 21.97 per cent.

Immunity from this disease for a length of time, by removing the incentive of fear, has the effect of diminishing the number of vaccinations and of correspondingly increasing the number of susceptible subjects. Under these conditions, the introduction of a case, especially if it is not at once placed under proper restrictions, is very apt to spread the disease.

Variola was brought to Philadelphia by a workingman from Sheffield, England, in February last. The case was a light one, and its nature was not suspected until three children of the household were taken sick. By the unfortunate neglect of the physician in attendance, the disease was allowed to become distributed before the authorities were apprised of its existence. Had a notification of the first case been promptly made, the spread of the disease would, in all probability, have been prevented. The rigorous application of preventive measures uninterruptedly continued after the existence of the disease was discovered, had the effect of confining it within moderate limits, and of finally suppressing it. These measures consisted in vaccination, isolation, and disinfection. Twenty public vaccinators successfully vaccinated 25,000 persons in six months. In addition, many times this number of persons were vaccinated at private expense. At least fifty-five per cent. of the cases were isolated in a special hospital, and the remainder in their homes with the consent of a medical officer of health, and under his supervision. Disinfection was conducted under the direction of a trained official, aided by his subordinates. The immediate notification of cases, so important in the official management of contagious diseases, was secured by a stringent law, assisted by the pressure of public opinion.

The banishment of smallpox is theoretically practicable, but practical experience teaches us that its restriction is all that can be expected, even under the most perfect management. The prevention of no disease is better understood than that of smallpox, and yet the consummation of measures aimed at this object is constantly hindered by agencies over which there can be no absolute control. To stamp out the disease, early or late, requires the complete application, in all its details, of a perfect method, which, however well understood and scrupulously attempted, is hardly ever successfully accomplished. Hence it is that only approximate results are obtained, even under the best management, the success of these results, as in all undertakings, being commensurate with the correctness of the methods pursued and the timeliness and thoroughness of their application.

WOUND TREATMENT WITHOUT DRAINAGE.

Ever in modern times has it been the ideal of the surgeon to have wounds heal without subsequent disturbance or attention after the post-operation dressing has been applied. Manifestly this will never be possible for all wounds, but every day we see the range of this much to be desired innovation widen, and at no distant time we may confidently expect to heal a majority of our operative and traumatic wounds by primary intention, without either drainage or redressing. The present necessity for drainage is the greatest shortcoming of our ideal, but much valuable work is being prosecuted in that direction, and the near future may be expected to clear up

that which at present is probably misunderstood or falsely interpreted.

Perhaps chief amongst the recent workers in the direction of healing large wounds without drainage is Rydygier, who has been carrying on experiments upon quite an extensive scale (*Wiener med. Wochenschrift*, No. 18, 1888). He, of course, has only attempted thus to treat wounds which seemed favorable to his purpose, but it will be seen that this includes cases which might appear exceedingly unfit for healing without drainage. He concludes that such attempts should be strictly confined to wounds which we feel confident are entirely freed from all diseased tissues; that the most complete disinfection of the wound area must be practised before operation; that antiseptic irrigation must not be employed after beginning the operation; that all unnecessary sponging and other manipulation of the wound must be strenuously avoided, and that primary suture be employed, leaving small interstices here and there between the stitches which are to be allowed to fill with clot, and dry as rapidly as possible. Hence no protective is to be used, except in those cases in which the wound edges cannot be made nearly to approximate. Dryness, flat compression, and antiseptic protection are the features of the dressing and after-treatment. Drain tubes are directed to be introduced later, if the case should progress unfavorably; but, in Rydygier's hands, this was necessary in only about sixteen per cent.

He has been able to put this method of wound handling into successful use even in cases of hip-joint disease—surely a crucial test. The use of antiseptic — hence irritating — solutions upon the wound has been abolished, and, consequently, the main necessity for drainage (to carry off the immense ooze which is thereby produced) is done away with at once. Four cases of excision of large lymphomata of the neck have thus been dealt with, and thorough primary union secured, as likewise have breasts been excised, the scapula resected, tuberculous bones chiselled out, etc., with, in all, but sixteen per cent. of failures. The non-successes, however, were only partial, and in no wise affected the patient for the worse. The method has been found of especial value in cases of surgical tuberculosis, in which, heretofore, long healing drainage sinuses have been a serious drawback or cause of relapse.

The Fifth Otological Congress will be held in 1892, at Florence.

Bellevue Hospital, New York, has hitherto had no place of worship for its convalescent inmates other than the amphitheatre used by the students on week days. The corner-stone of the new Townsend Chapel was laid last week by Bishop Potter. The building will cost $25,000, and will embrace a free reading-room and library for the use of the patients and nurses.

Dr. O. W. Wight, of Detroit, died October 12th, from typhoid fever. Dr. Wight was widely known through his vigorous administration of the health offices of Milwaukee and Detroit, and through his sanitary and medico-legal writings. He had been admitted to the bar previous to his entering upon the practice of medicine; to a mind widely versed in knowledge, he added acute powers of observation and an originality in the application of his learning.

Lloyd Morton, M.D., of Pawtucket, R. I., died on the 16th inst., in the sixty-first year of his age. He died suddenly, of apoplexy, by which he was prostrated while in attendance upon a patient, to whose house he was called at 3 o'clock A.M.

Dr. Morton, the son of a physician, was born in Halifax, Mass. He was graduated from Brown University in 1844, and from the Woodstock (Vt.) Medical College in 1851. He had resided and practised medicine in Pawtucket since 1852. A widow and one son survive him.

The deceased was a prominent and respected citizen, and stood high in his profession. He joined the Rhode Island Medical Society in 1864, was elected president of the same in 1872 and again in 1873. Subsequently, he was a member of its Board of Censors from 1878 to 1883 inclusive. He was a man of pronounced opinions, and at the same time of kind and generous impulses. As a physician and surgeon he was experienced and successful.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, October 18, 1888.

The President, A. Jacobi, M.D., in the Chair.

Dr. M. Allen Starr read a paper on

APRAXIA AND APHASIA; THEIR VARIETIES AND THE MODE OF DETECTION OF EACH.

His object in the paper, he said, was not so much to present a review of our present knowledge regarding these affections, as to indicate the methods of examination to detect *all* the symptoms present in patients suffer-

ing from them. The division of disturbances of speech into the two great classes of sensory and motor aphasia, had been followed by a further subdivision into word-deafness, word-blindness, agraphia and motor aphasia, and paraphasia.

The accepted notion of to-day is, that every word in ordinary use has a complex mental substratum, which may be termed the word-image, made up of a number of memory-pictures. Each object would be found to vary from another in respect of the memory-pictures which form its mental substratum. It is a fundamental position that involved, in the accepted theory of cerebral localization, that memories are the residue of perceptions, and are, therefore, localizable in the regions of the brain concerned in perception. It followed that these memories forming the idea of an object or an action, being distinct from one another, might be lost by disease of the brain having a limited extent, and that the character of the memories lost would depend on the location of the disease.

For the general symptom of inability to recognize the use or import of an object, the term *apraxia* is now employed; and since apraxia is a symptom which is very frequently associated with aphasia, and which, in fact, may lie at the basis of aphasia, it should always be looked for in a patient. To test for apraxia it is only necessary to present various objects to a person in various ways, and notice whether he gives evidence of recognition. He may or may not be able to name these objects; the question in point is, Is it evident that the object awakens an idea in his mind?

Having stated that the variety of apraxia known as blindness of mind is the one most commonly met with, Dr. Starr related the case of it recently reported by Macewen, which was of especial interest as affording the first example of its successful treatment by operation. (*British Medical Journal*, August 11, 1888.) The angular gyrus was exposed by surgical procedure, and it was proved that a portion of the internal table of the skull had been detached from the outer, and had exercised pressure on the posterior portion of the supra-marginal convolution, while a corner of it had penetrated and lay imbedded in the anterior portion of the angular gyrus. Removal of the bone, the displacement of which was the result of an accident a year previously, resulted in complete recovery from the pain and mental symptoms from which the patient suffered.

The variety of apraxia known as deafness of mind had recently been studied by Oppenheim and others, who noticed that while some aphasics retained their musical faculties, others lost the power to follow melodies, to appreciate music, or to hum or sing the tunes which they formerly knew. In view of the observations that had been made regarding this point, it was worth while to test intelligent patients as to their musical faculties. Apraxia had as many varieties as there were organs of sensation, and the facts which had been collected in regard to the different forms were of great interest, not only as throwing light on mental processes of association, but as indicating that those processes were carried on in definite areas of the brain and in tracts which connect those areas, and could be arrested by disease in these parts. One fact of special interest had been brought out by Dr. Starr's study of the cases of apraxia which he had been able to collect, and that was, that the lesion has always been found in the left hemisphere in right-handed, and in the right hemisphere in left-handed, persons; in other words, in the same hemisphere lesion of which has produced aphasia. It was true that apraxia, like aphasia, had been noticed in cases of paretic dementia, in which the disease is diffuse and situated on both sides; but this fact would not imply that a unilateral lesion alone was insufficient to produce the symptom.

In nine cases of apraxia with autopsy collected by Dr. Starr, the variety which existed was that of psychical blindness, and accompanied the form of aphasia known as word-blindness. In all the cases the lesion involved the cortex of the supra-marginal and angular gyri, or the tracts posterior to those parts in the white matter beneath them. It was noticeable that this symptom of apraxia was always associated with some form of aphasia. Hence all cases of aphasia should be examined for apraxia. From the lesions observed, it would seem that at present we must locate our memory-pictures of objects on one side of the brain, and on the same side which presides over speech.

Dr. Starr then directed attention to the second set of memory-pictures which make up the word image. Each word, he said, was composed, as far as its own image went, of four separate memories, each of which might be lost separately.

1. If the memory of the sound of the word is lost, the memory cannot be called to mind, and cannot be recognized when heard.

2. If the memory of the appearance of the word is lost, the visual image of it cannot be called to mind or recognized, and the patient will be unable to read or to write spontaneously.

3. If the memory of the effort needed to pronounce a word is lost, a true paralysis of articulation occurs, though the muscles may not be weakened. This is the ordinary form of motor aphasia, due to a lesion of Broca's centre.

4. The independence of the effort-memory necessary for writing and connected with movements of the hand from the effort-memories of speech has been established. When these were lost alone the condition was known as agraphia. In such a state the pen could not be used. When a word could not be called to mind, it could not, of course, be written; but words could often then be written by dictation, if the person was one who was accustomed to writing much. Hence sensory agraphia and motor agraphia must be distinguished; the former being a part of word-blindness, the latter not at all associated with inability to read.

These forms of aphasia are due to a loss of distinct memory-pictures. These several memory-pictures which are united in the word-image might thus be reasonably regarded as separate from one another in their location in the brain. But since they *are* joined to form the word-image, it follows that the association-fibres joining the various areas are as necessary to the use of even a single word as the various areas with their memories. It is really by association only that an object or a word becomes a subject of thought or use. There is one form of aphasia in which the lesion is known to affect a great association-tract, viz., paraphasia, or the aphasia of conduction of Wernicke. In this condition the word-hearing and word-uttering process are perfect, but their connection is broken. The patient can understand what is said to him, and can pronounce many words well; but

he misplaces words, using one word for another. Such patients may even talk jargon. It is, therefore, evident that the processes of association should be most carefully tested.

In many cases of aphasia the symptoms are not such as to point to one of these pure forms of aphasia, but a combination of the characteristics of these forms will be found. The patient then had a mixed form of aphasia, in which both sensory and motor elements were combined. Still, in such cases, a thorough examination would demonstrate that one or the other pure form was present in excess, and this would indicate in which direction the lesion lay. The facts that all the various speech areas are supplied with blood by the middle central artery, and the frequency with which emboli lodge in this artery instead of plugging up a small branch of it, explain the frequency of mixed aphasia, and the rarity of pure forms—which are due to small areas of softening.

To examine an aphasic thoroughly, Dr. Starr said it was necessary to test:

(1) The power to recall the spoken or written name of objects seen, heard, handled, tasted, or smelt.

(2) The power to understand speech and musical tunes.

(3) The power to understand printed or written words.

(4) The power to speak voluntarily. Does he talk clearly? Does he mispronounce words? Does he misplace words? Does he talk jargon?

(5) The power to repeat a word after another.

(6) The power to read aloud. Does he understand what he reads?

(7) The power to write voluntarily. Can he read what he has written?

(8) The power to write at dictation.

(9) The power to copy.

(10) The power to recognize the use of objects seen, heard, felt, tasted, or smelt.

In conclusion, Dr. Starr read the detailed histories of two cases illustrating some of the varieties of aphasia described, and presenting points of special interest.

Dr. W. R. Birdsall said that this was unquestionably one of the most fascinating of all the separate studies of the nervous system. In the first case in which he had ever made out the diagnosis of aphasia independently, the patient was an ignorant fellow, who was accustomed to play the violin at dances. He was almost totally aphasic and agraphic, except that he could write "yes" and "no," and sign his own name. There was, however, no word-deafness or word-blindness; and the musical sense was not impaired to the slightest degree.

Dr. E. D. Fisher said that he saw one of the cases mentioned in the paper in connection with Dr. Starr, and he recalled very well the great difficulty that was experienced in getting at some of the points desired, especially in determining the presence or absence of hemianopsia. It seemed to him that in some cases there might be something more besides aphasia or apraxia. There was probably a general loss of intelligence represented by a cortical lesion not localized. Rather than a localized lesion, there was some interference with the whole sensorium. Another interesting point that suggested itself was whether the lesion might not sometimes be only in the association fibres, and at a considerable distance from the cortical centres. These fibres are the easiest means of transit, and it seemed to him that the question, whether the lesion was cortical or subcortical in any particular case, could only be determined by a post-mortem examination.

The President said that it appeared to him that the difficulties which Dr. Fisher had mentioned really did exist. Hence it is that some physiologists, like Goltz, are inclined to doubt the correctness of the cerebral localization now in vogue.

Dr. Starr said that all the diagrams, except his own, designed to illustrate aphasia (by Broadbent, Wernicke, Charcot, and others) had on them an intellectual centre, with which all the memory-centres are connected by converging lines. He did not believe, however, that there was any such thing as an intellectual centre independent of these other centres; nor did he think that there was any need of an intellectual centre. If intellectual centres did exist, they must, unquestionably, in accordance with the phenomena that had been observed, be situated in the same location as the memory centres. In regard to the point raised by Dr. Jacobi, he thought that physiologists are less liable to arrive at correct conclusions concerning cerebral localization than pathologists.

Section on Theory and Practice of Medicine.

R. C. M. Page, M.D., Chairman.

Stated Meeting, October 10, 1888.

Dr. Landon Carter Gray read a paper on

Neurasthenia; its Differentiation and Treatment.

He first directed attention to the fact that functional nervous diseases are largely disregarded by the general practitioner because of the modern development of the study of them, although the need of their proper classification is widely felt, especially by neurological specialists. For this reason it was that the writings of the late Dr. George M. Beard had had such a success in Germany. Dr. Gray did not believe that true neurasthenia is as prevalent as the followers of Beard would have us believe. He stated that in his opinion there are three forms of neurasthenia, the reflex, the lithæmic, and the simple. The reflex form is due to vicious habits and reflexes from non-nervous organs; the lithæmic is due to so-called lithæmia; and the simple form is that in which there is true nervous prostration. The points of differential diagnosis of these various forms were then dwelt upon. But neurasthenia is also to be differentiated from a number of nervous diseases—especially the early stages of the latter—such as the morbid fears (for which Dr. Gray suggested the name of functional insanity), and which really belong to the insane diseases; melancholia, especially the mild cases, in which suicide is often committed; the early stages of mild chronic forms of insanity; neurotic conditions in which the individual is subject to migraine, hysteria, angina pectoris, or anginoid attacks; the early stages of general paresis of the insane or of locomotor ataxia; and a peculiar affection described a year ago by Dr. Hughes Bennett and called by him muscular hypertonicity, in which the symptoms are those of weakness and exaggerated reflexes of the lower extremities.

The prognosis of these different forms is variable, depending upon the severity of the reflex cause, when present, and the possibility of thorough treatment. The

treatment of the reflex form is the removal of the cause, if possible. The lithæmic form is to be treated by moderate laxatives (the most satisfactory of which he had found to be the fluid extract of cascara sagrada), dilute nitro-muriatic acid (in twenty drop doses before meals), and, if the nervous symptoms are severe, by rest. In any case rest is a most important adjuvant, and should be proportioned to the needs of each particular case; it being better to have rather too much of it than too little. The diet should be regulated to a moderate degree by the entire withdrawal of either starchy or nitrogenous material for a short time, and then by cutting down the starchy material permanently by at least fifty per cent. In hot weather it is sometimes advisable to cut off the nitrogenous material for several weeks, and a complete change of air is often of the greatest benefit.

In the true cases of neurasthenia the best treatment is that advocated by Dr. Weir Mitchell, by rest, forced alimentation, massage, and faradism. Large doses of iron and malt extract should also be given with this treatment; the great difficulty with which is, however, that patients are apt to be disappointed at the loss of their muscular strength on first getting out of bed. It should be explained to them that this will gradually return; but great care is necessary with many patients at this period to prevent them from losing the flesh and red blood that have been gained. Galvanism is an agent of great value in all these forms of neurasthenia, and it should be used as early as possible, except when the case is to be put to bed. It should be applied by means of large sponges, one at the nape of the neck and the other on the dorsal spine; five to fifteen milliampères of electricity being used, and the sitting continued every day for from three to five minutes. Massage was an uncertain remedy, often irritating the patient, and was only to be used in connection with the rest treatment mentioned.

DR. E. N. BRILL said that but for Beard the affection, which is in reality only a convenient symptom-group, without pathological foundation, would never have been elevated to the position it occupies. Neurasthenia, as its name indicates, is simply exhaustion of the nervous system, and it may be dependent on any physical or mental condition which lowers the vitality of the individual. The trouble may originate in either local or general disturbances of the nervous axis. In general, he said, he was entirely in accord with the views of Dr. Gray.

DR. E. C. RIGGS, of St. Paul, said that in that peculiar sense of fulness of the head, scarcely amounting to pain, which Dr. Gray had mentioned in connection with lithæmic neurasthenia, he had found the bromides and ergot very efficient; while in the spinal type he had derived the most benefit from galvanism. Statical electricity, which he found was not looked upon with very much favor in New York at present, he had also used with good effect in many of these cases. It seemed to him to have a really useful application, but even if its effects are only psychical, as claimed by many, it might perhaps be well to use it with care in certain instances, just as Charcot employs hypnotism for its psychical influence. In the course of his remarks Dr. Riggs referred to the case of a young lady whom he believed to be suffering from neurasthenia; not being able to find any organic disease to account for the condition present. She continued to grow weaker and weaker, however, and afterward another practitioner made the diagnosis of a malignant tumor. At last she died and none of the organs was found to be diseased, nor were any new growths observed; the projection of the spine forward, in the patient's emaciated condition, having been mistaken for a tumor during life.

DR. W. R. BIRDSALL said that the term was one which had puzzled him not not a little—what to do with it, and whether he ought to use it or not. While he believed in neurasthenia itself, he said he often felt as if he were trying to cloak his ignorance in so designating a case. He recognized that it was insufficient for a class of cases sometimes met with. He thought, unquestionably, that we must admit a neurasthenic element in disease; yet at the same time when we attempt to apply it to a group of symptoms we find that it often fails. In many individuals the nervous tendencies predominate, and, as is well known, this is often the result of heredity, and it seemed to him that the great danger is in assuming that we have a congenital neurasthenic condition to deal with, when the symptoms are in reality due to local causes or merely temporary conditions. The class of cases which Dr. Gray called the lithæmic would probably comprise the greater number of these, and it is important that they should not be treated on the basis of an unstable or defective hereditary nervous system. The same difficulty is found in dealing with the insanities. If we are to use the term neurasthenia at all, then, he thought we should confine it to the class of individuals who suffer from hereditary defective nervous systems.

There was one point in which he did not quite agree with Dr. Gray. The latter had stated that in the class of reflex cases all that is necessary to do is to remove the cause. There is often, however, an acquired condition, the result of the reflex irritation, in which the whole nervous system is at fault. The removal of a local cause, whether about the eye, the nasal cavity, or elsewhere, is not always sufficient. In many cases we are also obliged to treat the individual for other neurasthenic symptoms cropping out in different forms. The classification of Dr. Gray was a convenient one, although it was difficult to make any classification that was wide enough. The first two forms, which were based on causation, were quite satisfactory. The third variety, simple neurasthenia, he did not altogether understand.

In the lithæmic class of cases there is a great field for study, and he was quite interested in Dr. Gray's treatment. The question of rest or of exertion for the patient was one which he thought must be specially determined in each individual case. In many instances increased activity of a kind entirely different to what the patient had been accustomed constitutes the most satisfactory means of treatment. Of the modes of exercise that may be tried, mountain climbing is undoubtedly one of the best. It secures a pure atmosphere, and increases respiration and the quantity of air taken into the lungs. In this way an amount of oxygenation and tissue-change is obtained which can hardly be brought about in any other way. The majority of these patients take very little exercise ordinarily, and it is important that the exertion made should not be too violent or prolonged. Another advantage of this moderate exercise is the mental occupation which it affords. Very few of the

cases are free from a hypochondriacal element, and the exercise of the muscles in tramping, rowing, etc., offers just that mild diversion which is needed, particularly if the patients are provided with the right sort of a companion, which is quite an important point. This hypochondriacal element is one of the most difficult to get rid of.

He stated that he had very little to say in way of criticism of Dr. Gray's paper. As he had said in the beginning, a large number of these cases do not belong to the hereditary class of unstable nervous temperament, but result from various causes in those who originally had no such tendency; among these causes being digestive troubles, business anxiety, emotional strain, rather than over-work proper, and sexual excesses, whether natural or unnatural. In the latter class of cases there was a peculiar unstable condition of the vasomotor system and often an exhaustion of all the nervous centres. This was an almost endless subject, and the question of therapeutics must be settled specially in each case. In conclusion, he said that if we use the term neurasthenia, he though it should be with the proviso that it is understood to comprise a group of symptoms which may belong to various conditions.

Dr. Wm. H. Thomson said that he thought the term neurasthenia is a very impressive one to use sometimes to patients, but otherwise he abominated it. It was to be placed on the same level as tonic, a word that led to more bad practice than any other in medicine, because remedies which act in all sorts of different ways are all called tonics. Neurasthenia was not near as good a word as anæmia, which at all events implied one special condition, and he thought it could not fail to lead to bad practice. He supposed that he had a great many patients coming to him all the time who were the subjects of neurasthenia—at least, that is what they said that other physicians told them that they had.

When a patient comes to him affected with nervous debility without appreciable organic disease, he always puts to himself the question whether the individual is not suffering from one of four things, viz., virtual starvation, over-strain, some unnatural drain upon the system, self-poisoning. Those who were the subjects of virtual starvation (usually females), it would be found, ate no breakfast worth speaking of, and probably took for their other meals principally tea, bread, and sweets. They did not take sufficient food to maintain their respiration and circulation, and the rest cure was, therefore, the best for them. In the second class rest and food were required, and often a change of surroundings. In the third class the drain should be checked if it could be done, and the patient would get well. The fourth class, that of self-poisoning, was the commonest of all. Two patients that had recently consulted him would illustrate this variety. One of them suffered from cloudy mind, with insomnia at night and dulness during the day, and he was cured with bismuth, calumbo, and naphthalin. The other case was very similar, and was also cured by intestinal antiseptics.

It was only very recently, Dr. Thomson said, that, after paying special attention to various divisions of the organism in turn, we were coming back to that old part of the body which our forefathers used to regard as of so much importance, the bowels. At all times fermentations are going on in the intestines, and at the best moments of our lives putrid ptomaines are going into the kidneys, the liver, and other organs. He was entirely satisfied now that the symptoms which are called uræmic are not due to urea in the blood at all, since the patient exhibiting them may be freely passing urea of the kidneys all the while. The trouble with such patients as he was now speaking of was, that they were suffering from prolonged self-poisoning, resulting from a deficiency of the natural antiseptics of the intestines, viz., the secretions. This was the lithæmic neurasthenia spoken of by Dr. Gray. In its diagnosis the pulse and the urine were his particular guides. In all the first three classes to which he had referred, there was an extremely weak and compressible pulse; while in all the lithæmic cases there was the opposite of this condition. There was either fulness or high tension after meals. In the first three classes the urine was of low specific gravity, and either neutral or alkaline in reaction. In the lithæmic cases, while there might be a low specific gravity if the kidneys were involved, as a rule the specific gravity would be high at certain times of the day. The urine also contained a large amount of urates, and was acid in reaction.

As to the question of therapeutics, he had faith in only one real cure, and that was for the patient to go and camp out in a tent in the woods. This would entirely change the character of the pulse and urine, and would clear up the nervous symptoms more completely and satisfactorily than any other method of treatment. No affection of this kind is ever seen in the nomadic races who live in tents, or in any individual who breathes enough. The trouble is that we do not breathe enough, and this is especially true of women.

Dr. A. Jacobi said that of late it had been the tendency in medicine to get rid, as far as possible, of all names given to symptoms merely. This was shown in such words as dropsy, paralysis, and even epilepsy. Neurasthenia is, in reality, less dispensable than any of these. We can speak of it properly as only a symptom, and it is a symptom common to so many conditions that the sooner it is gotten rid of the better. It is not simply weakness alone; we have been told that it is a chronic malnutrition of the nervous centres due either to various adventitious causes or to a hereditary tendency. But congenital neurasthenia does not exist alone. With it is associated weakness of the circulation and of the whole constitution. In every case of so-called neurasthenia, then, it should be our endeavor to make a diagnosis, if possible, of the original condition that gives rise to the symptoms met with.

As regards Dr. Gray's therapeutics, he thought that twenty drops of dilute nitro-muriatic acid were too large a dose, and he thought it much more philosophical to give this remedy after than before meals. In health lactic acid is present in the stomach during the first half hour after taking food, and in abnormal conditions there are fat acids, whose presence indicates an alkali rather than an acid.

Dr. A. D. Rockwell said that although unprepared to discuss the question at length, he could not refrain from the statement that he believed in the existence of neurasthenia just as much as he believed in the existence of malaria. With limitations, the term is a valuable one, although he thought it had been very much abused. The most important point of differentiation was

between primary nervous exhaustion and lithæmia. As to the manner of dealing with the lithæmic condition, the only way was for the subject of it to find out for himself what he could eat and what he could drink, and how he must work.

DR. S. BARUCH said that he was convinced that there was a complex of symptoms which was best designated by the term neurasthenia. In its treatment the principal indication is to promote tissue-change, and perhaps the most valuable method by which to secure this is hydro-therapy. Many of his patients suffering from this trouble he directed to take a cold plunge bath every morning; care being taken to secure prompt reaction. He still believed in the term tonic also, and he thought the cold plunge is one of the most valuable tonics we have.

DR. E. D. FISHER thought that the term neurasthenia is a valuable one, as it is very convenient to use until our knowledge of nervous diseases has become more complete than it is at present. The principal objection to its employment is the danger of mistaking for the condition it implies some of the grave organic diseases, especially in the incipient stage. It is, therefore, necessary to be on our guard in this respect. As regards the treatment of neurasthenia, since it represents merely functional disturbances, so far as we know, uniformity is impossible, and each case must be handled according to its individual circumstances. Personally, he had found dilute nitro-muriatic acid a very useful remedy in a large number of cases, and he usually combined it with Fowler's solution. Whether it can be defended on theoretical grounds or not, he always orders it to be taken fifteen minutes before eating, and, given in this way, it has often proved successful in improving the appetite and digestion, and in removing the nervous symptoms.

DR. GRAY, in closing the discussion, said that one of his objects in writing the paper was to elicit such an expression of opinion from various observers as he had now listened to. On the whole, it seemed to him that there was a very immaterial difference between his own standpoint and that of some of the speakers who objected to the use of the term neurasthenia. There are certainly many symptoms not of organic origin which we cannot classify without resorting to some such expression. It is, therefore, of practical service to retain it, and the subdivision into the three classes which he had indicated seemed to him a convenient one. In the future such advances will no doubt be made, that many points which are now obscure will be cleared up, and many of our present views modified.

The question as to the proper way of using nitro-muriatic acid, that had come up, seemed to be very much like that of calomel. While physiologists claim that the latter has no direct action on the liver, practical physicians go on using it with very good results. It was an actual fact that, of all the drugs of which he had made use for the relief of the so-called lithæmic cases, the one that had proved of the most value was dilute nitro-muriatic acid, and he had found, by long experience, that it acted most efficiently when given before meals.

As to the question suggested by Dr. Riggs, whether those suffering from neurasthenia do sometimes die, he had known of three cases, although he had not personally seen any of them, in which this seemed to be the fact. All of them were in the hands of skilful and experienced physicians, and in two of them autopsies were made, nothing being found at the examination in either instance to explain the cause of death. All the three patients simply gradually sank from exhaustion after several years of suffering.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, October 15, 1888.

THE PRESIDENT, J. R. MACGREGOR, M.D., IN THE CHAIR.

DR. J. ADLER read a paper entitled

SOME REMARKS ON AKROMEGLIA.

He said that in 1886 Marie first described a new affection to which he gave the name of akromeglia. This designation, which simply meant enlarged extremities, was not very satisfactory, but it had now been generally accepted, and in our present total lack of knowledge regarding the pathology of the disease, it would perhaps answer as well as any other. Since Marie's paper had appeared, several cases had been reported in Europe, but the patient presented this evening was the first that had ever been known in this country.

She was a native of Germany, thirty-four years of age, married, and first came under observation in February last, at the German Hospital. Her mother had died from the effects of a fall, but her father was still living. She also had three brothers living, all in the enjoyment of robust health. She was strong and healthy, she stated, up to the age of eighteen or twenty, the time of the onset of her present trouble not being clearly remembered. She began to menstruate in her fifteenth year, but the periods were always irregular and at the end of three years disappeared altogether. She thought she was about twenty when she first noticed that her feet would swell from time to time, although a bandage or a tight-fitting shoe, she said, would always readily reduce the swelling. About this time she also noticed some enlargement of the submaxillary and other glands.

The patient was unable to give any exact account of the present abnormal growth. She was married in her twentieth year, and when she was twenty-three her wedding ring became so deeply imbedded in the tissues of her finger that it had to be removed with a saw. She suffered principally from pain in the back and weakness, and was also subject to frequent attacks of migraine. The pain in the back she attributed to a long ride, from the effects of which she never recuperated. She was unable to walk, and spent most of her time in a semi-recumbent position.

On looking at the woman, one was at once struck with the immense size of the head and the marked projection of the lower jaw. At the first glance, it looked like a case of myxœdema, or one in which there had been complete extirpation of the thyroid gland. The entire cranium was greatly enlarged, and the protuberance of the occiput was especially marked. The lower jaw was immense, and the tongue was greatly hypertrophied and flabby. There was no alteration in the teeth, except that those in the lower jaw were separated to some extent from each other; and the hair was abundant. All the

lymphatics of the neck were greatly enlarged. On a superficial inspection there was an apparent lack of the thyroid gland, but a more careful examination, especially during the act of deglutition, showed that the left lobe and the isthmus could be distinctly felt, although the right lobe seemed to be wanting. No trace of the thymus gland could be detected. The clavicles were markedly enlarged, especially at their sternal extremities. The ribs were also greatly enlarged, and beginning kyphosis and a peculiar bulging shape of the chest, due to their hyperplasia, could be observed. There was comparatively little adipose tissue at any point. The bones of the arm and forearm all showed enlargement of the extremities, and there was reason to believe that slight lengthening of the shafts had also taken place. The hands were immensely enlarged, although there was no deformity of the nails, as has been noted in some of the other cases of akromeglia. The muscles everywhere were flabby and atrophied. The skin was markedly hypertrophied, but remained for the most part soft and pliant.

The same general condition of affairs was found in the pelvis and lower extremities. The feet were enlarged even more than the hands, being simply colossal in size, and there was also enormous hyperplasia of the epiphysial region and the patellæ in the legs. It was noticed that there was marked hyperæsthesia in all the hypertrophied parts, even slight pressure causing the patient to wince. As regards the internal organs, a careful examination of the eyes with the ophthalmoscope revealed no organic disease. Repeated chemical and microscopical examinations of the urine showed no evidence of any kidney trouble, and the red and white corpuscles of the blood were both found to be normal in number and appearance, although to the eye the patient seemed anæmic. The heart and lungs and all the other organs, as far as could be ascertained, were entirely normal. The appetite was fairly good, but the bowels showed a tendency to obstinate constipation.

The electrical examination showed some departures from the normal. The resistance of the skin to the faradic current was enormous. Otherwise the cutaneous sensibility was not diminished. As regards the galvanic current there was considerable diminution of the electrical excitability, which was most marked in the peronei of both lower extremities. Still, there was no evidence of any degeneration going on in the nerves, and the want of electric excitability could well be explained on other grounds. There was evidence of well-marked psychic degeneration in the patient. She was described as having been a bright and lively girl, but she was now very dull and apathetic.

Dr. Adler then went on to make some general remarks on akromeglia, founded on the observations of European authorities. In most particulars, he said, this case corresponded very closely with those met with abroad, but there was one feature which was peculiar to it (being noted in none of the others), viz., the widespread hyperplasia of the lymphatics. As regards the post-mortem appearances in this affection, Klebs was the only author who had made anything like a satisfactory report. He had found a general hyperplasia of the connective tissue and marked proliferation of the bloodvessels. There was also enlargement of the various nerves, especially the ganglia of the sympathetic. In the brain he found well-marked hyperplasia of the hypophysis cerebri, and the question naturally arose whether there was any connection between the enlarged hypophysis and the enlargement of the nerves. Klebs was inclined to attribute the disease to the proliferation of bloodvessels, but this was purely fanciful and speculative, and at present the true pathology of akromeglia remained shrouded in profound mystery. As regards the matter of prognosis, this was not particularly bad so far as life was concerned. In Europe two of the cases which had been first observed as long ago as 1867 were still alive. In some of the cases there were abnormal conditions of the heart. In most of them the thyroid gland was diminished in size or apparently altogether lacking; but in two it was markedly hypertrophied, and was no doubt diseased. Amenorrhœa was a constant characteristic of the disease.

Dr. W. R. Birdsall expressed the great pleasure it afforded him to see this case, the first of its kind ever reported in America. He did not think that he could throw any light on the pathology, though there seemed to him to be some mysterious connection between akromeglia, myxœdema, and extirpation of the thyroid. He said that he had at present under observation a young girl, suffering from amenorrhœa, who had developed some enlargement of the extremities of the phalanges of the hands, and, to a less extent, of those in the feet. It might, possibly, be an incipient case of akromeglia, but it was as yet too early to form a definite opinion in regard to it. As regards the electrical reactions in Dr. Adler's case, he thought we ought to be very guarded in drawing conclusions.

Dr. Adler said that it seemed to him that the hyperplasia in and about the nerves might of itself offer a sufficient explanation of the diminished electric excitability.

Dr. A. L. Carroll said that profound gratitude was due to Dr. Adler for the most admirable clinical demonstration which he had given of his unique case. Ever since he had first read an account of this new disease in the journals, he had been waiting in the hope that some one would find a specimen of it in this country, and it now afforded him extreme pleasure to have the opportunity of seeing the first one reported.

The question of treatment having been suggested, Dr. Adler stated that, in the total absence of knowledge of the cause of the disease, all treatment, so far as interfering with its progress was concerned, was without avail. The patient was simply kept in bed, and her functions regulated as well as possible. The attacks of migraine, to which he had referred, could always be efficiently combated with antipyrin.

Dr. J. Lewis Smith presented a

CASE OF ATHETOSIS.

As this was a comparatively rare affection, he thought this case ought to go on record. The patient was a girl of eighteen in his service at Charity Hospital. Both her parents had died of consumption. She stated that she was well up to the age of seven years, when she had an attack of scarlatina, complicated with diphtheria. This was followed by general dropsy, and she said that it was at this time that she first noticed the paralysis of the left side of the body from which she still suffers. One year later the arm began to be drawn backward behind the body, and it could now be seen in that position, like

a rudder, with tonic contraction of the extensor muscles, and the fingers thrown far back. Soon after the appearance of the paralysis, the patient began to suffer from epilepsy. The attacks were for a time of the nature of *petit mal*, but had gradually grown more severe, and now constituted *grand mal*.

DR. M. ALLEN STARR, at the request of Dr. Smith, prepared a communication concerning the case, which Dr. Smith then read, in which he gave a *résumé* of some of the latest researches in regard to the condition here met with. In it he stated that he found that all recent writers mention athetosis as a frequent complication of spastic infantile hemiplegias connected with epilepsy. In this condition club-foot was apt to be present, as here, and the patient walked on the toes. Such cases presented undoubted evidence of an irritation carried down to the spinal cord from the cortex, and as there was irreparable injury in the cerebral centres, nothing could be expected from treatment.

DR. W. R. BIRDSALL, on the invitation of Dr. Smith, made a demonstration of the case. He first called attention to the fact that the face and the left side were involved slightly in the contracture. Sometimes, when she brought the affected arm forward with the other arm—an action which required considerable exertion, the foot, which was habitually inverted, would become inverted. At night, as was usually the case in such patients, during sleep, he had no doubt that the arm became relaxed. These cases are mostly instances of infantile hemiplegia, and all that he had observed had begun before the age of ten years. There could be no doubt that Dr. Starr's explanation of the pathological condition is the correct one. There is a destruction of tissue in the cortical areas, by reason of which the impulses from the brain are transmitted irregularly, and not in a coördinate manner. The condition varies from the ordinary contractures met with in hemiplegics, in there being more mobility, and it also differs from ordinary athetosis, in which there are more movements with but little contracture. It was, therefore, a mixed case. Athetosis, as is now well known, is a symptom of hemiplegia, and particularly infantile hemiplegia. In infants an athetoid condition of the fingers is normal, these members being constantly in motion, and the earlier the paralysis occurs, the more marked will be the athetosis. This case was almost the exact counterpart of one that he had seen in a boy who also was in one of the city institutions on the island.

DR. DANIEL BROWN read a paper on

THE ARREST OF SECRETIONS IN THE ERUPTIVE FEVERS.

He took scarlatina as the type, and said that it is not so much the drain itself that proves fatal as the accidents and sequelæ liable to attend it. There is a marked determination to the skin and the mucous and lining membranes, and unless the secretions can be kept in efficient operation, serious inflammations are likely to result from the congestion incident to the irritation produced by the poison in the system. He is in the habit of commencing his treatment with small doses of bromide of potassium or sodium, and tincture of aconite root, the object of the bromide being to allay nervous irritability, and of the aconite to diminish the frequency of the pulse. In a short time he commences the administration of carbonate of ammonium, which for the last twelve years he said he had regarded as his sheet-anchor in the treatment, on account of its stimulating effect on the secretions. The dose is very small, only one-half or three-quarters of a grain, and it is usually repeated every hour or so, in a solution containing elixir of cinchona. The skin is kept anointed with vaseline, and at night he often gives small doses of jalap and calomel, as advocated by Professor William H. Thomson. Under this plan of treatment he found that the eyes or ears are seldom affected, and kidney trouble seldom ensues as a sequela. The treatment, of course, varies according to circumstances in different cases; but the chief point that he always has in view is the maintenance of the secretions.

DR. CHARLES A. LEALE said that while he regarded scarlatina as an acute, self-limited, infectious disease, there is always a certain amount of deleterious matter in the system to be gotten rid of, and it is of great importance to pay attention to all the glands and secretions, so that the poison may be eliminated. He would certainly be much delighted if he could find a remedy which would act as a preventive of complications and sequelæ but he did not know of one at present. The carbonate of ammonium, so lauded by Dr. Brown, he should think would only add another foreign element to the blood, and he believed that pure water would be much more serviceable in keeping the secretory organs free.

DR. S. B. W. MCLEOD said that he believed that, as a general rule, the less medicine is given the better, though after the acute stage the tincture of chloride of iron is usually of service in shortening convalescence.

DR. C. S. WOOD said that it was to be borne in mind that the fatality of diseases like scarlatina varied very greatly in different epidemics. At present the scarlet fever met with in New York is of a comparatively mild type, and the percentage of deaths from it is very small, except in those cases accompanied with diphtheria, which seemed to be now the complication most to be dreaded. The views advocated in the paper he believed were correct, and he had always found that aconite in small doses had a good effect on the function of the skin. In all the zymotic diseases he had been in the habit, for the past thirty years, of employing hyposulphite of sodium after the first day or two, and he was convinced that the sulphurous acid which was set free from this compound had a most beneficial effect in counteracting the poison in the system, whatever it might be. In many cases of scarlet fever, it seemed to him that this remedy had not only the effect of modifying the severity of the disease, but also of actually cutting short the attack to some extent.

DR. FARRIES thought that in scarlatina nothing fulfilled the indications better than aconite in small doses to lower the pulse, and a mild diuretic and sudorific containing buchu or uva ursi with a little sweet spirits of nitre. In addition, the surface of the body might be sponged every two or three hours with lukewarm water containing a little carbonate of sodium, for the purpose of reducing the temperature.

DR. LEALE said that in 1865, when he was in the army in Washington, where infectious diseases, particularly pyæmia and typhoid fever, were very prevalent a thorough trial was given the hyposulphite of sodium in this class of affections, and the conclusion was reached by the surgeons who experimented with it that it had no

appreciable affect upon them. In acute febrile diseases the two great objects are to eliminate and to maintain.

The President said that there were a certain number of cases of scarlet fever in which death resulted, not from any accident or sequela, but from the direct violence of the attack; the poison introduced into the system being so malignant as promptly to overwhelm the nervous centres and the powers of life like an avalanche. As regards the glandular system, there is always danger of trouble. For instance, in the kidneys, as the result of over-stimulation and over-action in eliminating a poison to which the organs are not accustomed, the epithelium of the glomeruli is apt to be thrown off, and in consequence of this tubular nephritis results. In the zymotic diseases in general, he thought other methods of treatment besides those aiming at securing elimination are often called for, and it is highly desirable that we should have at our command remedies which may act directly on the poison and have the effect of preventing fermentation. In conclusion, he said that in his experience he had found that, as a rule, any looseness of the bowels, whether occurring spontaneously or resulting from the use of cathartics, had an unfavorable effect.

Dr. Brown, in reply to the President, said that he did not by any means claim to cure all his cases. He quite agreed that the malignant cases referred to did sometimes occur; but in these he believed that if only a few doses of such remedies as the bromides could be given to allay the nervous irritability produced by the poison, there would result a certain amount of improvement, even if the effect was not sufficient to prevent a fatal termination; while in others, which would unquestionably prove fatal if left to themselves, death might be averted by the prompt measures adopted.

CORRESPONDENCE.

OPHTHALMOLOGY IN VIENNA.

To the Editor of The Medical News,

Sir: In a recent visit to the eye clinics of Vienna, I observed many little points in practice, especially in the technique of operative procedures, which may be of interest to ophthalmologists on this side of the Atlantic.

The principles of antiseptic surgery are thoroughly and religiously carried out, and have contributed much to assure success in these delicate operations. The instruments are kept in an antiseptic, hard-wood case, and are thoroughly boiled in pure water, before and after each operation. They are then extracted with forceps, and spread upon a porcelain slab covered with a moistened sheet of iodoform gauze. The operator having rendered his hands aseptic with soap and water, and with a 1 : 1000 bichloride solution, proceeds to disinfect thoroughly the conjunctiva with a 1 : 10,000 bichloride solution, being careful to evert the upper eyelid, and cleanse the internal canthus. The unaffected eye is then covered with a square of iodoform gauze and pledget of cotton, held in position by a strip of muslin passed obliquely, the extremities of which have been rendered adhesive with diachylon ointment. The operation completed, the eye is again washed out, the wound lightly dusted with iodoform powder, the same dressing applied as on the other eye, and protected with a roller bandage, starch bandage, or metal protective, according to the indications.

Plastic operations. For ectropion, instead of the ordinary operation of fitting in an attached flap from the face or forehead, transplantation, somewhat after the method of Prof. Thiersch, of Leipsic, the grafts being taken from the arm, has been utilized with the best results. The grafts are covered with moistened protective, iodoform gauze, cotton, and a starched bandage, and the denuded surface of the arm is preferably dressed with the dry protective powder of Prof. Thiersch,[1] and a dry dressing.

Iridectomy. When performed for optical purposes, the small, angular keratome is always employed, being considered safer than the bent, broad needle. When, however, it is performed for other than optical purposes, the large, triangular, bent keratome is preferred, and, in some cases, the small Graefe knife. The grasping and excision of the iris are done in the usual manner. In all cases the curette is employed to liberate any portion of the iris entangled in the incision; the wound is lightly dusted with iodoform, and a compress and metal protector applied.

Cataract extraction. The incision used by Prof. Fuchs, and by his assistant, Dr. Saltzman, is a modified Graefe linear incision, entirely in the sclerotic, the puncture and counter-puncture being somewhat higher than that ordinarily attributed to von Graefe. The iridectomy is performed in the usual manner. The anterior capsule is lacerated with the capsule forceps, which remove a segment of the capsule, and which have entirely replaced the cystotome. The removal of this segment was formerly accomplished by means of an iris forceps and scissors, after the laceration by the cystotome (Keyser). The lens and capsule are delivered in the usual manner, by pressure with a Daviel's scoop, and the iris is very carefully redressed with a curette. The dressing consists of the one already described, being supported and protected by a wire shutter (*augen schuts gütter*), an irregularly rectangular frame, bound with black braid, and secured by four tapes. Secondary or capsular cataracts are not so frequent after the use of the capsule forceps as when the cystotome is employed; but when they occur, and especially after discission, they are depressed with a needle, very much after the method of the old couching (reclination) operation.

Sclerotomy, as now generally performed, is not looked upon with favor, but the sclerotomy of de Wecker, with a small Graefe knife, is highly recommended.

Removal of foreign bodies. For the removal of foreign bodies from the vitreous, Hirschberg's electro-magnet is used, the same care being exercised to render the needles aseptic. The incision is made, with a Graefe knife, through the conjunctiva sclerotica, unless the object is known to be lodged in some other situation.

Enucleation is performed by the more rapid method, without the use of the strabismus hook. The tendon of the external rectus in the left (or the internal in the right) is firmly grasped with a fixation forceps, and, with the curved, sharp-pointed scissors, the conjunctiva is separated from its corneo-scleral attachment. The superior and inferior rectus are divided by sweeping the scissors round with one blade beneath and the other above the

[1] The formula for which is, zinci sulph., aluminis, pulv. talci, equal parts.

tendon. Traction is made, and by two or three successive snips the nerve is reached and divided, and nothing remains but the rectus on the other side, and a small quantity of connective tissue.

James K. Young.

Philadelphia, September 24, 1888.

STERILIZED MILK.

To the Editor of The Medical News,

Sir: In a letter published in your issue of October 6, 1888, page 403, I am somewhat warmly rebuked for "careless stricture" of the method of steaming milk suggested by Dr. J. A. Jeffries and others.

As Dr. Jeffries acknowledges that one steaming does not completely sterilize milk, I fail to discover wherein I have sinned in striving for a more perfect method, which may be taken as a standard for practical purposes. Whatever is worth doing at all, is surely worth doing well.

Dr. Jeffries claims that from milk steamed once "the child will obtain fewer bacteria than from the mother's nipple." Has he made an actual comparative count? Until he does so, the profession must decline to accept this dictum.

The most singular statement Dr. Jeffries makes, however, is that inasmuch as babies continually suck bacteria from their toes, etc., the few bacteria taken in steamed milk can do them no harm. This reasoning may satisfy Dr. Jeffries, but it will probably not be approved by the profession, since Pasteur, Kueppe, Lœffler, Lister, Schröder, and von Dusch have demonstrated that while boiling does kill the bacteria, there is subsequent to the boiling a development of infusoria and of bacilli capable of producing spores which will precipitate casein under alkaline reaction, and that nothing short of a continuous exposure for half an hour to a temperature of 86° F. will sterilize milk completely.

The object of my paper was chiefly to impress upon the profession the importance of sterilizing milk for infants, in the hope, that "when the facts referred to receive general recognition in the profession, dairymen would find it to their interest to obtain proper apparatus for sterilizing large quantities of milk and delivering it in appropriate sealed vessels to consumers in large cities." (The Medical News, July 7, 1888.) That this is not an Utopian idea, is demonstrated by the fact that it has already been adopted by a firm on Boylston Street, Boston, which claims to furnish "sterilized cow's milk preserved unsweetened in clean glass bottles."

Until this idea is more generally adopted, I welcome Soxhlet's apparatus and the methods of Drs. Jeffries, Rotch, and Caillé as steps in the right direction.

DIET IN THE CONVALESCENCE OF TYPHOID FEVER.

To the Editor of The Medical News,

Sir: The discussion upon the management of the convalescent stage of typhoid fever, which took place at the recent Medical Congress, and your editorial (Oct. 13th) upon the same subject, both seem to me very timely and of more than usual interest.

From my own somewhat extensive experience, I am rather surprised that there should have been any disagreement in the matter. I have long ago concluded that the convalescent period of typhoid fever is about as critical as any other, and that if we know anything at all about the management of the disease, it is that the patient should be restricted to liquid food for at least seven days after the temperature has reached and remained at the normal, and longer if there still exist any abdominal pain or tenderness.

The necessity of such a course has so frequently been unpleasantly forced upon my attention, that I have come to regard any unheeding of the warning as being dangerously culpable. Very respectfully,

George B. Fowler, M.D.

11 West Forty-fifth St., New York,

NEWS ITEMS.

An Injunction Preventing the Unauthorized Publication of Lectures.—The suit of Dr. Theodore G. Wormley, Professor of Chemistry and Toxicology in the Medical Department of the University of Pennsylvania, against Walter B. Saunders, a publisher, to restrain Saunders from publishing and selling books on general and medical chemistry made up of condensations from lectures delivered by the complainant, was argued last week in the Court of Common Pleas of Philadelphia.

It was admitted by the defendant, as a matter of law, that the deliverer of oral lectures still has the right of property in those lectures, but in this case it was claimed Dr. Wormley had abandoned his right of property because he permitted the defendant to publish the lectures without protest. Mr. Saunders said that the books containing the substance of the lectures had been sold on the market for several years, and that during all the time he has been selling these books he never received any notice from the complainant, or protest against their sale or publication. He believed that Dr. Wormley knew of these publications and sales.

The answer to this was that there was no evidence that Dr. Wormley knew of the publications, and that in point of fact when he did find out, about six years ago, that another party was printing and publishing his lectures, he compelled that person to surrender up all of the remaining copies and they were burned at the University of Pennsylvania.

Judge Allison, applying the principle of law stated above, said that the answer of the defendant failed to state that Dr. Wormley assented to the publications, that the only length it goes is to state the defendant's "belief" that Dr. Wormley knew of them, and defendant does not say that Dr. Wormley did not object to them. Judge Allison held that, as such averments had not been made, Dr. Wormley's right of property in the lectures remained unaffected, and the preliminary injunction which was granted restraining the publication and sale was accordingly continued in force.

A National Health Organization Wanted.—At a meeting of the Councillors of the Massachusetts Medical Society, held October 3, 1888, the following resolves were unanimously adopted:

That in the opinion of the Councillors of the Massa-

chusetts Medical Society, the present epidemic of yellow fever in several States of this Union has again made evident the imperative need of some organization on the part of the general government for the protection of the public health—an organization that shall be independent of existing bureaus, and solely devoted to this most necessary function of any form of government.

That this resolution be sent to the President of the United States, to members of Congress, and to the Boards of Health of the several States.

Treatment of Foul Ships.—In order to stimulate shipmasters to aid in securing a clean ocean-going fleet, the following regulation concerning the treatment of foul ships has been adopted by the Marine-Hospital Service, and will be observed at all National Quarantine Stations:

1. When a vessel arrives at any National Quarantine Station from an infected port, and requires disinfection, she will be subjected to *ordinary disinfection*, as provided in former regulations.

2. When any vessel shall arrive at a National Quarantine Station in such foul condition as to render her dangerous from a sanitary point of view, and is found to require cleansing and disinfection, having at any former time within one year been subjected to ordinary disinfection, such vessel will be required to undergo *extraordinary disinfection*, which, in addition to the ordinary measures, will include holy-stoning, scraping, the taking out of rotten wood, a second disinfection, and interior repainting, all of which will be required before granting a certificate of free pratique.

Rules for a Healthy Milk Supply.—According to Dr. E. H. Bartley (*Brooklyn Medical Journal*, October, 1888), the following rules contain some of the most important guides for the protection of the dealer in milk, as well as for the protection of the public:

1. The milk of diseased cows should not be sent to market. Any condition that produces a fever in a milch cow should be regarded as rendering the milk bad.

2. The milk of cows fed upon distillery swill, or those fed entirely or largely upon fermenting brewer's grains, should not be sold for infant's food.

3. Cows should not be allowed to drink stagnant pond or ditch water.

4. Milk from cows that are overheated or worried, at the time of milking, should not be sent to market.

5. If the udders are dirty, they should be washed clean before milking.

6. The milk should be cooled outside of the stable, and the cans should be covered during the process, to exclude air and dust. Milk should be kept at a temperature below 60° F., but ice should never be put into it.

7. Warm milk should never be received from the dealer, nor should the can be left out on the sidewalk in summer.

8. Milk should always be kept covered, and should never be kept in an ice-box with meats or vegetables possessing an odor.

9. Ice-boxes, stores, and wagons in which milk is kept, should be kept clean and sweet by occasional washing with chloride of lime followed by clean water, or soap and water.

10. When possible, only full cans should be received. A small full can is better than a large one partly filled, as the agitation and churning of the milk is less in a full can. Avoid the unnecessary handling of milk. The necessary agitation of shipping and delivering is an injury to it.

11. Milk that has been brought back from the morning rounds should not be mixed with other milk; it should be cooled at once, and sold as soon as possible.

12. If milk is kept over night, a small portion of it should be boiled to see if it will curdle, before it is sold.

13. Each and every dairy's milk should be tested daily.

14. It is best to make a contract with the one who delivers the milk to you to furnish that of a given test by the lactometer, say 105 to 110, and giving at least ten per cent. of cream.

15. Milk which contains dirt settling to the bottom of the can, blood, offensive odors or taste, should not be sold to customers.

16. *Cleanliness* in the handling of milk *is absolutely essential to its wholesomeness*.

Arsenical Dyes in Drapery.—In spite of many warnings impressed by precept and experience, arsenical pigments continue to be used in house decoration and to injure health as heretofore. A typical example of poisoning due to this cause is reported to have occurred quite lately in the Civil Engineering College at Cooper's Hill. The facts related are the following. Some of the students, with an eye for the beautiful, had, it appears, adorned their apartments with cretonnes and Indian muslins of great brilliancy. About the same time a singular epidemic became prevalent in the establishment and was attended with the irritable condition of the alimentary tract and other symptoms characteristic of the action of an irritant poison suspended in the atmosphere. The presence of arsenic was naturally suspected, but the wall-papers did not contain it. The cretonne and muslin decorations, however, were found on examination to be highly arsenical, and one piece, it is said, contained rather more than nineteen grains of this poison in the square yard. Here then was the source of an otherwise inexplicable state of general ill-health which had been observed among the students for a year past. Happily the cause at work was detected before any fatal consequences had occurred, and probably a liberal allowance of exercise in the open air had much to do with this result. The lesson taught by this occurrence is not a new one. It merely rehearses the characters of a once familiar danger and shows that it still exists. The public must therefore now decide whether it will, in the face of such practical instruction as this, continue to choose articles of dress or household ware with regard to custom or to their cheap attractiveness alone, and without a question as to quality. Nor would we warn purchasers to be chary only of the more gaudy hues, for even such colors as black and dark blue are frequently unsafe. Arsenic is no doubt the ingredient most to be avoided, but it should be remembered also that aniline dyes have often proved injurious. It appears likely, indeed, that this is to some extent a consequence of the fact that arsenic is freely used in their manufacture.—*Lancet*, July 28, 1888.

Precautions against Fires in Theatres.—The Prefect of Police in Paris has issued a new set of regulations with

regard to the fire brigade service in theatres, which will, it is thought, reduce very much the risk of fire, so far, at least, as it can be reduced in the many theatres in Paris which have always been, and must remain, from the position they occupy, regular death-traps. A certain number of firemen are allotted to each theatre, who under no pretence are to be called out of the theatre, or to receive visits from friends or acquaintances. The chief of the detachment has the responsibility of seeing that all the apparatus for extinguishing a fire is in its allotted place and in proper order, and the commissary of police is to satisfy himself that this has been done before the theatre opens.

During the representation the chief of the detachment must be constantly moving about to see that the men are at their posts; that no one is smoking in the corridors or carrying open lights; and that access to the reservoirs and fire-plugs is not hampered by placing any scenery or stage properties in the way. He is to examine the manometer, and, if he finds that there is a deficiency of pressure in the water-mains, he must inform the nearest post of the fact. In the event of an insignificant outbreak, recourse is to be had only to the apparatus within reach of the *foyer;* but if the outbreak is of a more serious character, the nearest post is to be informed by telegraph.

At the close of each representation the firemen are to make a round of the theatre, and see that the iron curtain is lowered, the buckets filled, and the folding doors closed, and, in the event of these not working smoothly, they must be repaired at once.

The manager of the theatre is required implicitly to obey the orders of the district commissary of police, who, in the event of an outbreak of fire, assumes the sole command of the theatre until the arrival of the Prefect of Police or the chief officer of the Fire Brigade.—*British Medical Journal*, October 6, 1888.

A Noble Fee.—Sergeant-Major Freyer, M.D., I.M.S., has received a fee of one lakh of rupees (£10,000 sterling) from H. H. the Nawab of Rampur, as a token of esteem as well as an acknowledgment of his valuable services in the successful treatment of himself and General Azimuddin Khan, the popular head of the Administrative Agency of the State, who had suffered for nearly three months from a malignant rheumatic fever; his recovery has been the occasion of great rejoicing at Rampur. This is said to be the largest fee ever received by a medical practitioner in India, and probably has never been exceeded in any country.—*British Medical Journal*, October 6, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM OCTOBER 16 TO OCTOBER 22, 1888.

PAGE, CHARLES, *Colonel and Assistant Surgeon-General, Medical Director of the Department.*—Will proceed to and inspect the Medical Department at Forts Ellis, Texas; Supply, Reno, Sill, and Gibson, Indian Territory; Fort Leavenworth, Kansas, and the Leavenworth Military Prison, in the order named, and upon completion of this duty, return to these Headquarters.—Par. 1, *S. O. 127, Headquarters Department of the Missouri, Fort Leavenworth, Kansas*, October 15, 1888.

COMEGYS, EDWARD T, *Captain and Assistant Surgeon.*—Is relieved from duty at Madison Barracks, New York, and will report in person to commanding officer Fort Bayard, New Mexico, for duty at that post, relieving First Lieutenant and Assistant Surgeon William D. Dietz.—Par. 18, *S. O. 240, A. G. O., Washington*, October 15, 1888.

DIETZ, WILLIAM D., *First Lieutenant and Assistant Surgeon.*—On being relieved by Captain Comegys, will report in person to commanding officer Alcatras Island, California, for duty at that post, reporting by letter to the commanding general Department of California.—Par. 18, *S. O. 240, A. G. O., Washington*, October 15, 1888.

MUNDAY, BENJAMIN, *Captain and Assistant Surgeon.*—Is relieved from duty at Jefferson Barracks, Missouri, and will report in person to the commanding officer Fort Sisseton, Dakota, for duty at that post, relieving First Lieutenant and Assistant Surgeon John L. Phillips, and reporting by letter to the commanding general Department of Dakota.—Par. 11, *S. O. 242, A. G. O., Washington*, October 17, 1888.

PHILLIPS, JOHN L., *First Lieutenant and Assistant Surgeon.*—On being relieved by Captain Munday, will report in person to the commanding officer, Fort Lyon, Colorado, for duty at that post, reporting by letter to the commanding general Department of the Missouri.—Par. 11, *S. O. 242, A. G. O., Washington*, October 17, 1888.

By direction of the Secretary of War, the following named officers of the Medical Department will report, in person, on October 23, 1888, to the President of the Army Medical Examining Board, ArmyBuilding, New York City, for examination for promotion: JOHN DE B. W. GARDINER, *Captain and Assistant Surgeon;* WILLIAM C. GORGAS, *Captain and Assistant Surgeon;* C. N. BERKELEY MACAULEY, *Captain and Assistant Surgeon;* W. L. KNEEDLER, *First Lieutenant and Assistant Surgeon;* EDGAR A. MEARNS, *First Lieutenant and Assistant Surgeon.* Upon the completion of their examination, the officers named will rejoin their proper stations.—Par. 1, *S. O. 239, A. G. O., Washington, D. C.*, October 13, 1888.

BALL, R. R., *First Lieutenant and Assistant Surgeon* (U. S. Army).—Is granted leave of absence for one month, with permission to apply for an extension of one month.—Par. 3. *S. O. 129, Headquarters Department of the Missouri, Fort Leavenworth, Kansas*, October 18, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING OCTOBER 20, 1888.

MAGRUDER, A. F., *Surgeon.*—Ordered to Marine Barracks, Washington, D. C.

STONE, E. P., *Assistant Surgeon.*—Detached from the "Richmond," and ordered to the "Minnesota."

KEENEY, J. F., *Assistant Surgeon.*—Detached from the "Minnesota," and ordered to the "Richmond."

MCCORMICK, A. M. D., *Assistant Surgeon.*—Detached from the Bureau of Medicine and Surgery, and ordered to the "Vermont."

MOORE, A. M., *Surgeon.*—Detached from Naval Station, New London, Connecticut, and ordered to the "Kearsarge."

AUSTIN, A. A., *Passed Assistant Surgeon.*—Ordered to Naval Station, New London, Connecticut.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE TWO WEEKS ENDING OCTOBER 20, 1888.

ARMSTRONG, S. T., *Passed Assistant Surgeon.*—Granted leave of absence for sixteen days, October 17, 1888.

WOODWARD, R. M., *Assistant Surgeon.*—When relieved at Marine Hospital, Boston, Mass., to proceed to Marine Hospital, Chicago, Ill., for duty, October 12, 1888. Granted leave of absence for thirty days, October 17, 1888.

CONDICT, A. W., *Assistant Surgeon.*—Relieved from duty at Marine Hospital, Chicago, Ill.; ordered to Marine Hospital, Boston, Mass., October 12, 1888.

ANTISEPTIC MEDICATION.[1]

BY FREDERICK P. HENRY, M D,
PHYSICIAN TO THE EPISCOPAL AND PHILADELPHIA HOSPITALS.

My purpose in bringing the subject of antiseptic medication before this Association is not so much to make an elaborate report on the existing knowledge concerning it, the principles on which it is based, the results it has accomplished, and my own experience of its application, as to elicit a general expression of opinion upon what appears to me the foremost therapeutic question of the day.

The great principle of antisepsis is of general application in the treatment of disease. It is not limited to the domain of surgery, although to surgeons is due and gratefully accorded the merit of having shown the dangers due to absorption of products of fermentation and putrefaction and the means of avoiding them. The revolution thus brought about has been witnessed by every member of this Association. It is an accomplished fact and, at the present time, the applications of antisepsis in this field are so perfect, so precise, that surgery, in some of its departments, may almost be ranked among the exact sciences.

Antisepsis, in surgery, consists in preventing the absorption of toxic substances from a pathological surface. This is true also to a certain extent in medicine, although here, in many instances, the surface from which absorption takes place is physiological. The difference between antiseptic medicine and antiseptic surgery is one of degree rather than of kind. In the former the antiseptic agent is directly applied to the absorbent surface; in the latter it can, in most instances, only exert its action after having run the gauntlet of the greater portion of the intestine, or even after it has been absorbed and excreted. The problem in the latter case is much the more difficult of the two, but is one which, as I propose to show, is in the course of successful solution.

LAVAGE.

A well-defined line can be drawn between gastric and intestinal antisepsis for the reason that in the former we have one remedial measure *par excellence* to which all others are subordinate. I refer to lavage, and it is an interesting fact that Dujardin-Beaumetz, who opposed this method of treatment when first introduced by Kussmaul in 1867, is now one of its most ardent advocates. He believes it to be indicated whenever the stomach is dilated, no matter what may be the cause of the dilatation. The operation, which may be compared to catheterism for the relief of a distended bladder, is not to be performed without certain precautions. In the first place, it should not be performed too frequently. Once in twenty-four hours is often enough. Secondly, the water employed should be at, or near, the temperature of the body. Thirdly, in order not to interfere with the digestion of which the stomach may be capable, it should be performed during a period of abstinence from food, *e. g.*, early in the morning. These precautions are by no means founded on theory alone. If lavage is repeated too often, it not only fatigues the patient, but may lead to grave accidents. For example, in a case reported by Dujardin-Beaumetz to the *Soc. Méd. des Hôpitaux*, October 26, 1883, the patient experienced great relief from the treatment and having learned to wash out his stomach for himself, acquired the habit of doing so several times a day. This abuse of the method gave rise to muscular contractions which, beginning in the upper extremity, soon became general, and the man died with all the symptoms of tetanus. Lavage has been most often employed in the treatment of dilatation from pyloric stenosis, and certainly with most satisfactory results. The painful distention of the stomach, the nausea, regurgitations, and vomitings are, in most cases, allayed by this simple means.

There is another form of gastric disorder often overlooked and only recently clearly differentiated, in which lavage is of most signal service, viz., that in which the gastric juice, instead of being secreted only when there is food in the stomach, is poured out when the viscus is entirely empty. This condition of hypersecretion must not be confounded with hyperacidity. The latter consists in a too liberal response to a physiological summons, while the former is gratuitous. First described by Reichmann in 1882, cases have since been reported by Sahli, Schütz, von den Velden, and especially by Riegel, who, in the course of eighteen months, observed twenty-nine cases. According to the latter, lavage should be practised in cases of hypersecretion just before the principal meal and in no other affection is it attended with greater benefit.

[1] Read by title before the Association of American Physicians, Washington, 1888.

For washing out the stomach simple water is sufficient, but when the viscus is emptied it may be finally cleansed with an antiseptic solution, such as salicylic acid three-fifths per mille, or borax two-fourths per cent. These harmless substances are quite efficacious, although benzoic acid, naphthalin, potassium permanganate, and resorcin are recommended. The latter substance is unsafe, except in very weak solution. Escherich[1] reports a case of poisoning from lavage with a one per cent. solution of resorcin. The patient was a woman, æt. thirty-five, who, after lavage, became restless and cyanotic and soon lost consciousness. Clonic and tonic spasms then set in, the latter affecting particularly the masseters and the respiratory muscles. There were trismus and prolonged spasm of the glottis with stoppage of respiration, during which the face was extremely livid and cold drops of sweat stood upon the forehead. After life had been maintained for about two hours by continual artificial respiration, natural breathing and consciousness returned, but the action of the heart now became weaker and it was only by the most energetic measures that life was saved. For hours the patient lay in a stupid, drunken-like ("rauschartig") condition.

INTESTINAL ANTISEPSIS.

The principal field of antiseptic medicine is the intestine, and this fact, which is one of increasing importance, has been recognized ever since Selmi, in 1872, discovered in the products af putrefaction, and even in fresh vegetable tissues, certain substances closely resembling the vegetable alkaloids to which he gave the name of ptomaines.

It is, however, justly claimed, that Semmola, who twenty years ago administered the alkaline and earthy sulphites with the object of destroying certain supposititious substances of a toxic and pyrogenic nature, was the first to institute a treatment based upon the idea of intestinal antisepsis.

At the present day it is very generally held that many forms of diarrhœa are due to irritation by substances which have escaped the powerful antiseptic action of the bile and gastric juice, while it is believed by some that many of the grave nervous symptoms of the continued fevers, the so-called typhoid symptoms, are due to the absorption of similar products.

The therapeutic problem is to administer such substances as will supplement the defective action of nature's antiseptic secretions, a problem which, as I have already stated, is in the course of successful solution. It is not my intention in this paper to enumerate the many substances that have been used to fulfil this indication, but merely to give some details concerning the few of which I have had some experience.

Naphthalin.—This substance was first employed by Rossbach in 1884 as an intestinal antiseptic. He obtained excellent results from it in the treatment of chronic intestinal catarrh, either with or without ulceration, and in typhoid fever, in which disease, when early administered, he believes it exerts an abortive effect. Thirty-five cases of typhoid in Rossbach's medical service at Jena were treated with naphthalin by Götze, all of which took over seventy grammes in the course of their treatment; many of them over a hundred and fifty grammes. The favorable effect of the drug was shown by the number of the stools, which averaged from one to three daily. Severe diarrhœa, requiring the addition of opium to the treatment, was observed in but three cases. The pain in the ileo-cœcal region rapidly diminished, disappearing, as a rule, on the second day. On account of the dark color of the urine produced by the drug, this fluid was frequently examined and the albuminuria in this series of cases was no more frequent or severe than in cases of typhoid in general. In one case in which death was caused by croupous pneumonia there were acute nephritis and typhoid ulceration of the renal pelvis, the former being due to the latter.

Of the 35 cases, 17 (50 per cent.) were so materially shortened in their course that the term "abortive" is fairly applied to them, while the course of the fever was favorably influenced in the others. Of the 35 cases, 3 died, but not, it is claimed, from typhoid. In the first, a vulvo-vaginitis extended to the large intestine and bladder, which were found in a state of diphtheritic inflammation. Of the other two, the first died of croupous pneumonia of the right upper lobe; the second of double bronchopneumonia and tracheal diphtheria. The claim that these deaths were not due to typhoid fever is, in my opinion, preposterous, and, therefore, the mortality, instead of being nil, as Götze would have it, is about 9 per cent. This is small, but the cases are too few to warrant any deductions under this head. The favorable course pursued by the great majority of Götze's cases would lead one to expect still better results from a more extended use of the drug.

There is a large concourse of testimony to the good effect of naphthalin in chronic intestinal catarrh, the results obtained by Rossbach, Pauli, Pribram, Kraemer, Widowitz, and Wilcox having been invariably good. An extensive experience with this drug during a recent six months' term at the Philadelphia Hospital, enables me to corroborate their statements.

In the *St. Louis Med. and Surg. Journal* for March, 1887, Dr. R. W. Wilcox, of New York, gives his experience with this drug in the treatment of

[1] Centralblatt für Bakteriologie und Parasitenkunde, Bd. ii., No. 21.

thirty-two cases of diarrhœa, most of them chronic. "All the cases were relieved in periods of from one week to two months; generally about ten days were sufficient for a cure." The cases of Wilcox, like my own, were nearly all adults.

Dr. Josef Widowitz[1] has employed naphthalin in thirty-three cases of intestinal catarrh in children, and concludes that in the so-called dyspepsia of children with clay-like stools and vomiting of curds, naphthalin is without effect, while in all other forms of intestinal catarrh in children it deserves the preference over all other remedies. This apparent exception to the beneficial action of the drug is, in reality, none, for the condition referred to is gastric or gastro-duodenal catarrh. Widowitz administers naphthalin to small children in the following formula:

R.—Naphthalin. pur. . . . . 0.30–1.
Mucilag. gummi Arab.,
Aq. chamom. . . . āā 40
Olei menthæ pip. . . . gtt j—M.

After shaking well give a teaspoonful every two hours. The amount given during the day should be from 0.3 to 1 gramme.

If one may judge from the practice of those who have employed this drug, their opinions with reference to its dose are very different. For example, the dose employed by Kraemer,[2] whose success with naphthalin has been brilliant, did not exceed one gramme daily. With this amount he speedily cured ten cases of intestinal catarrh which had lasted a year in spite of other treatment. He also succeeded in completely expelling the oxyuris vermicularis in cases which had resisted all the usual vermicides employed both per os and per clysma.

On the other hand, Wilcox believes that the most frequent cause of failure with this drug is due to the use of too small doses, and considers the administration of less than sixty grains daily as a "needless waste of very good medicine." Accurate dosage is certainly not essential to the administration of this drug. It is insoluble, not only in water, but in acids and alkalies, so that it reaches the intestines unaltered and, in fact, appears, for the most part, unchanged in the feces. A minimum part of it is absorbed and appears in the urine partly as such and partly as alpha-naphthol. Although the amount that passes out with the urine is small, its antiseptic effect is so great that, according to Rossbach, the urine of patients who have been taking naphthalin may be kept for weeks, and even months, in a warm place without losing its acid reaction and without decomposition.[3] In accordance with these facts, the internal employment of naphthalin in light chronic cystitis has been attended with excellent results. In one or two days the cocci disappear, the pus sediment diminishes, and there is marked improvement in the local and general conditions. In severe, chronic, incurable cases, temporary improvement is the most that can be expected, as in a case of tuberculosis of lungs, bladder, and kidneys reported by Rossbach.[1]

With reference to certain unpleasant effects that have attended the administration of naphthalin, Rossbach states that, with the exception of slight burning in the urinary passages lasting only a few days, and fugitive pains in the neighborhood of the kidneys, serious symptoms due to the drug itself were observed in only 2 out of 150 cases. Severe strangury was observed in these 2 cases, both of which were tuberculous. One was in the last stage of pulmonary and intestinal tuberculosis; the other, in whom an inflammation of the prepuce set in on the third day of administration of the remedy, bore it well after it was suspended and resumed in smaller doses. Evil effects from this drug are almost invariably due to the fact that it is impure. A case in point is that of a butcher's powerful apprentice, who, after the third gramme of naphthalin, suffered from severe strangury. An examination of the drug showed that it was impure, being gray instead of white. On the day following, the same patient took seven grammes of a pure preparation without a bad symptom.

While large doses of naphthalin are being administered, the urine is of a dark, even black, color, but this fact is of no evil significance. When administered with ordinary care, the worst that can happen is occasional burning pain in the urinary passages, and to refuse, on that account, to employ in chronic diarrhœa a remedy which has cured many of the most obstinate cases, would be, to quote Rossbach, about as sensible as to banish iodine and potassium iodide from therapeutics because now and then they give rise to acute coryza and palpitation of the heart.[2]

The mode in which naphthalin and other drugs intended to act directly on the intestine are prescribed, is by no means unimportant. Probably the best method of administration is that recommended by Unna. The drug is made into a mass with some fat, such as cocoa butter, which melts at the temperature of the body, and each individual pill is surrounded with a layer of the same substance. They are then coated with a layer of keratin (Hornsubstanz) which is insoluble in the acids of the stomach. The keratin is applied to the pills in solution in ammonia, but before this it is digested in an artificial gastric juice to free it from substances which, but for this process, would be dissolved in the

[1] Jahrbuch für Kinderheilkunde, Bd. xxvi Hefte 3 und 4, 1887.

[3] Einfluss des innerlichen Naphthalingebranches auf die Harnfäulniss. Rossbach, Berlin. klin. Wochenschrift, Nov. 17, 1884.

[1] Loc. cit. [2] Berlin. klin. Wochenschrift, April 6, 1885.

stomach. The keratin coating of these pills is dissolved by the alkaline fluids of the small intestine and their fat is saponified so that the remedy is set free to exert its local action. Unna has employed in this manner tannin in intestinal catarrh and ext. filicis maris in cases of tapeworm, with good results, and recommends that astringents and styptics be thus administered, especially in intestinal hemorrhage.[1] Dr. F. Kræmer, of Munich, has employed these pills and thinks that by this mode of administration many of the unpleasant effects attendant upon the use of naphthalin are avoided.

Probably the most common mode of administering naphthalin is in gelatine capsules. It is important, therefore, to remember that gelatine capsules should not be given to a patient who is taking alcohol, as they are rendered insoluble by that substance. Tannic acid has the same effect. This subject is referred to in an editorial in *The Southern Practitioner* for September, 1886, in the course of which the writer mentions the fact of a physician having prescribed tannic acid in gelatine capsules. Gelatine capsules are not only insoluble in a stomach which contains alcohol, but also in one that is suffering from the effects of alcohol. "When the stomach is inflamed and irritable, following excess in the use of spirits, medicines should not be given in capsules (gelatine)." "Neither chloral nor morphia should ever be given in this form to inebriates; it is useless."[2]

THYMOL.—In THE MEDICAL NEWS of September 3, 1887, I published my experience with thymol in the treatment of twelve cases of typhoid fever. My attention was first called to this drug by Martini's elaborate article in the *Annali Universali di Medicina e Chirurgia*,[3] February, 1887, and I was induced to publish my observations with it, not only because they were corroborative of Martini's statements, but also because they were confirmed by my colleague, who succeeded me at the Episcopal Hospital and who continued to employ the drug. Since that time I have used thymol in eight additional cases of typhoid fever and in a large number of cases of diarrhœa, acute and chronic. With reference to the former I have only to quote from my article in THE MEDICAL NEWS: "The favorable effect of the drug was evinced by a steady descent of the temperature, by a gradual diminution in the daily number of stools, by the absence of mental excitement, and, most conspicuously, by the clean, moist tongue presented in every instance." In the series of twenty cases there has been one death which was caused by one of the rarest events in the course of typhoid fever—rupture of the spleen.

That thymol when taken *per os* exerts an antiseptic action upon the intestinal contents, is proved beyond doubt by the fact that, during its administration, phenol disappears from the urine. "This substance, one of the most constant products of intestinal putrefaction, is eliminated, for the most part, by the urine, where it is found even in health, and experimental therapeutists regard its amount in that fluid as a test of the effect of an intestinal antiseptic."[1]

The symptoms known as "typhoid" are common to a number of diseases and their distinct amelioration after the administration of an intestinal antiseptic is strong evidence in favor of the view that they are largely due to poisoning from absorption of products of intestinal putrefaction. On account of its great insolubility, a property upon which its value as an intestinal antiseptic largely depends, thymol must be prescribed in pill or capsule. One of the best excipients for thymol is medicinal soap. As to the dose, my practice has been to give from 30 to 40 grains in twenty-four hours—two 2½ grain pills every three or four hours, although much larger quantities may be given with perfect safety and, perhaps, with still better results. I have given thymol to all the cases of diarrhœa, acute and chronic, under my care during a six months' service at the Philadelphia Hospital, and, excepting a few cases of intestinal tuberculosis, with invariably good results. I regret that I cannot obtain the number of these cases in time for publication. To those familiar with the hospital in question, it is scarcely necessary to say that my opportunities for testing the drug were great.

MERCURY.—As I have no present intention of writing a treatise on antiseptic medicine, I will neither refer to the various modes of administering mercury nor discuss the question how far its beneficial effect, in general, may be of an antiseptic nature, but will simply give my experience of its employment in the treatment of erysipelas.

The evidence that erysipelas is a local disease due to a microörganism is overwhelming, but, if I may judge from a recent discussion in a Philadelphia medical society, it has not yet come to the knowledge of some of the most prominent members of our profession. I will, therefore, briefly recapitulate the result of an investigation of the subject.

It has been thoroughly demonstrated by Fehleisen and others that erysipelas is caused by the presence of a living organism, a micrococcus, in the lymphatic vessels of the skin. This organism, which is usually observed in the form of chains or strings of beads, and is, therefore, known as a streptococcus, has been isolated by successive cultures and inocu-

[1] For description of these pills see article by Pribram, Wiener med. Presse, February 1, 1885.

lated into rabbits with the result of giving them an attack of erysipelas. The animals inoculated were nine in number, and of the nine, eight had a well-marked attack of the disease, starting from the tip of the ear in which the inoculation was made. The period of incubation—*i. e.*, the time between the inoculation and the first signs of inflammation, varied between thirty-six and forty-eight hours. Denucé, a French observer, has repeated these experiments upon six animals, five rabbits and one dog, with positive results in every case. Such evidence would be accepted by most individuals as sufficient to prove the dependence of erysipelas upon a micro-organism; but, Fehleisen has gone a step further, and inoculated seven human beings. He did this on the ground that it was not only for the benefit of science, but for that of the individuals themselves, although it does not appear that they were consulted on this point. It has long been observed that chronic eczematous affections, glandular swellings, lupus, and multiple sarcomatous tumors have disappeared after an attack of erysipelas, and it was upon individuals afflicted with such diseases that the experiments were made. All but one of these experiments were successful from the standpoint of experimental pathology, but the therapeutic results hardly warrant the addition of the streptococcus of Fehleisen to the Pharmacopœia. In fact, a woman forty years of age, with scirrhus of the breast, who was inoculated with erysipelas by Janicke and Neisser,[1] died four days after the operation. It was a satisfaction to these experimenters to observe at the autopsy that the micrococci artificially introduced had penetrated the cancer cells and destroyed them in large numbers. The remedy, however, if such it can be called, was undoubtedly more malignant than the cancer itself.

The above facts are quite sufficient to prove that erysipelas is a local parasitic disease, and to justify a local germicidal method of treatment. A treatment based on these views of the nature of erysipelas was first recommended by Hueter. It consisted in the subcutaneous injection of a two per cent. solution of carbolic acid, manifestly with the object of destroying the parasite. Its success was not striking, and an attempt to improve it was, therefore, made by Dr. Kühnast, of Freiburg, who concluded from a study of three cases that multiple scarification and the application, with rubbing, of a five per cent. solution of carbolic acid, were the best treatment yet devised. This may be true; but, if so, there are numerous exceptions to the rule. In the first place, this method cannot be applied to that part of the body—the face—which is the most common site of erysipelas, on account of the danger of subsequent scarring. Secondly, it is so painful that the operation must be performed under ether. Finally, in the case of children and weakly individuals its upholder recommends that boric or salicylic acid be substituted for carbolic. Surely the objections to this treatment are so great that it can never come into general use.

[1] Centralblatt für Chirurgie, 1884, p. 401.

Thinking that the want of success attendant upon the subcutaneous injection of carbolic acid might be due to the inherent inefficacy of that drug, I have lately been treating erysipelas with hypodermatic injections of the bicyanide of mercury. My reason for employing this salt in preference to corrosive sublimate is that the former is compatible with cocaine while the latter is not. A hypodermatic injection of corrosive sublimate is so painful that few will consent to its repetition, while the bicyanide, as I have employed it, is comparatively painless. The following formula is the one I am accustomed to use:

R.—Hydrarg. bicyanid. . . . grs. ij.
Cocain. hydrochlorat. . . . grs. iv.
Aquæ destillat. . . . . ℥ss.—M.
Fifteen minims to be injected beneath the skin.

I have made about two hundred injections of this mixture in cases of syphilis and erysipelas, always using the dose above mentioned, and have never seen any untoward constitutional symptoms from it, beyond a momentary faintness which I attributed to the cocaine. Several of the patients were delicate women.

I have treated ten cases of erysipelas capitis[3] with injections of the bicyanide, and without entering into details I may state that when the disease is beginning, for example, at the side of the nose and extending toward one or both cheeks, this treatment tends to abort it. It is of great importance that the injection be made, not into the inflamed patch but a little beyond its border.

Erysipelas, from a pathological standpoint, consists of two stages. During the first there is an accumulation of micrococci in skin which is apparently healthy. During the second there is a displacement of the micrococci by out-wandered white cells which dispose of the former by incorporating them into their substance so that under the microscope they present a granular aspect. In order, therefore, to abort an attack of erysipelas the injection must be made in the apparently healthy skin at least one-half inch beyond the advancing border of inflammation. I have seen at least three cases of erysipelas which were aborted by the treatment above outlined. These, all hospital cases, were seen at an early period of the disease, while, in the others, it was widespread at the time of admission. I do not consider this treatment effectual after the disease has lasted more than forty-eight hours. It is a singu-

[3] My thanks are due to Drs. Atlee and Dercum for their assistance in carrying out this treatment.

lar fact that in the majority of my cases, the injections of the bicyanide gave rise to abscesses. I consider the fact singular because the substance injected is a powerful antiseptic, and because I have given about one hundred and fifty of the same injections to two women with syphilis, without the slightest suppuration ensuing. In using the injections strict antiseptic precautions were employed: among others the needle of the hypodermatic syringe was heated in a spirit lamp.

The following abstract will serve as a sample of those cases treated at a comparatively early stage:

John H. W., æt. fifty-one years, admitted April 19, 1888, with erysipelas in both cheeks, but more extended on left side. The attack began four days ago at the site of a recent cicatrix resulting from an injury received about four weeks previously. Febrile reaction was slight, the temperature at evening being 100°. The urine was free from albumen. Fifteen minims of the bicyanide solution were injected into each cheek beyond the border of the inflammation.

20*th*. The cheeks are not so much inflamed and the inflammation has not extended. Two injections were given, both on the left side; one in the temporal region, the other in the neck.

21*st*. The inflammation is gradually subsiding in the cheeks and *has not extended its area*. The temperature fell to normal on the 22d, and did not subsequently rise above 99°. The man was discharged from hospital on the 30th of April.

In another case, seen when the inflammation had not lasted more than twenty-four hours and involved only a small area about the ala nasi, one injection effected a cure.

Certain facts seem to show that the micrococcus of erysipelas develops most rapidly when the part affected is exposed to the air; or, rather, this is an inference from the effects of a treatment which excludes the air from it. For example, Mr. Barwell, of Charing Cross Hospital, has treated erysipelas by the application of white lead paint, with the result of speedily relieving the pain and reducing the fever; the patient rapidly recovering. W. Otto, of Germany, following the suggestion of Barwell, has excluded the air with a mixture of two parts wax, twenty parts of "Siccativ," and one hundred parts of linseed oil varnish ("leinölfirniss"). His cases, five in number, all did well, the disease in no case lasting longer than ten days.

One of the latest remedies proposed for erysipelas is ichthyol,[1] which is a yellowish-brown oily substance obtained by distilling a bituminous matter found in the Tyrol, and composed of the fossilized remains of fishes and marine animals. It is used in the form of the sodium or ammonium sulph-ichthyolate. Von Nussbaum claims that this substance will abort erysipelas, but it did not do so in the only case in which I gave it a thorough trial. The course pursued by this case was, however, remarkably favorable. Von Nussbaum supposes that ichthyol alters the tissues in such a manner as to make them an unfit medium for the growth of the parasite. It is, however, quite as likely that both it and the white paint, as well as the liniment used by Otto, act by excluding the air. Whether this be the case or not, such measures are probably antiseptic in their action, although inferior in this respect to a method such as that I have described and employed, which brings the germicide in direct contact with the germ.

The lack of time and space forbids a further consideration of this interesting subject. Otherwise, under the head of intestinal antisepsis, I would have referred to some interesting facts concerning the action of cotoin, salol, and bismuth salicylate.

In conclusion, I will merely refer to certain observations which not only show that microörganisms may subserve some useful purpose in the economy, but convey the hint that, by taking advantage of their opposing tendencies, we may yet compel them—the germs of fermentation and putrefaction—to play the *rôle* of antiseptics.

The first set of observations to which I refer are those of Rietsch.[1] In this investigation cultures of the microörganisms of cholera asiatica, of typhus, and of the staphylococcus aureus in 2.5 per cent. peptone solution, were precipitated with alcohol. The precipitate was separated by filtration, washed repeatedly and dried, and the powder thus obtained was tested with reference to its power of digesting albumin. The result was that neither the tubercle nor the typhus bacilli were capable of digesting fibrin, either in alkaline or neutral solution. On the other hand, the cholera bacillus and the staphylococcus aureus, in neutral solution, digested fibrin and the resulting fluid gave the reaction of peptone. In weak alkaline solution the fibrin was also attacked, and in neutralizing with HCl, a precipitate took place which gave the reactions of syntonin and globulin. The digestive capacity of these bacteria, thus demonstrated, had already been suspected on account of the liquefaction of the gelatine in which they are sometimes cultivated.

The second set of observations are those of Hirschler,[2] who found that in mixtures of albuminoids and carbohydrates, the bacteria which first develop are invariably those that decompose the latter. For example, in milk, notwithstanding the presence of numerous casein-decomposing bacteria, the acid fer-

[1] See paper by Dr. Edward Martin, in Journal American Medical Association, 1888.

[1] Contribution à l'étude des ferments digestifs sécrétés par les bactéries. Journal de Pharmacie et de Chemie, 1887, 1 Juillet.

[2] Quoted by Escherich—Beiträge zur antiseptischen Behandlungsmethode der Magen-darmkrankheiten des Säuglingsalters. Jahrbuch für Kinderheilkunde, Bd. xxvii. Hefte 1 und 2, 1887.

mentation first sets in. In such cases the withdrawal of carbohydrates and the substitution of a purely albuminoid diet is indicated. On the other hand, in cases of putrefaction of albuminoids, with offensive stools, all proteids are to be temporarily withdrawn and carbohydrates substituted. The acid fermentation of the latter is the result of bacteria which are inimical to those causing the horribly offensive stools. These most suggestive facts lead directly to the belief that the time is not far distant when what we now somewhat vaguely speak of as a well-regulated diet will be one selected not exclusively with reference to the nice adjustment of its proteids and carbohydrates, but also with a view to the mutual relations of the minute organisms which subsequently develop within it.

SUBGLOTTIC LARYNGEAL TUMOR.[1]

By E. FLETCHER INGALS, M.D.,
of Chicago.

Cartilaginous tumors of the larynx are so rare that I believe the report of a case which, although at present incomplete, seems in a fair way to be cured by endolaryngeal treatment, will be of general interest.

At the New York meeting of the American Laryngological Association in 1884, Dr. Morris J. Asch[2] presented the history of a case of laryngeal ecchondrosis together with a *résumé* of the literature of the subject. He cites eight cases besides his own, only two of which were accurately diagnosticated and treated during the patient's lifetime, and only one of these had been treated by endolaryngeal methods.

By consulting the library of the Surgeon-General's Office at Washington I have been unable to find records of any other cases excepting one of immense fibro-enchondroma of the hyoid bone and larynx which was skilfully removed by Dr. Azzio Caselli[3] twenty-four hours before the patient's death. This, however, should hardly be included with laryngeal growths, although at first it seemed to spring from the outer surface of the thyroid cartilage.

Dr. Asch's case, in which the tumor grew from the upper part of the thyroid cartilage, and Stoerk's case, in which it occupied a site at the base of the left arytenoid and vocal process, are the only ones that have been successfully treated by endolaryngeal means. Virchow says[4] that from the thickness and hardness of these tumors "they cannot be removed *per vias naturales*."

In the case which I have to report the tumor was seated below the glottis, and although a cure has not been effected, four applications, made at intervals of from four to six weeks or more, caused a diminution from its largest dimensions (about the size of a split cherry) to one-tenth of that size, and I feel confident that from two or three more applications it would have been entirely destroyed; therefore I feel justified in recommending a careful trial of the treatment in similar cases. The history is as follows:

Mr. X., æt. twenty-four, commercial traveller, came to me July 24, 1886, complaining of almost constant hoarseness which dated from exposure in a tornado about a year previously. His general health was perfect and there was *positive evidence of no specific taint.* The vocal cords were slightly congested, and at about the middle of the left cord there was a small conical outgrowth about three millimetres in diameter. In the subglottic region just below the anterior commissure I found a small, yellowish, somewhat conical tumor, measuring, as nearly as I could estimate, four millimetres in thickness at its highest part and six or seven millimetres across its base. Its surface was smooth but slightly nodular, and its base occupied partly the inner surface of the thyroid cartilage and partly the inner surface of the crico-thyroid membrane. Other portions of the larynx were normal.

A solution of sulphate of zinc was applied by spray to the larynx and an astringent spray was ordered for daily use by the patient. This was continued for about four weeks, when I again saw the patient. There had been little or no improvement.

At that time, as a forlorn hope, I directed iodide of potassium to be taken in doses of from five to fifteen grains three times a day. I saw the patient only twice during the next month, and made no further local applications. He continued to take the iodide of potassium in doses ranging from ten to twenty grains t. i. d. for eight months, but during the last six weeks previous to his fifth visit to my office in July 15, 1887, he had taken no medicine and had not used the spray. The cartilaginous tumor had increased in size so that, as near as I could estimate, it was six millimetres in thickness and fully a centimetre in diameter at its base. The outgrowth had disappeared from the vocal cords and the congestion had subsided.

At this visit, now fourteen months ago, I decided to suspend all other treatment and try the effects of cauterization with chromic acid. I anæsthetized the larynx with a ten per cent. spray of cocaine and then applied the caustic accurately to the whole surface of the tumor until it appeared of a uniform brownish-yellow color. This I succeeded in doing, without touching surrounding parts, though shortly afterward I found that the diffusion of the acid had tinged the anterior half of the vocal cords of a yellowish color.

Six days later I found the larynx highly congested and I then applied a spray of a thirty-grain solution of sulphate of zinc. I did not see the patient again until the end of a month, when I found the tumor materially reduced in size. I again applied the caustic in the same manner.

He returned again at the end of two months,

[1] Read at the American Laryngological Association, in Washington, September, 1888.

[2] Trans. Amer. Laryngological Association, 1884, p. 66.

[3] Ann Univ. di. Med. e chir., 1880, cclii. pp. 504–516.

[4] Virchow, Path. des tumeurs, vol. i p. 442.

when I find from my notes that his voice was perfect and as a result of two applications of chromic acid the growth had diminished to two-fifths of its former size. Owing to the patient's business engagements the tumor was not cauterized at this time, but two months later, December 22, 1887, I cauterized it again, and again two months later I repeated the treatment. One month later, March 15, 1888, I found the tumor diminished to about one-tenth of its former size. On this date I made the sixth cauterization.

I did not see the patient again until the 7th of August, about five months, when the tumor appeared to me somewhat larger than at the last treatment, or about one-fifth of its largest size. I again cauterized it with chromic acid. I saw the patient once more at the end of a month and found that the growth had been reduced about one-half by the last application. He was usually hoarse for three or four days after each treatment, therefore, because of his business engagements, further treatment was postponed until the end of September.

Dr. J. E. Rhodes, who has seen this case with me two or three times, concurs in my belief that the treatment would speedily eradicate the growth if two or three applications could be made at intervals of three or four weeks. I expect to follow this course the present fall and hope to be able to report a perfect cure.

In making the applications of chromic acid I used an aluminium wire on the end of which a small amount of the acid was fused. Over this wire I slipped a section of small rubber tubing which had been cut away at its lower end to expose the acid in front. The section of tubing was made secure by tying it with a silk thread, which was extended along the wire to the handle so that there could be no possible chance of its dropping off. This I have found the simplest and most convenient instrument for applying caustics to the larynx. The rubber tubing protects the surrounding parts better than any other device I have seen. The instrument is simple, it may be bent in any direction, it is easily cleaned, and it does not get out of order.

70 State St., Chicago.

HEART WITH THREE CAVITIES.

Partial Transposition of Abdominal Viscera.[1]

By M. HOWARD FUSSELL, M.D.,
of Manayunk, Philadelphia.

Louisa D., aged twenty-one months. Parents healthy; had one other child, which died of summer complaint, aged two months. Louisa was born September, 1886, after a very easy labor, weighed about five pounds, and was apparently perfectly healthy. No cyanosis except that common to infants immediately after birth. It nursed and rested well, and I left it at the end of two weeks, having no idea of its serious malformation.

At the age of three months the child was brought to me, with the statement that she continually "grunted," giving the impression to those around that her clothing was too tight. Her appearance was quite normal. On examination the "grunt" was found to resemble closely the expiratory moan of pneumonia. Respirations not markedly accelerated; pulse regular and not over-rapid. On auscultation an exceedingly loud double blowing murmur was heard, with greatest intensity in the mitral region, but conducted equally over the entire area of both chests. The heart was not markedly hypertrophied. It was impossible to decide whether the murmur had its origin at the tricuspid or mitral valves. There was no cyanosis and no œdema.

Thinking the moan came possibly from the overburdened heart, the little patient was put on half drop doses of tincture of digitalis, with the result of stopping the moan for several months.

During the spring and summer following the patient had many attacks of bronchitis and diarrhœa, but she grew fairly well and cut the usual number of teeth at the proper periods. She walked at twelve months. It was noticed now, however, that she began to fail in strength, and though she would take nothing but the breast it was thought best to wean her, and now began the real trouble. It was only by forcing that she would take milk, and she would eat nothing but sugar, clear starch, and dirt. She would eat ordinary starch by the handful, and whenever she could get near any earth eat it as so much sugar, and would cry lustily whenever she was taken away from the dirt. Gradually she ceased to walk, and finally would not stand alone. She was tempted by every imaginable thing, but would eat absolutely nothing but milk, sugar, starch, and dirt.

On December 12, 1887, I was called to see her on account of a bad cough. This at first promised to be one of her frequent attacks of bronchitis. However, her temperature rose to 103° F., pulse 160, regular, and respirations 80 per minute. Consolidation of right base developed. There was characteristic blowing breathing over the whole lower right lobe. The child had pneumonia, and, contrary to my faintest hope, made a good recovery and appeared better than she had for a year; she even began to walk a little, and lost her desire for dirt and would eat very slightly of cracker, but still clung to her milk, sugar, and starch. Her heart had gradually grown. After her attack of pneumonia I find the following note: Præcardia bulging, apex beat beyond the nipple line; dulness from mid-sternum to beyond the nipple line. A loud double murmur over the whole chest. Liver dulness extends below the umbilical line.

[1] Read before the Pathological Society of Philadelphia.

The patient did well until the beginning of May of the present year, when I was called, and found her propped up, the subject of orthopnœa, countenance livid, finger-nails extremely blue, heart's action irregular, breathing labored and irregular, chest full of mucous râles, no œdema of the extremities. The child was the picture of one suffering from heart failure. I thought the end had certainly come; but under a free use of digitalis and nitroglycerine she became quite comfortable, and the cyanosis disappeared almost entirely for nearly two weeks, at the end of which time the right hand and foot began to swell gradually, general anasarca took place, and the patient gradually failed, dying with extreme suffering on June 18th.

Post-mortem thirty-six hours after death. Dr. George Dock, of Philadelphia, kindly made the section. The child was small for the age of twenty-one months. There was œdema of the extremities and face, and the belly protruded by what proved to be ascitic fluid.

Heart.—On opening the chest the heart was seen occupying almost the entire anterior portion of the chest. The auricle was greatly distended. The

Fig. 1.

ascending vena cava passed up on the left side of the spinal column and apparently entered the left auricle. After noting the anomaly, the heart and lungs were removed entire and dissected at leisure.

The entire heart was much hypertrophied. The auricles and right heart were in a state of extreme distention, giving a typical picture of heart failure. While in this distended condition the auricular portion was seen to be of much greater size than the ventricular portion, at least half as large again (Fig. 2). The right ventricular portion was much more developed than the left, the right ventricle evidently forming the apex (Fig. 1).

The aorta arose to the right of the pulmonary artery; the ascending and transverse portion of the arch was dilated to at least twice its original size (Fig. 1). The ascending vena cava entered the auricular cavity far to the left and posteriorly. The descending vena cava was absent, its place being supplied by the two innominate veins, the right entering about the position of the superior cava, the left entering the left auricular portion in the anterior part (Fig. 1).

The pulmonary veins were normal in position and number.

The heart was opened by making an incision in the pulmonary artery and following that vessel into the right ventricle. The wall of the ventricle was half an inch thick and filled with a moderately firm clot. Its cavity had three outlets, viz.: the aorta, the pulmonary artery, and the auriculo-ventricular orifice. The pulmonary orifice lay close to the septum to the left of the aorta, and was guarded by two healthy semilunar valves. It was much contracted by thickening of the ring, was of triangular shape, and of about the calibre of a crow-quill (Fig. 3).

The aortic orifice was to the right of the pulmonary and would easily admit the tip of the little finger—it was protected by three valves (Fig. 3). The auriculo-ventricular orifice was placed posteriorly to the above two. It admitted the tips of three

fingers. The valves protecting this orifice were evidently incompetent. The right half of the ring was protected by a large valve, which was attached to the apex by a papillary muscle. Posteriorly, and joined

to the posterior edge of the above valve, is a nodular formation, evidently an attempt at a second valve. The remaining portion of the ring was perfectly smooth and free from any valvular attachment. It is formed by the free upper edge of the ventricular septum. From this portion of the ring a muscular band three-eighths of an inch wide runs to the septum.

The free edge of the large valve was the seat of nodular thickenings. The ventricular septum was imperfect, connecting with the left ventricle by means of a small semilunar opening at the upper edge. The septum was about one-fourth of an inch thick. The left ventricle was abortive, its cavity holding scarcely more than a drachm. Its walls were about half the thickness of those of the right ventricle. There was no vessel given off from this cavity, the only openings being the auriculo-ventricular and the small opening into the right ventricle. The auriculo-ventricular opening admitted the index finger; the anterior portion was free from valvular attachment and was formed by the free edge of the ventricular septum in common with the free portion of the ring on the other side. The remainder of the orifice was protected by a valve having its anterior attachment at a point in common with the anterior attachment of the valve on the right side and the posterior attachment in common with the abortive valve on the left; it was attached to the walls by chordæ running to the papillary muscles, one on the anterior, the other on the posterior wall.

Another and perhaps the proper description is, that there is but *one* auriculo-ventricular orifice which is common to the right and left ventricles, and protected by valves as described above, the two ventricles communicating by a small semilunar opening in the upper part of the septum.

On opening the auricular portion, the septum was found wanting, and there was no trace of foramen or valve. The walls of the cavity were one-eighth of an inch thick. The capacity was sixty c. c. There were two complete auricular appendages. The common auriculo-ventricular orifice was well seen at the bottom of this cavity.

The ductus arteriosus arose from the left pulmonary artery and was patulous.

Lungs.—Right not fully divided into its three lobes, and there was an attempt at a fourth lobe. Left, the entire lower lobe was consolidated apparently by an infarct, but no embolus was found.

The *liver* was a typical nutmeg, almost round, of monstrous size, occupying half the abdominal cavity, exceedingly hard.

The *œsophagus* passed to the right of the spinal column, entering the cardiac end of the stomach in the right hypochondriac region.

The *spleen* consisted of three distinct portions curiously nodulated with an attempt at a fourth division. It lay attached to the stomach in the right hypochondrium.

The *stomach* was entirely on the right side under the right lobe of the liver, the pylorus lying in an almost normal position, but pointing forward, and the cardiac end lay along the column posteriorly on the right side. The duodenum ran anteriorly.

Pancreas short and round, with the head pointing anteriorly; duct presumably opening into the ductus, commences about one inch from the pylorus.

Cæcum lay in right iliac region, but was anterior.

Colon ran half way up on right side, crossed the column, and lay in folds in the right iliac region.

The *kidneys* were cyanotic.

This is the fourth specimen of malformed heart presented to the Philadelphia Pathological Society, and the third of its class. The first was presented by Dr. Darrach, in 1858, and is reported in vol. i. of the *Transactions*. Save that the orifice of the pulmonary artery was entirely obliterated, it was a counterpart of this specimen. Dr. Rex presented a malformation in 1874, vol. v., which was doubtless of the same class, but the aorta was connected with both the right and left ventricles. Dr. Eskridge presented a specimen in 1883, but the malformation was almost exclusively in the right side, being an

abnormal septum in the right auricle, the openings and vessels being normal.

Practically, the heart which I have described consists of two cavities, only the one ventricle and one auricle taking any active part in the circulation.

However, I think it must be classed with that more common form of malformations in which there is an attempt at the four cavities, arrest of development taking place at a later period of development.

When the arrest of development takes place very early there are only two cavities or perhaps three, but almost universally there is but *one* vessel leading off from the common ventricle, arrest having taken place before the division of the primary artery.

In the class of which I think this forms one, there are two arteries, two auricular appendages, with a more or less complete formation of the septa of auricles and ventricles. The orifice of the pulmonary artery is always more or less contracted, sometimes, as in Darrach's case, entirely obliterated. The aorta may arise to the right of the pulmonary artery, as in this case, and always has connection with both ventricles, the septum ventriculorum being deflected usually to the left. Hunter supposed these defects were caused by some obstruction occurring in the pulmonary artery in early fœtal life, while the septum of the ventricle is incomplete, necessitating a flow of blood into the left ventricle, preventing a separation of the two ventricles, causing a deflection of the septum to the left and a dragging of the aorta to the right.

Meckel concludes that incompleteness and deflection of the septum are primitive defects, the blood finding a free outlet from the right ventricle through the aorta; the pulmonary artery becomes more or less abortive, and the orifice is contracted during the process of development.

Peacock believes that the defects are due partly to the arrest of development, by which the earlier position of the aorta is retained, and partly to obstruction of the pulmonary orifice and consequent distention of the right ventricle, causing the septum to be deflected to the left.

189 Green Lane, Manayunk.

SUCCESSFUL TREATMENT OF A CASE OF EXOPHTHALMIC GOITRE BY SULPHURIC ACID.

By WM. E. MAGRUDER, M.D.,
of Olney, Maryland.

Six years ago I had an obstinate case of exophthalmic goitre in a lady about twenty-two years of age. This case presented the usual symptoms of that disease, viz.: enlargement of the thyroid gland, with decided pulsation, protrusion of the eyeballs, palpitation of the heart, frequent pulse (120 to 140), anæmia, etc. I treated the case for more than two months with very little improvement in the condition of my patient, using the various remedies usually prescribed in that disease, such as digitalis, iron, quinine, aconite, strychnine, ergot, belladonna alone and in various combinations, and electricity, both galvanic and faradic. I then gave aromatic sulphuric acid in combination with digitalis and ergot, and found a decided improvement in a very short time. This combination, however, soon disagreed with her stomach, and I then gave the acid alone (20 gtt. every four hours), and the improvement continued.

After beginning the use of the acid, the pulse became less frequent, the pulsation soon ceased in the thyroid gland, and the enlargement gradually decreased, as did also the protrusion of the eyeballs. For about one year there was a tendency to a recurrence of the disease, but it always yielded promptly to the acid, and so marked was the relief afforded that the patient resorted to its use whenever she felt a return of the symptoms. She is now perfectly well.

I have never seen any mention of this treatment for this disease, and it may not act in another case as it did in the one reported above, but it is certainly worth a trial. I have had no other case since upon which to test the treatment, and therefore have hesitated about reporting it, but I hope others may try it and publish their results.

This treatment was suggested to my mind by reading in *Clinical Observations on Functional Nervous Disorders*, by C. Handfield Jones, the following remarks:

"Sulphuric and nitric acids have certainly some claim to be regarded as *toners of the vasomotor nerves*. They cannot be supposed, of course, to act in their original form on the parts they influence, as their quality must be lost the moment they enter the circulation. They cannot be mere astringents like tannin. When sulphuric acid restrains a choleraic purging, or colliquative sweating, these effects must surely be produced through the nerves that regulate the arteries of the internal and the external integument. Its special nervine action is attested by the following quotation from Dr. Pereira: 'No remedy is so successful in relieving the distressing itching, formication, and tingling of the skin as sulphuric acid taken internally.'"

Something to give tone to the vasomotor nerves seems to be indicated in this disease, and the sulphuric acid certainly seemed to have that effect in this case.

MEDICAL PROGRESS.

Tuberculosis in Children.—In an article on this disease in the *Archives of Pediatrics*, for Oct. 1888, Jacobi, with that characteristic clinical acumen which marks this teacher's utterances, deplores the present fashion of feigning contempt for internal remedies. He believes that arsenic is a remedy of great value. The doses must be small. A child a few years old may take two drops of Fowler's solution daily, or a fiftieth or a fortieth of a grain of

arsenious acid for weeks or months in succession. This amount may be divided in three doses, administered after meals, the solution largely diluted. There is no objection to combining it, according to necessity, with stimulants, roborants, or narcotics, and to giving it for an indefinite period, unless the well-known symptoms of an over-dose—gastric and intestinal irritation and local œdema—made their appearance. But they seldom will, particularly when small doses of opiates are judiciously added to them. In almost every case, perhaps in every one, it is desirable to administer it in conjunction with digitalis.

In the vertebrate animal, digitalis increases the energy of the heart-muscle and its contraction; thereby it increases arterial pressure and diminishes the frequency of the pulse. By increasing arterial pressure it favors the secretion of the kidneys, improves the pulmonary circulation, empties the veins, thereby accelerates the flow of lymph and the tissue fluids, and exerts a powerful influence on the metamorphosis of organic material—that is, general nutrition. Besides, what it does for the general circulation and nutrition it also accomplishes for the heart-muscle itself. The bloodvessels and lymph circulation of the latter are benefited equally with the rest.

Thus digitalis, while being called a cardiac stimulant, contributes largely to the permanent nutrition and development of the organ. This effect is not only of vital importance for the economy of the system on general principles, but an urgent necessity in view of the fact that there appears to be a relative undersize of the heart, either congenital or acquired, in cases of phthisis; and there is certainly such a predominance of the size of the pulmonary artery in the young, particularly over the aorta, that the normal succulence of the lung becomes pathological quite readily when the insufficiency of the heart-muscle tends to increase low arterial pressure within the distribution of the pulmonary. The selection of the preparation to be administered is not always an indifferent matter. The infusion and the tincture are not always well tolerated by the stomach; digitalis, not being a soluble alkaloid but a glucoside, is not always reliable in its effects, and not of equal consistency and strength; a good fluid extract is borne well and may be taken for a long time. A child a few years old may take about two minims of the former daily, more or less, for weeks and months, or its equivalent in the shape of the extract (two-thirds of a grain daily); the latter can easily be given in pills, to be taken in bread, or jelly, and combined with any medicines indicated for special purposes, such as narcotics, or nux, arsenic, or iron; the latter to be excluded in all feverish cases, or in all cases as long as there is fever. As long as there is no urgent necessity for a speedy effect, digitalis will suffice by itself; as a rule, it does not operate immediately in those small doses. The addition of strophanthus, sparteine, or caffeine, all of which are speedily absorbed and eliminated, and exhibit their effect rapidly and without the danger or inconvenience of cumulation, will prove advantageous in many cases.

Other medicines have been used in great numbers. Specifics have been recommended, and symptomatic treatment been resorted to. The success of the latter depends on the judgment of the individual practitioner. No text-book or essay can teach more than general principles and their adaptation to the average case, and the measures to be taken in a number of exceptional occurrences. The indications for the use of narcotics, stimulants, expectorants, and febrifuges will change according to the cases and their various phases and changes. In every case the necessity may arise for antipyrin, antifebrin, phenacetin, salicylate of sodium, or quinia. It may be necessary to decide the question whether the administration is to be made through the mouth, rectum, or subcutaneous tissue, or how their effects are to be corrected or combined. I have often found that a hectic fever would not be influenced by quinia, or by antipyrin, or salicylate of sodium. But the combination of the first with one of the latter would frequently have a happy effect.

Fissures of the Tongue.—These obstinate and painful lesions may be speedily cured, according to SCHWIMMER, by applying the following mixture five or six times daily:

R.—Papayotine . . . . 2 parts.
Glycerin,
Aquæ . . . . āā 10 parts.—M.
—*Revue de Thérapeutique*, Oct. 15, 1888.

Glycerine Suppositories.—Suppositories of glycerine may thus be made: Ten parts of particularly hard, dialyzed stearin soap are dissolved in hot water, the solution mixed with ninety parts of pure glycerine and passed through a steam filter; the filtrate, melted, is divided into one hundred parts and poured into moulds. The suppositories are firm and transparent; as they are hygroscopic, they should be incased in tin-foil. Two sizes may be prepared, one of about 26 grains, another of 38; the former should contain about 24, the latter about 36 minims of glycerine. Dietrich's idea to combine glycerine with soap is most happy and rational, as soap, which has long been used in suppository, is a vehicle which does not interfere with the action of glycerine, but aids it.—*Prager medicin. Wochenschr.*, September 19, 1888.

Hypodermatic Treatment of Syphilis.—VOLLERT, of Strasburg, brings forward the succinimide of mercury, given subcutaneously, as of much value in syphilis. It appears to have several advantages over mercury glycocoll, its solution being much more stable, and the injection being less painful, and causing a smaller amount of infiltration at the seat of puncture, besides which its cost is decidedly less. When properly applied, the injection rarely, if ever, sets up suppuration. According to Prof. Wolff, the best way of operating is to run the needle into the middle of the subcutaneous fat of the buttock, not perpendicularly to the surface, but parallel to it, then to inject the liquid very slowly, gently stroking the swelling formed, so as to distribute and disperse the liquid over a somewhat extensive area. The daily injections are made alternately into the right and left buttocks. The strength of the solution recommended by the author is 2 per cent., corresponding to about 1 per cent. of mercury, so that each Pravaz syringeful contains 0.01 gramme of mercury. The average number of injections given to each patient is about nineteen; in severe cases, however, thirty or thirty-five injections are required. Dr. Vollert has not as yet been able to make any observations on the excretion of mercury by the organism after the treatment;

but, speaking from the point of view of clinical experience, after having given 523 injections to twenty-eight patients, he considers mercury succinimide bids fair to prove a very valuable drug for subcutaneous injection in case of syphilitic disease.—*Lancet*, October 13, 1888.

Chemical Reactions of the Cholera Bacillus.—In 1886, Poehl first noticed that cholera bacilli produced a reaction with the mineral acids, which he designated "cholera red." In 1887, Bujwid independently published a similar observation in the *Zeitschrift für Hygiene*. Since then the latter has given the subject a good deal of attention, as at times it may be important for the physician in a given case not to have to make cultures of the bacilli from stools suspected to be choleraic, but to be able to recognize the bacillus by some chemical reaction which can be readily performed. Jadassohn (*Breslauer ärztliche Zeitschrift*), from his investigations, was unable to indicate which particular acid furnished a characteristic reaction with the cholera bacillus, as other microörganisms behaved similarly under like conditions. After careful studies, Bujwid describes a reaction for the cholera bacillus which he considers characteristic. To a two per cent. sterilized solution of peptone a half per cent. of common salt and bicarbonate of sodium is added to produce an alkaline reaction. This solution is contaminated with the bacillus and placed in the thermostat for twenty-four hours. If to the mass is now added hydrochloric, phosphoric, sulphuric, or oxalic acid a beautiful violet-red color results, prettiest with hydrochloric acid. Several other bacilli (Finkler's, Denecke's, Miller's) give the same reaction, but only after a longer time and in a less pronounced degree. Salkowski believes that the reaction is produced by the indol formed by the bacilli.—*Wiener medizin. Presse*, No. 40, 1888.

Emmenagogue Powder.—

℞.—Powdered absinthe . . gr. xxxviij.
Powdered yarrow . . gr. xxxviij.
Powdered saffron . . gr. xix.—M.

Divide in pulveres No. V.

Sig.—One powder each day, for five days preceding the expected menstrual period.

The Treatment of Lichen Ruber Planus.—Herxheimer (*Berl. klin. Wochenschr.*, No. 37) recommends applications, with a brush, of ten per cent. solutions of chrysarobin-traumaticin, twice weekly, until the eruption has disappeared.—*München. medicin. Wochenschr.*, September 25, 1888.

Terebene in Bronchorrhœa.—Martin has obtained in bronchorrhœa excellent results from terebene. He mentions one particularly aggravated case of long standing, in which it was given in a mixture containing ♏x of gum terebene, ♏x of spirits of chloroform, ʒj of mucilage of tragacanth, ʒss of syrup, water to ʒj. This proved most palatable to the patient. Four doses and sometimes five, were given in the course of twenty-four hours. The effect upon the bronchial secretion was immediate, and steadily maintained. The heart also seemed to respond to the stimulant nature of the drug, and its effect upon the atonic and flatulent condition of the bowels and stomach was remarkable. The tongue cleaned, the appetite increased, digestion became comfortable, with consequent increase in general strength. No nerve symptoms were noticed, as was the case when brandy or whiskey was given. From the day the terebene was ordered there was a steady improvement of a most marked character. —*Medical Press*, Aug. 29, 1888.

For Cough.—In certain cases of cough in which the paroxysms are frequent and expectoration difficult, the hydrochlorate of apomorphine is highly spoken of by Stocquart. Very minute doses are generally sufficient, only three or four milligrammes being given during the whole day. It is generally accepted, and cases of intolerance are very rare. When they do occur, they consist chiefly of colicky pains, nausea, and diarrhœa. As the solution of hydrochlorate of apomorphine is an unstable compound, he advises the addition of a few drops of chlorhydric acid, which will insure its preservation and not affect its therapeutical value.—*Journal de Médecine*, September, 1888.

The Constant Current in Epilepsy.—Dr. Niemeyer has obtained some successful results in epilepsy, by combining the employment of the constant current to the brain in combination with the internal use of small doses of bromide of potassium. The anode was moved about over the forehead, the cathode being held in the hand; or the anode was fixed on the nape of the neck, while the cathode was moved over the forehead, or applied immovably over the gyri centrales of both sides. The treatment was carried out for ten months, the result being that one patient had no attack for two years and three months; another, who had previously had an attack about every month, had, after treatment, only two fits in twenty-five months; and a third patient, who had been in the habit of having three or four fits a day, remained free for seven weeks.—*Lancet*, October 13, 1888.

Antiseptic Sponges for Gynecological Operations.—The sponges are kept in the following solution for twenty-four hours:

℞.—Hydrarg. chlorid. corrosiv. . 1 part.
Acid. carbolic. . . . 5 parts.
Alcohol. . . . . 60 "
Aquæ bull. . . . . 500 " —M.

The fluid is then expressed and the sponges dried in the air. After they have been thus disinfected, the sponges may be impregnated with one of the following solutions:

℞.—Acid. boric. . . . . 15 parts.
Aquæ bull. . . . . 500 " —M.

Or

℞.—Acid. tannic. . . . . 30 parts.
Aquæ bull. . . . . 500 " —M.

Or

℞.—Liq. ferri chlorid. . . . 40 parts.
Aquæ bull. . . . . 500 " —M.

—*Medicin. Chirurg. Rundschau*, Oct. 1; from *Wiener med. Wochenschr.*, No. 32, 1888 (*Journ. de Méd.*, July 29, 1888).

Treatment of Intra-cranial Abscess. — CHAUVEL advises early operation, since by the use of antiseptics the dangers are trifling. The symptoms, at best, are exceedingly obscure, but if one has reason to suspect suppuration no time should be lost. The most common seat is in the temporo-sphenoidal lobe, and if treatment directed to the ear alone has failed and the cerebral symptoms are alarming, trephine the mastoid and wait a few days. If no amelioration occurs, the cavity of the cranium is to be opened. The landmarks of the operation are as follows: A horizontal line drawn backward from the external canthus, crossed by two vertical lines drawn one in front and one behind the pinna. The point for opening is to be selected on the horizontal line, midway between the two perpendicular lines. One comes here directly on the squamous portion of the temporal bone, and the only large vessel to avoid is the middle meningeal artery. The abscess is then evacuated and antiseptic rules strictly observed.—*L'Union Médicale*, October 11, 1888.

Tobacco and Bacteria.—The popular belief in the germicidal virtues of tobacco-smoke (which we note as being revived in connection with the alleged immunity enjoyed by the cigar-makers of Florida during the recent yellow fever epidemic) has received some confirmation in the scientific researches of Dr. Vincenzo Tassinari, first assistant of the Hygienic Institute of Pisa University.

In a preliminary note on his experiments (*Centralblatt f. Bakteriologie*, Bd. iv., No. 15), he describes the simple apparatus he designed to test the effect on pathogenic organisms of exposure to the fumes of tobacco. The apparatus consists in a chamber formed by two glass funnels placed horizontally, and connected together at their mouths by paraffin. In this chamber is suspended from a loop of platinum a small piece of linen, with the threads of its lower extremity immersed in a culture-fluid containing the microbes. The chamber is connected at one end by a tube with a cigar or cigarette, and at the other, by a tube containing a plug of cotton-wool (to serve as a filter) with the mouth of the experimenter. The smoke as it is exhaled, therefore, thoroughly surrounds the linen soaked in the culture-fluid, and, after the experiment, which lasts from thirty to thirty-five minutes, involving the consumption of from three and a half to four and a half grammes of tobacco, the chamber is opened, and the linen allowed to fall into a test-tube containing fluid gelatine. Control experiments were also, of course, made.

The microörganisms subjected to this treatment included: 1. Spirillum choleræ Asiaticæ. 2. Spirillum Finkler-Prior. 3. Bacillus anthracis. 4. Bacillus typhoabdominalis. 5. Bacillus pneumoniæ (Friedländer). 6. Staphylococcus pyogenes aureus. 7. Bacillus prodigiosus. The result varied with the variety of tobacco and the kind of microbe, but in every instance there was marked (sometimes very great) delay in the development of colonies in the gelatine as compared with that of organisms dealt with similarly, but without exposure to tobacco-smoke. Indeed, the development of some was entirely prevented. For example, in the third series of experiments cited, in which large Virginia cigars were used, the development of bacillus prodigiosus was delayed for seventy-two hours, that of staphylococcus pyogenes aureus for seventy-three hours, of bacillus anthracis for ninety-seven hours; whilst of the others, mentioned above, no development of colonies took place after from a hundred and twenty-eight to a hundred and sixty-eight hours.

Dr. Tassinari attributes these results to the chemical action of the ingredients of tobacco-smoke. He proposes to extend his researches more fully, both as regards the effect of different kinds of tobacco upon these and other microörganisms, especially the tubercle bacillus, and to determine the time of exposure, as well as the amount of tobacco necessary to produce the full effect. He hopes also to ascertain what substance or substances are responsible for the germicidal action.—*Lancet*, October 13, 1888.

Treatment of Diphtheria.—The three rules to be followed for the successful treatment of diphtheria are, according to RENOU:

To saturate the inspired air with antiseptics.

To feed and tone the patient to the greatest possible degree.

Never to touch the throat with any medicament, and to give internally only alcohol and quinine.

The facility with which this treatment may be applied, especially in the case of children, the certainty and rapidity of absorption, are elements which recommend a thorough trial.—*Bulletin Général de Thèrapeutique*, October 15, 1888.

The Use of Creolin in Ophthalmic Practice.—GRUNHUT (*Prager medicin. Wochenschr.*, September 26, 1888), using creolin for a period of four months, did not observe the good results which have been claimed for its employment in ophthalmic practice. He used an emulsion of one per cent. and a vaseline ointment of one per cent. The remedy has the disadvantage of causing a burning sensation, lasting generally but a few minutes, though in some cases longer, associated with such severe pain and protracted irritation as, in some cases, to necessitate a liberal use of cocaine. The cheapness of creolin is thus offset by the high price of cocaine. The emulsion must be used fresh, as in the course of a few days the creolin separates as oily particles and the activity of the preparation is impaired. It is conceded that creolin possesses antiseptic properties and diminishes secretion in catarrhal affections of the conjunctiva, in trachoma and dacryocystitis. In the form of an ointment, rubbed once or twice a day on the lids, creolin exerts a useful influence in various forms of blepharitis, especially in the secretory and excoriative forms, though it cannot be said that it possesses any advantage over the ointment of the yellow oxide of mercury. In simple catarrh, even with swelling, better and speedier results may be had from nitrate of silver. Creolin would only be preferred when it was desired to substitute another remedy for silver nitrate. The excellent results claimed by Purtscher and Grossmann in the papillary form of trachoma were not confirmed; nor could more be said of pannus trachomatosus. In cases of keratitis threatening iritis, creolin was not well borne, on account of its irritating influence. Creolin thus plays but a minor *rôle* in ocular therapeutics. Its opacity renders it unavailable for operations upon the eye.

CALOMEL IN PHTHISIS.

THE observation is somewhat trite that in therapeutics empirical measures of recognized value are, with widening knowledge, often found to have a scientific basis. The present generation of physicians has as little personal knowledge of the indiscriminate use of calomel as of indiscriminate bleeding, and it is fortunate that this is so. This generation, however, knows that there are occasions in which prompt and free phlebotomy means the saving of a life, and, therefore, still carries the thumb lancet in its pocket-case. Not less does the doctor of to-day recognize in calomel, rightly used, an important remedy in certain of the acute infectious diseases. At the same time, its dangers and its uselessness, as once employed, are too well known to permit of anything like a revival of the old methods of prescribing it.

The use of calomel in pulmonary phthisis was common in the early part of the present century. Many authors regarded it as almost a specific remedy in this affection. Among these may be named Delafield (1818), Dessault (1809), Mecker (1822), Chricton (1823), Clark (1836), and others. Trousseau considered calomel useful in laryngeal phthisis where there was no underlying syphilitic cachexia, and where other remedies had failed. Broussais, Andral, and others advised the use of quicksilver in certain forms and at various periods of consumption. Hufeland considered quicksilver as much of a specific in scrofulosis as in syphilis.

For a half century the use of mercurials in phthisis seems to have been forgotten. Recently, however, the attention of the profession has been very generally drawn to the anti-parasitic action of the preparations of mercury in the treatment of bacillary phthisis. Auber and Gougenheim (1886) injected corrosive sublimate into lung cavities: Lepine used the same treatment in croupous pneumonia: Barthal and Moritz used mercurial inunctions in pneumonia; Kubassof employed this treatment in the management of consumption as first advised by Plasse. Plasse's work is especially noteworthy as resting, to a certain extent, upon experimental research. He found upon inoculating rabbits with tuberculous matter, that those animals previously treated by mercurial inunctions developed very few tubercles, or escaped altogether. The favorable influence of small doses of calomel upon certain forms of anæmia is well known. Cases are occasionally observed in which the prolonged administration of iron having failed, rapid improvement takes place under a treatment of calomel, with improvement of appetite, relief of habitual constipation, and restoration of the menstrual function. Especially is this method of treatment useful in the anæmia of syphilis, as pointed out by Keyes, and in the anæmia of "scrofulosis" and pulmonary consumption.

Quite recently MARTELL (*Prag. med. Wochenschr.*, No. 25, 1888), and DOCHMANN (*Therapeut. Monatsh.*, September, 1888), have published communications on the important subject of the calomel treatment of tuberculosis. J. C. WILSON, at about the same time, reported some clinical studies in the treatment of enteric fever and pulmonary phthisis by hypodermatic injections of calomel at the recent meeting of the Association of American Physicians in Washington (THE MEDICAL NEWS, October 13, 1888).

That calomel administered by the mouth or hypodermatically exerts a favorable influence in certain cases of tuberculous disease, there is no room to doubt. Whether it exerts a specific action upon the local pulmonary lesions, or upon the growth and development of the tubercle bacilli, cannot at present be asserted. With the exception of Wilson, those observers who have published their investigations into this method of treatment since its recent revival, incline to the view that the favorable in-

fluence of calomel is due to the direct germicide action of the mercurial salts. Dr. Wilson regards it as probable that the mercurial salts, even in small amounts, act upon the tissues rather than upon the germs themselves, and suggests that this action is preventive, tending to retard or prevent the splitting up of the complex chemical compounds of the tissues and the production of ptomaines, and that this increased resistance on the part of the tissues, by opposing processes necessary to the growth and multiplication of pathogenic microörganisms, stands in the way of their continuous development. Whether the mercurial salts, administered by the mouth or hypodermatically, enter the circulation in the form of an albuminate of mercury, or in the form of a double chloride of mercury and sodium, has not yet been established. Torsellini (1886) has shown that pepsin in the presence of small amounts of hydrochloric acid greatly increases the solubility of calomel, without converting it into mercuric chloride, and concludes that the solution is the result of a ferment action of pepsin upon the calomel.

THE TREATMENT OF FATTY HEART.

Dr. Forchheimer's paper on "Fatty Heart," and the discussion to which it gave rise, at the recent meeting of the Association of American Physicians, at Washington (The Medical News, October 6, 1888), brought into strong prominence the importance of the clinical distinction between fatty infiltrations of the heart and fatty degenerations of that organ. The pathological distinction is, as a rule, clear enough. The one is a fat overgrowth in the sub-pericardial connective tissue, in the grooves and furrows of the surface of the heart, and in the fibrous septa of the myocardium. When such overgrowth of fat becomes excessive, its presence interferes with the contraction of muscular fibres, and, consequently, with the nutrition of the heart, the force of which becomes impaired by atrophy of some groups of fibres, and secondary fatty degeneration of others.

Fatty infiltration is due to the causes which produce general obesity, and is associated with that condition. Dr. Forchheimer's expression, "obesity of the heart," well describes it.

On the other hand, fatty degeneration of the heart is a disease of the myocardium. The albuminoid constituents of the muscular fibre are split up, and microscopical particles of fat are deposited in their place. This condition may be caused by any of the numberless agencies, both constitutional and local, which seriously derange the nutrition of muscular tissue, and is only exceptionally associated, as, for example, in chlorosis, with general obesity. Where fatty degeneration is due to local disturbances of blood supply, as in obliterating endarteritis of a branch of the coronary arteries, the fatty change is usually of limited distribution, and since the unaffected parts of the wall of the cavity retain their normal contractile power, there is danger of the softened spot of degenerated tissue yielding upon stress, and rupture taking place—an accident which is, in point of fact, far from rare.

While the pathological pictures of these two conditions merely touch at their borders, or at most only slightly overlap; their clinical pictures, which alike represent cardiac inadequacy without positive physical signs, are superimposed. The differential diagnosis must, therefore, rest upon the constitutional rather than the cardiac morbid phenomena. The presence of general obesity—and the recognition of the conditions of life favoring fat accumulation will, in the absence of the evidences of the constitutional or local causes of derangement of nutrition, often justify the diagnosis of fatty infiltration; the reverse, that of fatty degeneration.

The diagnosis is, at present, of the highest importance in view of the growing interest and widening use of the dietetic-mechanical method of treating chronic diseases of the heart devised by Oertel, of Munich. While it may be admitted that certain cases of fatty degeneration, such as result from anæmia, chlorosis, or the acute infectious diseases, may be cautiously subjected to this treatment, and that some of them are likely to receive permanent benefit from it; it is obvious that a large majority of such cases, and especially those occurring in the degenerative period of life, are not only unlikely to be benefited by it, save in the most general way, but are also liable to disastrous consequences. On the other hand, the method of Oertel, which is essentially his method of treating obesity, is the method of choice in fatty infiltration. Whatever may be the result of experience in its use in other forms of heart disease; whatever the outcome of the assaults now being made upon it on both sides of the Rhine, we may confidently predict that the combination of a guarded restriction of fluids, a diminished dietary, from which fats and excess of carbo-hydrates are excluded, and carefully regulated and graduated hill-climbing under well-thought-out rules, to which

the name of the famed professor of Munich has been given, will constitute a permanent acquisition to our treatment of obesity of the heart as of the obesity of the body of which it is a part. The difficulties of diagnosis will always demand extreme caution in advising the use of this method in doubtful cases.

THE TREATMENT OF PELVIC ABSCESS IN WOMEN.

Among the topics of practical interest discussed at the Congress of American Physicians, the treatment of pelvic abscess in women elicited information of value not only to the obstetrician and gynecologist, but to the general practitioner.

Regarding the etiology of the affection, septic and non-septic causes were recognized. The former commonly arise during parturition, and are a part of puerperal infection; less frequently the gonococcus originates the septic process. The latter are the secondary causes of inflammation of the female genitalia, exposure to cold, and derangement of menstruation. The original focus of inflammation is very commonly the epithelial tissue of the endometrium and tubes, less frequently, the connective tissue of the pelvis. The determination of the time when suppuration occurs is difficult; persistence of the phenomena generally recognized as denoting pus formation for several weeks justifies an operative exploration. The extension of the process may involve the septa and connective tissue of the pelvis very extensively, and spontaneous evacuation may follow, in the direction of least resistance.

Regarding treatment, palliation is rarely successful, except in cases of non-septic origin. The destruction of the focus of infection should be attempted as early as possible, before pelvic tissues are generally involved. In the absence of a fluctuating tumor accessible per vaginam, laparotomy is indicated. Should the abscess be found in a tube, extirpation should be done. If an ill-defined abscess is found, it should be drained with gravity, per vaginam, a tube being generally passed into Douglas's cul-de-sac. Extirpation of the sac of an ill-defined abscess is rarely possible, but is effected by natural processes when drainage is established. If vaginal examination discloses a fluctuating tumor, it should be opened, preferably by uterine dressing-forceps whose tips are sharpened, or by a director. A flexible rubber drain, and antiseptic irrigation will complete the cure.

Piercing the pelvic tissues with an aspirator needle is injurious, and inefficient for diagnosis; aseptic laparotomy is more certain, and safer.

In cases recognized promptly, and treated efficiently, the prognosis is good, not only for recovery, but as regards the reproductive functions of the patient. Should an abscess be diagnosticated, after laparotomy, in the extra-peritoneal tissues, it may be evacuated advantageously by incision parallel to Poupart's ligament.

The American Public Health Association will convene at Milwaukee, Wisconsin, Tuesday, November 20, at 10 o'clock A. M., and continue four days. The meetings will be held in the Atheneum Hall.

The following topics have been selected for consideration:

1. The pollution of water-supplies. 2. The disposal of refuse matter of cities. 3. Animal diseases dangerous to man. 4. Maritime quarantine, and regulations for the control of contagious and infectious diseases, and their mutual relations.

Precedence will be given papers upon the above subjects, although other papers of a sanitary nature will be received by the committee. The topics given indicate the subjects which it is desired to consider, yet they are not to be regarded as the exclusive topics of the meeting. Papers of ability and practical application upon any subject connected with the public health interests will be received.

The possibility of the importation of yellow fever from South America is illustrated by a recent case at Brooklyn. The captain of a steamer from Para died last week of the fever at St. John's Hospital in that city. It would appear that the captain was the only person who went ashore at Para, and he sickened as he drew near to the harbor of New York. He alone was on the sick-list while passing through quarantine. He was so feeble that he could not stand erect while the customary examination by the port-official was in progress; he sat in his chair while talking with that officer. After his death, the steamer was ordered back to quarantine, and the crew, which had been discharged and dispersed, were found and returned to the same place for observation. The opinion of the medical attendants of the case, confirmed by an autopsy, is that it was a clear case of *vomito*. The health officer of the port has expressed doubt as to the correctness of the diagnosis of the fever in this captain's case, stating that there is no evidence that yellow fever has existed at Para.

We are in receipt of the English edition of Sir Morell Mackenzie's account of "The Fatal Illness of Frederick the Noble." It is a duodecimo volume of 246 pages, and is illustrated by drawings showing, among other things, the appearance of the vocal cords before and after operation, the different canulæ used, with their position *in situ*, and von Bergmann's alleged "false passage" and the resulting abscess. In his preface Sir Morell complains, with reason, that he has been refused access to the documents deposited in the State Archives bearing on the late Emperor's case, which had been granted the German physicians, and which include "the written refusal of the Emperor (then Crown Prince) to submit to any other external operation than tracheotomy."

Mr. Edgar S. Werner, of New York, announces a reprint of Mackenzie's work, together with an English translation of the official report of the German physicians.

SOCIETY PROCEEDINGS.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, September 12, 1888.

The President, J. Solis-Cohen, M.D., in the Chair.

Dr. J. Solis-Cohen read a paper on

SYPHILIS OF THE LARYNX, TRACHEA, AND BRONCHI.

Syphilitic processes are among the most important morbid processes affecting the larynx and trachea. Not only do they injure the structural integrity of the organs directly; but, by their location in the regions occupied by the origin and course of nerve supply, they lead to denutrition of the tissues generally, and to serious motor impairments of the muscles of the larynx. So varied are the manifestations of syphilis, and so important to the welfare of the patient their timely recognition, that considerable detail is proper in their elucidation. In hardly any other department of living pathology has the laryngoscope been of more signal service than in dispelling obscurities in the conception and comprehension of syphilitic disease of the larynx.

The distinctions between secondary and tertiary syphilis, as manifested in the upper air-passages, are so irregular and uncertain, that many writers prefer the terms recent and tardy. In fact, however, secondary lesions are sometimes tardy and tertiary lesions sometimes precocious. Secondary lesions are sometimes present as the sole manifestation of that period. Sometimes they precede cutaneous manifestations. Most frequently they occur in subjects already affected with what are known as mucous patches in other portions of mucous membrane, or with early cutaneous syphilides.

Pathology.—The earliest and far most frequent manifestations are subacute and diffusely hyperæmic conditions of portions of the mucous membrane, of varied extent and intensity; an erythema with turgescence, but without hypersecretion, occurring within from six to ten weeks after infection. The affected surface exhibits at first the usual rose-color of congestion, but, as stases, infiltrations, and hæmic transudations occur, it becomes more or less livid in patches which present mottled or flaky discolorations. Superficial erosions often ensue. Occasionally, deep-seated ulceration occurs. Sometimes paresis of the muscles of the larynx is produced. The erosions may be due simply to denutrition of epithelium from mere pressure by infiltrations; or to disintegration of a characteristic proliferative lesion known as the papule or mucous patch, by some termed broad condyloma, a product, according to Virchow, of the same histological character as the indurated chancre and the various gummous formations, namely, an infiltration of tissue with nucleated embryonic cells. These papules are characteristic, but by no means frequent syphilitic products in the larynx; and are so infrequent in the trachea that their occurrence there is denied by authorities the very highest. They are multiple recurrent lesions, almost invariably associated with mucous patches on other mucous membranes; usually lasting from three to five weeks, and sometimes much longer. They are observed from within a few weeks to a few months after infection; sometimes earlier, occasionally as late as eighteen months. They are far the more frequent in tuberculous subjects who have contracted syphilis.

The opinion is held by some that superficial ulceration is always due to their disintegration; and that they must have existed in many cases in which they have not been observed. Histologically they are composed of small-celled infiltrations into the corium and into dilated hypertrophied papillæ. Hence they occur in localities where papillæ exist. Consequently they cannot occur below the vocal bands. They are quite red when recent, but soon change to light gray as the epithelium thickens; they then appear as small, wrinkled, opalescent, flattish, ovoidal elevations, varying in size from pin-heads to small peas; depressed in the centre when mature, and when recent circumscribed with a peripheric inflammatory areola. They may subside without trace. When erosion takes place, the surface becomes punctatedly red from exposure of the papillæ. They may undergo destructive ulceration. They may become the starting-points of small pointed vegetations, histologically identical with papillomata. These are probably non-specific in character, though due to irritation excited by specific processes. They do not undergo ulceration, and rarely undergo absorption under specific medication. When forcibly removed, they repullulate quickly. Similar vegetations sometimes project from the edges of ulcerated patches of tissue. Though usually small, sessile, and multiple, they may acquire such bulk as to interfere seriously with respiration.

The erosions which occur on the surface of the papules or upon simply erythematous mucous membrane are usually superficial, but may extend through the mucous membrane and beneath it, under bad hygienic conditions. Under slight provocative exposures to cold and wet, fluxionary œdema sometimes takes place in their vicinity, occasionally to such an extent as to be menacing to life. The epiglottis often becomes very much thickened; the vocal bands thickened and dentatedly eroded. There seems to be no tendency for secondary lesions to extend from the larynx to the trachea.

Tertiary lesions come under notice most frequently in the stage of ulceration, usually following the liquefaction of gummous nodules, gummous infiltrations, or true gummata, as may be. The epiglottis is the most frequent seat; so frequent, that its lingual and lateral ulceration has been erroneously deemed pathognomonic of syphilis; but destructive lesions may occur in every portion of the larynx. The ulceration is both serpiginous and deep-seated, and while more commonly unilateral, there seems practically to be little limit to its phagedenic destructive ravages under unfavorable conditions, as it destroys and penetrates all the tissues, soft and cartilaginous. Slight provocation may produce fluxionary œdema in this stage also, which may be of the most serious character. Serious hemorrhages may occur from penetration of bloodvessels; and apnœa may ensue from incarceration of fragments of necrosed cartilages and soft tissues. Ulceration may be attended with proliferative vegetations which may occlude the air-passages. Superficial ulceration may heal with moderate cicatrization which eventually becomes hardly noticeable. Deep and extensive ulcerations heal under peculiar whitish, lustrous, stellate, retractile cicatrices, similar to those which follow burns. Instead of cicatrization, adhesions may take place between contiguous raw surfaces, and strictures of various kinds be formed in consequence.

The gummous lesions preceding these ulcerations are of three kinds: small gummous multiple nodules or nodular syphilides; diffuse gummous infiltration; and gummata proper, usually isolated.

Small gummous nodules (nodular syphilide, Lewin) vary in size from that of small bird-shot to that of peas, and are usually grouped in well-defined determinate figures in the body of the mucous membrane, and often so contiguous as to appear confluent. Gummata proper present as firm hemispherical nodules or tumors, from the size of peas to that of cherries or almonds, and sometimes much larger, in the connective tissue beneath the mucous membrane; usually uniform in outline, sometimes lobulated; undiscolored or reddish at the base and yellowish at the summit. Gummous infiltrations present as more or less longitudinal or more diffuse submucous thickenings corrugating the surface of the mucous membrane. All these products may undergo absorption.

When not absorbed, gummous nodules undergo purulent liquefaction. At this time they become softer, and more yellowish at the summit, the mucous membrane at the base becoming more inflamed and thickened, the whole mass looking not unlike a furuncle. The summit becomes perforated, and gives exit to thickened, yellow pus, with granular admixture of débris at first. The orifice rapidly enlarges by ulceration until it becomes fully as large in circumference as the nodule was, or larger; and readily coalesces with ulcerations from contiguous nodules. The ulceration extends in depth until it occupies the entire volume of the nodules, and then may penetrate all the tissues beneath, even to the perichondrium and cartilage.

The ulceration of the nodulous syphilide, as studied in a series of cases by Lewin, is said to take place more from periphery to centre than the reverse, being shallow at first, and then gradually deepening. The ulcer is round, depressed, and sharply bordered. Its bed is covered with a secretion which, from previous fatty degeneration, or purulent metamorphosis, is either thickish, or nearly lardaceous, or composed of purulent detritus.

The more longitudinal and diffuse gummous infiltrations undergo liquefactive ulceration much more slowly; but the subsequent ulceration, when unchecked, extends much more rapidly, and becomes more readily serpiginous and phagedenic; so that, coalescing with similar conditions in the vicinity, large surfaces in continuity become involved in its ravages. As it extends in superficies it penetrates slowly in depth until it also involves the deeper structures close to the perichondrium, and sometimes to the cartilage. Ulceration varies in rapidity, extent, and penetration according to the succulence or resistance of the tissues contiguous. The ulceration from diffuse gummous infiltration is preceded, according to Lewin, by extensive fatty degeneration of its surface, which gives it an almost grayish-white tinge. This is soon followed by actual defects which, at first shallow, increase in depth, and gradually penetrate to the perichondrium and the cartilage. These ulcers are characterized, like those from the nodules, by sharp definite circumscription, and by their being surrounded with an inflammatory swollen zone. They appear often as though a piece of swollen tissue had been cut out. The edges are often beset with slight crenations, which give them a gnawed appearance, but are never undermined; and their bottom is covered with a yellowish-white adherent mass, composed of pus, fatty detritus, and shreds of tissue. Gummata proper sometimes remain unchanged for prolonged periods. When they undergo degenerative metamorphosis there is formed, according to Lewin, only the characteristic viscid fluid, suppuration being exceptional. Ulceration takes place, however, in some instances, and penetrates deeply into the tissues beneath, as in the other two forms. Under unfavorable hygienic conditions of system, or of surroundings, the phagedenic ravages may become uncontrollable. They have been known to attack an artificial opening made to prevent suffocation by a gumma (Holden, *New York Medical Journal*, January 29, 1887).

Perichondritis and chondritis being set up after either form, the ulceration may penetrate the cartilage to the tissues external, forming a perichondrial abscess, which ruptures externally by a more or less circuitous route, whence the fragments of dead tissues are discharged.

Taken in point of frequency, the cartilaginous structures seem to be vulnerable in the order following: epiglottis, posterior vocal processes, arytenoids, supra-arytenoids, cricoid, cuneiform, and thyroid. Coming to the softer parts, the vocal bands are attacked next in frequency to the epiglottis, the left band far more frequently than the right, the interior supraglottic walls of the larynx, the aryepiglottic folds, the interarytenoid fold, the posterior wall, the ventricular bands, the subglottic walls of the larynx, the exterior of the soft parts in the pyriform sinus. When the cartilages are attacked, whether primitively or consecutively, the chain of morbid phenomena is perichondritis, chondritis, calcification, caries, necrosis, and elimination of sequestra in crumbled masses and in fragments. The elimination of dead cartilages may consume months, and even years. It usually takes place by the interior route, occasionally by the exterior. In both instances abscess and fistula are formed, and elimination of large fragments by the

interior route sometimes produces suffocative paroxysms, and occasionally actual suffocation.

The epiglottis, as repeatedly noted, is especially vulnerable to the syphilitic process, and every variety of lesion possible may ensue in any extent, from insignificant erosion to complete destruction, the character of the lesion depending upon that of the structure destroyed. It is this, as pointed out by Seiler, which gives such an irregular conformation to the epiglottis when its glands have been destroyed.

Exulceration of the entire mucous membrane at the edge reveals the exposed cartilaginous structure as a yellowish-white stripe embedded between two thickened masses of spongy-looking tissue. Ulceration of the cartilage often commences at the anterior surface in the form of a round ulcer with thickened excavated edges. Destructive ulceration usually progresses from the side and from the edge. When the valve is only partially destroyed, its remains may present two or more irregular fragments separated by fissures of varying depth, or a single fragment of any breadth, from a small stripe to nearly the entire bulk.

When totally destroyed the orifice of the larynx is separated from the post-lingual sulcus by a more or less irregular ridge of ulcerated tissue, which, after cicatrization, presents as a pale, deformed stump. This, however, does not, as rule, prevent glutition, and in some instances does not even interfere with it; the occlusion of the larynx being effected by the base of the tongue, on the one hand, and by close approximation of the ventricular bands and sphincter-like approximation of the aryepiglottic folds, on the other.

The other cartilages, when the subject of destructive progressive ulceration, are macerated out of their investments, as it were. The ulcerative process extends into the cartilage surrounding it, if a small one, or circumscribing a portion of it, if it be a large one. The cartilage then perishes by necrosis, is laid bare, and becomes detached from its connections, in some instances remaining entangled in a sort of pocket scooped out of the soft tissues, The necrosed cartilage finally breaks through to the interior, and is usually discharged by expectoration. If it be situated below the glottis, paroxysms of suffocation may ensue, or even actual apnœa, as from any other foreign body. Exfoliations of the cricoid cartilage are the most frequent source of these untoward results, which, however, sometimes ensue from exfoliations of the thyroid.

The ulcerative process sometimes penetrates blood-vessels and hemorrhage follows. Such hemorrhage has been known to terminate fatally (Turck, *op. cit.*, p. 413, illustrated).

The vocal bands frequently sustain permanent lesion varying from minute losses of substance to entire destruction. Transversal dentated erosion of the border is not uncommon, and detachment from the posterior vocal processes not infrequent. Sometimes abundant irregular papillary proliferations take place, forming mobile, projecting, pyramidal, or irregular dendritic vegetations, which project like soft, mobile stalactites into the interior, and which are large enough, in exceptional instances, to demand operative interference. Similar conditions and productions may prevail with the ventricular bands. Superficial ulcerations may heal with moderate cicatrization, which eventually becomes hardly noticeable. In deep and extensive ulcerations, when cicatrization occurs, a peculiar lustrous, whitish, stellate, contractile cicatrix is formed, similar to the syphilitic cicatrix in other mucous membranes. Instead of cicatrization, adhesions often take place between ulcerated surfaces, and thus a variety of injurious morbid conditions occur. The vocal bands may become united by a broad fibrinous band stretching between them, or by a similar obturator formed of their thickened and distended mucous membrane. The membranous web thus formed between the vocal bands usually unites them for a variable distance, commencing at the commissure, the posterior border of the structure being crescentic in outline. Exceptionally the cords may become involved their entire length, with an orifice in the central portion of the web (Navratil).

This membranous union has been known to take place in six days (Rossbach: Langenbeck's *Archives*, vol. xiv.). In a case watched by Sommerbrodt (*Berlin. klin. Woch.*, April 1, 1878), the anterior third united in fourteen days, and the union of the bands was complete in six weeks. In other cases the vocal bands become united without any membrane intervention.

Other adhesions sometimes take place, which may seriously impair glutition, phonation, and even respiration. These comprise depression of the epiglottis to one side or the other, or to an aryepiglottic fold, and preventing proper closure of the valve or complete elevation; adhesion of the epiglottis to either lateral pharyngeal wall; adhesion of ventricular to vocal bands, sometimes preventing closure of the glottis, and often producing a shrill, weak, piping voice; adhesions anteriorly of the two vocal bands or of the two ventricular bands; adhesions of the inner surfaces of the mucous membrane of the arytenoid cartilages, so as to fix the vocal bands immovably in the median position. Other results of syphilitic laryngitis are hypertrophies, diffuse and discrete, of mucous membrane, connective tissues, or muscular substance, and consequent stricture, varying in extent, locality, and interference with function; myopathic paralysis; muscular atrophy, and the development of morbid growths.

Perichondritis or chondritis, whether following ulcerative destruction of the soft tissues or preceding it, usually excites considerable fibrinous infiltration into the adjacent submucous connective tissue, producing a chronic fibrinous œdema. When extensive, this produces suffocative symptoms, and may threaten asphyxia. Sometimes the submucous infiltrations become organized and transformed into dense fibrous tissues incapable of undergoing absorption, and thus they produce deformity, occlusion of the larynx, and stricture. The strictures are often incapable of yielding to systematic dilatation, even when instituted early; and hence tracheotomy is usually necessary to provide artificial means for respiration below the seat of obstruction. After tracheotomy, the process may progress to complete obliteration.

These strictures are of the most varying form and calibre, some of them distorting the configuration of the interior of the larynx almost out of recognition. Fortunately, most of them occur in the supraglottic region, where they are far more accessible to effective treatment.

Lesions of either soft tissues or cartilage in the neighborhood of the important crico-arytenoid articulations excite non-specific inflammation of the joint which may

produce true or false ankylosis. Syphilis is probably the most frequent cause of this lesion. When the specific process invades the joint, the ligaments and perichondrium suffer, and true ankylosis, or luxation, or disarticulation, and even discharge of the arytenoid and supra-arytenoid cartilages may ensue.

In the latter stage of unrestrained lesion, the cachexia is much the same as in analogous advanced stages of tuberculosis.

Myopathic paralyses of the muscles of the larynx may occur in the later periods of secondary syphilis, and at any period of tertiary syphilis. They are most frequently unilateral, the left side being affected far oftener than the right. The onset is often sudden or acute, following severe or sudden exposure to cold and dampness. The paralysis often affects the dilator muscles, and bilateral paralysis of the dilators is not infrequent. Paralyses of the arytenoid muscle and of the entire constrictor group are the most frequent varieties. These paralyses differ in their pathological origin from other examples of paralysis in syphilis, which are due, respectively, to compression of the tract of the nerve-supply by diseased tracheo-bronchial glands or other structure, and to neural or cerebral lesions which present in the latter stages of the confirmed dyscrasia.

Tertiary lesions of the trachea are first observed so very frequently in the stage of ulceration, that it had been assumed that tertiary syphilis of the trachea always produces ulceration (Vierling). Schech and others have reported instances of resorption of gummata under specific medication. The clinical tendency, however, is to ulceration. Tracheal ulcerative lesions are sometimes unassociated with lesions elsewhere in the aërial tract. Much more commonly they are found associated with similar lesions in the larynx, in the bronchi, or in both.

Pharyngeal syphilis exists in many instances (thirty out of forty-six, collated by Vierling), and pulmonary syphilis in not a few (sixty out of fifty, Schech). They are often found associated with additional syphilitic lesions at a distance. In a large proportion of instances a primitive bronchus is affected, the left one the more frequently; in some, both primitive bronchi; in a few, the smaller ramifications (Vierling); and, exceptionally, even the minutest (Lancereaux). In some instances syphilitic lesion is confined to the bronchi (five cases, by Vierling). The upper portion of the trachea suffers most when the larynx is involved; the lower portion, when the disease is isolated or associated with syphilis of the bronchi. In some instances the middle portion alone suffers (Vigla and Charnal, Berger, Mackenzie, of Baltimore, Semon); exceptionally, the two extremities, with complete conservation of the middle portion (Tessier, cited by Rey).

When not occurring in direct continuity with similar lesion in the larynx, the most frequent seat of ulceration is on the anterior surface of the lower portion of the trachea just above the bifurcation whence it extends upward, or in patches continuously sometimes as far as the cricoid cartilage; sometimes almost completely around the interior in periphery, occasionally completely around. Multiple perichondritis is easily set up and results in abscess, denudation of cartilage, calcification, caries, and necrosis. Portions of dead cartilage are sometimes coughed up in fragments. Sometimes semi-detached portions project into the interior and interfere seriously with respiration and with expectoration. The ulceration usually begins in a number of small ulcers which extend in depth and in periphery, baring the perichondrium, and causing portions of the cartilaginous rings, or entire rings, to undergo denudation, necrosis, and exfoliation. Coalescence with similar ulcerating surfaces, or phagedenic extension, sometimes produces very extensive ravages which may involve nearly the entire circumference of the trachea, and nearly, occasionally quite, its entire length. Flaps of detached membrane sometimes fall over, producing valvular impediments to inspiration, or to expiration, according to the position of the attachments. The cicatrization of annular ulcerations produces stricture often so low down as to be beyond relief even from tracheotomy, the parts not being well adapted to respond to artificial dilatation. The strictures are irregularly ovoidal in shape, sometimes funnel-shaped, and of varying thickness from a few lines to that of several rings.

These cicatrices may reduce the calibre of the trachea so considerably as to prevent respiration. Occlusion to the calibre of a crowquill is not uncommon, and still greater occlusion has been noted in some instances. Annular stricture at the bifurcation may become so great as barely to admit the passage of a delicate probe. (Obtulowicz: *Cent. f. Chir.*, 1879, No. 7.)

Irregular annular dilatation of the trachea is often produced by the pressure of the air current above the stricture and sometimes below it. Even dilatation of the bronchi has been noticed.

Projecting ridges of cicatricial tissue below the point of stricture are sometimes so located as to occlude the inferior orifice of a tracheal canula more or less, a point not sufficiently recognized, for it might be practicable in some instances to push a canula into a position which would allow its inferior extremity to pass the obstruction.

Stricture of the bronchi is rare. It affects the left bronchus more frequently (Verneuil, *et al.*); sometimes the right one (Wilks, *et al.*); occasionally both (Virchow, *et al.*). The connective tissue around the strictured portions usually undergoes permanent sclerotic proliferation. Sometimes there is great peritracheal sclerosis, sometimes none. The peritracheal glands may undergo great enlargement. All these conditions superadded to the internal stricture, may greatly increase stenosis.

Ulceration sometimes penetrates through the trachea producing abscess opening into the œsophagus or the mediastinum, the aorta (Rokitansky: *Path. An.*, Bd. III, p. 22; Wilks: *Trans. Path. Soc.*, London, 1865, p. 52), the pulmonary artery (Kelly: Id., 1872, p. 45), or the vena cava (Turner: Id., xxxvii. p. 117). In at least two instances of ulceration of the left bronchus the left branch of the pulmonary artery has been found perforated (Vierling).

Inflammation around the trachea or bronchi sometimes produces adhesions to the œsophagus or to other tissues, which depresses the trachea and larynx and impairs their upward movements in glutition. Sometimes it produces peritracheal or tracheo-bronchial abscess. Abscess of a bronchus, sometimes deeply seated, has occurred after tracheotomy, apparently as a result of too assiduous swabbing of the canula.

The lesions of hereditary syphilis are almost identical with those of the gummous infiltrations of tertiary syphilis.

They sometimes appear very early. Ulcerations have been noticed in infants at two months of age (Parrot: *Prog. Méd.*, 1878, p. 653). Stricture from perichondritis has been noticed at the same age (Fränkel: *Wien. med. Woch.*, 1868, No. 18; Parrot: loc. cit.).

Symptomatology.—The laryngeal symptoms of secondary syphilis are not characteristic. They are chiefly comprised in dissonant alterations of the voice, either hoarseness, dysphonia, and in some cases occasional or temporary aphonia. The hoarseness is supposed to have some peculiarity which has been termed *raucedo syphilitica*, but this is not the case. In some instances it is simply due to the catarrhal laryngitis, in others to paresis of one or more of the constrictor muscles, or possibly to paralysis of the tensors. Respiration is not affected except in those instances in which œdema occurs in such a position as to occlude the passage for air, when it will be announced by dyspnœa and stridulous respiration, the characteristic symptoms of that condition. Titillation and cough are not as frequent as in inflammations of other origin. In many instances there is no tickling and no cough, no pain and no dysphagia.

Dysphagia is not present unless there be œdema of the parts utilized or pressed upon in glutition.

In tertiary syphilis of the larynx the symptoms are usually those of impairment of phonation, followed in severe cases by dyspnœa and stridor also, chiefly inspiratory. The stridor is worse at night from inaction of the auxiliary muscles of respiration. Should the mechanical impediment to respiration increase, inspiratory depression of the soft parts below the sternum takes place. If relief is not obtained, artificially or otherwise, asphyxia supervenes from imperfect aëration of the blood. Suffocation may occur suddenly from impaction of detached cartilage; but is more frequently slow enough in its approaches to allow time for tracheotomy.

Titillation and cough are more frequent in the earlier stages than in secondary syphilis; but they diminish after ulceration has taken place, except in so far as they are produced from time to time by morbid products detained upon diseased and adjacent surfaces. Pain is infrequent before the period of ulceration; after that it may be severe, and radiate into the ears as in other ulcerative diseases. In the early stage there is no expectoration. The earliest expectoration is of collateral catarrhal products only. As ulceration progresses it becomes muco-purulent, and then purulent and sanguineo-purulent, and mixed with detritus according to the stage and location of the lesion.

If gangrene takes place, the odor becomes fetid, and the expectoration contains fragments of dead, soft, and cartilaginous tissue, as may be.

Dysphagia ensues when the disease is in a locality to interfere with glutition, and odynphagia when ulcerations have occurred in the same localities.

In tertiary syphilis of the trachea the symptoms affect mainly the function of respiration, the voice often remaining normal even when breathing is seriously embarrassed.

Pain along the course of the trachea, if constant, is indicative of lesion at that particular point. Cases may run their entire course without any special symptom, even in the presence of stricture of the trachea, and of the bronchi, and of extensive disorganization as revealed at the post-mortem examination.

In hereditary syphilis, the symptoms are sometimes congenital and may remain practically continuous for years. Respiration and phonation are both affected. The cry of the infant sometimes possesses a shrill metallic resonance which has been compared to that of a tin trumpet. Cough is more frequent in the child than in the adult. Glutition is often difficult and sometimes painful. Expectoration occurs in the suppurative stages when the child is old enough to expel the products, which by infants are swallowed or retained in the air-passages. Laryngismus is a symptom of frequent occurrence in young children.

Etiology.—The probable condition attracting the manifestation of constitutional syphilis to the larynx is superficial catarrhal laryngitis from hereditary or acquired proclivity, or from exposure, or from abuse of tobacco, alcohol, or other indulgence, or from misuse of the voice. Such exposures cause more males to be affected than females, as there is no assignable sexual reason for preponderance. Tracheal lesions, on the other hand, have been reported more frequently in females, probably because the laryngeal lesion is attended to more promptly by the male. Syphilitic disease often extends by continuity from the oropharyngeal region to the larynx, principally along the pharyngo-epiglottic fold to the epiglottis, and thence along the aryteno-epiglottic fold, and from the two structures to the interior. Hereditary syphilis has been observed in intrauterine life (Monti: *Med. Times*, Phila., April 28, 1877, p. 336). Hereditary syphilis of the intensest character has been occasionally observed at a very early age, as in the case of an infant whose symptoms began with coryza in the tenth week of life, and terminated in death by suffocation from stenosis nineteen days later. Post-mortem, with examination, revealed, in addition to syphilitic lesions in the liver, destructive perichondritis of cricoid and left arytenoid cartilage, and fatty degeneration of the arytenoid and both posterior crico-arytenoid muscles and the left superior nerve (Fränkel: *Wien. med. Woch.*, 1868, Nos. 69, 70, cited by Ziemssen and by Mackenzie). Children less than a year of age often show laryngeal lesions of hereditary syphilis, and ulcerative lesions have been seen at two months of age (Parrot: *Prog. Méd.*, 1878, p. 635). Many cases occur in children but a few years of age, and sometimes the manifestations are deferred to the period of puberty or even later. Indeed, in opposition to the received opinion of syphilographers, I have reason to believe that in a few instances I have seen its manifestations delayed as late as the third and even the fourth decennium. True, in such instances as the latter it is quite possible that infection may have been acquired in some method unknown, without having been followed by any secondary manifestations, or that early hereditary manifestations may have escaped recognition. The secondary manifestations occur most frequently in adolescents and young adults. They appear most frequently at periods varying from a few weeks to a few months after infection, sometimes as late as the fourteenth or seventeenth month (Morgan). Tertiary lesions are most frequent at rather maturer ages, and occur occasionally in quite advanced life. They have been reported as early as the sixteenth month (Türck, op. cit.), and as late in their first appearance as the thirtieth (Türck), and even the fiftieth year (Mackenzie). Tracheo-bronchial tertiary lesions have been reported as appear-

ing as early as the ninth month after infection, but these lesions are usually coincident with the laryngeal lesions when not immediately consecutive to them.

Most of the instances of tracheal syphilis occur in individuals whose employments expose them to irritation from dusts of various kinds (Vierling: *Deutsches Arch. f. klin. Med.*, 1878, Bd. 21). Hereditary tracheo-bronchial syphilis is far less frequent than the laryngeal forms. It has been observed before the age of puberty.

Diagnosis.—Differential diagnosis between secondary and tertiary lesions is sometimes difficult, particularly in the transitionary period especially described by Whistler. The discriminating characteristics are less well marked in the laryngeal syphilis, perhaps, than in any other variety.

It may, however, be broadly stated that secondary lesions, erythematous, papular condylomatous, or paralytic, are superficial; and that tertiary lesions are gummatous, ulcerous, carious, necrotic, and deep-seated. Laryngitis occurring within a few months of infection is almost invariably secondary. Lesions appearing before the termination of the third year are presumptively secondary: those appearing within the third year, secondary or transitional; and those appearing after the termination of the third year, tertiary. Nevertheless, secondary lesions may be ulcerous, and undoubted tertiary manifestations have been recognized even within nine months of infection.

The history of the case, and the previous or actual presence of manifestations of syphilis elsewhere, are the main positive factors in the diagnosis of specificity, especially in the early stages of either variety. The later lesions of tertiary syphilis are often sufficiently characteristic; sometimes not at all so. In cases of doubt, antisyphilitic treatment will almost always detect a lesion of syphilitic origin, but not invariably. Hence, in instances of strong suspicion, the various methods of antisyphilitic medication should be thoroughly tried before that test is abandoned. This suspicion is justifiable in cases of obstinate chronic laryngitis, whether ulcerative or not, in individuals in whom no other appreciable local or constitutional cause can be detected.

Laryngoscopic inspection is an invaluable aid in diagnosis; though practically indispensable, it is inadequate for fully appreciating the extent of deeply seated lesions; and its revelations are not always sufficient to establish the diagnosis in the absence of corroborative lesions elsewhere. Erythematous and catarrhal inflammation of secondary syphilis, when diffuse, are not to the ordinary eye distinguishable from similar non-specific conditions. Circumscribed erythema, though usual in syphilis, occurs in non-specific laryngitis also, consequently that condition alone is insufficient for discrimination. Patchy erythema on the vocal bands, and elsewhere, may be regarded as characteristic. Not so, however, the shaded pigmentations at the extremities of the vocal bands.

Symmetric bilateral localization of erythematous and other patches is highly characteristic of secondary syphilis; but a contrary condition by no means excludes the diagnosis. Isolated bilateral congestion of the supra-arytenoid structures and of the cartilages of Wrisberg has been cited as pathognomonic. Nothing can be more fallacious or misleading. Enlarged inguinal and post-cervical glands furnish excellent corroborative testimony of syphilis.

Papules, or condylomata, upon an erythematous mucous membrane, are to be considered pathognomonic. Their recognition may require an exceptionally good light on the one hand, or repeated examinations on the other. They must be carefully discriminated from minute collections of mucus or of saliva.

Diffuse gummous infiltration is to be distinguished first from inflammatory syphilitic infiltration by the coexistence of gummous processes elsewhere, its more circumscribed contour, and its sharper definition. Differential diagnosis is much easier after it has reached the stages of liquefaction and ulceration.

Syphilitic ulceration usually proceeds from above downward, rarely in the opposite direction, and often in extension from ulceration in the pharynx. Repair usually proceeds from below upward. Apart from these guides, there is nothing positively characteristic enough to determine an ulceration to be syphilitic in character by mere inspection.

The absence of pain has been regarded as characteristic; but, on the one hand, carcinomatous ulceration often exists without pain, and, on the other hand, the ulcerative lesions of syphilis are sometimes attended with lancinating pains of the most severe character.

In the gummatous stage of tertiary syphilis diagnosis is not difficult. Nodular syphilides and gummata are recognized in the forms and at the localities mentioned under pathology. They may be confounded with other neoplasms, and with abscess. In cases of doubt, antisyphilitic treatment should clear up the diagnosis. The physical distinction between gummata and condylomata may in some instances be obscure (Semon).

The main reason why gummata are so infrequently seen as to have led some observers to an erroneous opinion as to their rarity, is that many patients do not present themselves until after the stages of liquefaction and ulceration have become established. When this stage has not been observed, and the larynx, as is more usual, is not inspected until after ulceration has considerably progressed, the appearances are not always characteristic. They may be confounded with those of lupus, carcinoma, and tuberculosis. The general diathesis, the clinical history, the existence of enlarged submaxillary and post-cervical lymphatic glands, the character of concomitant affections of the skin and mucous membrane, the aspect of the patient, assist in discrimination. Sometimes, too, tuberculous and syphilitic lesions coexist.

The typical tertiary ulcer, sharply defined, and below the surface of the mucous membrane, is more or less circular when recent, more or less crenated when reparation is taking place at one or more points of the circumference, and looking as though cut out with a punch when in œdematous tissues. Its borders are sharp, elevated, but not often undermined, and more or less rounded in their visible outline, and are surrounded by a more or less circumscribed inflammatory areola in the mucous membrane. The bottom feels hard to the probe on palpation. The bed of the ulcer is grayish, or lardaceous, yellow from fatty detritus, and covered with adherent concrete pus, through which, here and there, prominent rosy granulations often project. The surrounding tumefaction is harder and more indurated than in other varieties of ulcer. Purulent accumulations are rather indicative of the syphilitic process. At a later date

denuded or necrosed cartilage may be visible in suitably located ulcers.

In cases in which neoplasms have become developed at the seat of existing ulcerations or of cicatrized ulcerations or erosions, it is often impossible to pronounce as to their nature, even by the test of anti-syphilitic treatment. Not only do such neoplasms exist independently of the syphilitic process, or as the result of irritation provoked by syphilitic process in the vicinity; but when undoubtedly syphilitic in origin they rarely disappear under specific medication. Tertiary syphilis is usually recognizable in the stages of œdema of the larynx; and almost always in the reparative stages of cicatrization, or in the subsequent stages of stenosis, whether from cicatricial retraction or from organization of effused products.

Prognosis.—Secondary lesions, even when ulcerative, are most frequently curable without cicatrix or without any other sequel. Ulceration of the vocal bands sometimes leaves permanent defect of tissue. The prognosis is good except during temporary conditions of œdema, when it may be grave for the time being. The inflammatory congestion and turgescence are more chronic than in catarrhal inflammations, and are often recurrent. Actual hyperplasia is apt to remain permanent, even after cure of the syphilitic lesion, despite the most assiduous treatment; and when it occupies a vocal band the voice may be permanently impaired. The singing voice may remain imperfect, although the conversational voice be fully restored; the injured tissues being unequal to the nicety of adjustment requisite for cantation.

In tertiary lesions the prognosis depends mainly on two factors: First, on the impairment of the general health, and the significance of lesions elsewhere, especially in the brain and meninges and in other important organs. Second, in the extent of ulceration and the character of deformation or stricture which may follow. Temporary gravity exists in the presence of œdema; during the period of exfoliation of necrosed cartilages, and in acute bilateral paralysis of the dilator muscle, the result of exposure to cold or other cause, or to unilateral paralyses when the opposite side is immobile from gumma, or from crico-arytenoid ankylosis (Charazac: *Rev. Mens. de Lar.*, Sept. 1884), any of which conditions may demand prompt tracheotomy to prevent death by suffocation. Ulcerative lesions of the trachea may be fatal by hemorrhage from penetration of large bloodvessels; by pneumonia from access of food through perforation of œsophagus (Berger); or by septic processes due to rupture of the mediastinum. Permanent impairment of the voice is to be expected in all cases in which the vocal bands undergo serious injury, and in many in which permanent changes are likely to take place in other structures contiguous to the glottis.

Glutition is rarely affected, even after complete destruction of the epiglottis; and in exceptional cases difficulty is mainly confined to fluids swallowed without deliberation.

Stricture rapidly supervening upon hyperplasias is often amenable to active treatment, sometimes with striking rapidity (Krishaber: *loc. cit.*); but the more frequent stricture of slow progression can only exceptionally be brought under control.

Serious danger attends even cure of extensive ulcerative lesions in the interior of the larynx, for the resulting stricture, if severe, is likely to necessitate tracheotomy, with great probability of permanent retention of a canula. It is rarely amenable even to excision of cicatricial tissue by external access. Subglottic stricture is much more serious than supraglottic, and tracheal far more serious than laryngeal stricture. Stricture of the trachea, when low down, is practically insusceptible of amelioration; and death by slow apnœa, or by sudden suffocation, is the usual outcome.

When the syphilitic cachexia has advanced so far as to have produced incurable lesions in important viscera or in the cerebrum, death may ensue from these causes despite sustained cure of syphilitic lesions in the larynx. In cases complicated with paralysis of the dilator muscles of the larynx from cerebral lesion, the death may take place by occlusion of the glottis and suffocation, or by encephalitis and coma.

In hereditary syphilis the prognosis is very much the same as in tertiary syphilis; being much worse in infancy and childhood than in more delayed manifestations. The small size of the larynx renders stricture and intercurrent œdema far more significant; and the tendency to spasm of the larynx inherent to all laryngeal affections in childhood presents an additional element of danger. Fatal issues from these three causes are not infrequent. An element of uncertainty as to the final result remains in all varieties of syphilis of the larynx and trachea, due to the fact that permanent liability to recurrence prevails in many instances, despite the best apparent results of the most judicious treatment; and often, too, after prolonged intervals of immunity from any further manifestation of constitutional syphilis.

Treatment.—Fortunately, lesions even of great destructive and menacing tendency are amenable, as a rule, to treatment; often promptly.

The treatment, broadly stated, is that applicable to constitutional syphilis in general; mercury in the early manifestations and iodides in the late ones. In many of the latter, if not most, the mixed treatment combining the two specifics is the most serviceable. In congenital syphilis the gray powder is believed to be the most efficacious form of the drug. While willing to admit that secondary lesions often subside without traces and without much risk of subsequent tertiary manifestations, although mercury be withheld, I deem it the more prudent practice, and, therefore, the best practice, to employ mercury; in the belief that its specific constitutional influence affords the patient better protection as to future manifestations. As to the value of iodides in tertiary syphilis, there is no difference of opinion. Tonics are often indicated. All sources of irritation, exposures, excessive use of the voice, alcohol and tobacco, are to be avoided.

Sedative inhalations in vapor or spray are often of great topical benefit in subduing collateral inflammation; and antiseptic inhalations are indicated in gangrenous cases.

Secondary syphilis. Mercury may be administered by the stomach or by the skin. When the lesions are moderately severe or slow in progress, the corrosive chloride may be administered in doses of from one-sixteenth to one-eighth grain, three times a day. The green iodide may be given in doses gradually increased from one-sixth of a grain three times daily to the point of tolerance. The addition of extract of belladonna may cause it to be better borne by the stomach. In individuals in

whom serious gastric disturbance is produced before any specific effect has been noted, and in seriously severe cases and cases of rapid progress inunctions of a drachm of mercurial ointment daily are preferable, or pencillings with solutions of oleate of mercury in oleic acid, ten per cent. Lewin prefers hypodermatic injections of corrosive chloride. Concurrent stomatitis is to be combated by the internal administration of potassium chloride, or the use of a saturated solution of that salt, or of a weak solution of potassium permanganate as a mouthwash. It is hardly necessary at the present day to mention that salivation is to be avoided. In my own experience topical medication is, as a rule, superfluous in non-ulcerative secondary syphilis, and often unnecessary in the presence of ulceration. When topical medication seems necessary, inhalations of sprays of corrosive chloride (Demarquay), half an ounce or more daily of a solution containing one grain to four ounces of water, are useful locally and constitutionally. In particularly obstinate conditions, especially in the presence of hyperplasias, the topical application of solutions of iodine and potassium iodide in glycerine (Schnitzler), half a drachm and a drachm respectively to the ounce, made daily or at longer intervels, sometimes accelerates the cure.

In the transitional stage and in the tertiary stages, the mixed treatment has been the most beneficial in my own practice; one-sixteenth to one-eighth of a grain of the corrosive chloride, five to ten grains of potassium iodide in half an ounce or more of the compound syrup of sarsaparilla, three times a day. It may sometimes be necessary to increase the dose of the iodide up to the point of tolerance. In such cases the "grain to drop" solution is the most convenient preparation. The danger of inducing œdema of the larynx by sudden large doses must not be forgotten. When necessary, sodium or ammonium iodide may be substituted for the potassium salt, or hydriodic acid may be employed.

In the presence of œdema, hypodermatic injections of corrosive chloride (Lewin), one-thirtieth of a grain, twice a day for a day or two, and after improvement at intervals of three days or more, have proved quite efficacious. If amelioration is not prompt, and if the patient cannot be carefully watched by an attendant competent to interfere in an emergency, it is best, in my opinion, to perform prophylactic tracheotomy, instead of awaiting its urgent indication. The same rule is applicable to threatening cases of extensive hyperplasia whether from specific or from non-specific infiltrations.

Nevertheless, remarkably happy results, even in urgent cases of these kinds, have frequently followed active treatment by inunction (Krishaber) and by hypodermatic injection (Lewin). Intubation of the larynx from the mouth (O'Dwyer) has been recommended as applicable in many instances of œdema and constriction heretofore treated by tracheotomy. As yet, I know of no experience with intubation in this special connection.

Ulcerations heal more promptly when the constitutional treatment is seconded by topical cauterizations with fused silver nitrate, or with mercuric nitrate one part to from four to ten of water, or with cupric sulphate in crystal or saturated solution. Chromic acid, one part in from five to eight of water, has long been extolled (Isambert). Some prefer iodoform (Morgan). On the other hand, extensive ulceration often heals promptly under the influence of constitutional treatment alone.

Vegetations, detached flaps of mucous membrane, and semi-detached fragments of necrosed cartilage call for operative removal with cutting forceps, evulsion forceps, or snares, as may be most convenient, if these products are so located as to interfere with freedom of respiration or to threaten such interference. When these manipulations are impracticable, tracheotomy may be requisite. When tracheotomy has been performed under any of the conditions mentioned, the canula is to be removed as soon it has become apparent that its retention is no longer essential to the safety of the patient. Cicatricial stricture of the larynx may be treated by the introduction of the intubation tube through the natural passage (O'Dwyer). This treatment may be applicable to stricture high up in the trachea. Stricture in the middle portion of the trachea requires low tracheotomy and the introduction of a tube long enough to reach beyond the constriction. Stricture at the bifurcation is hopeless.

Paralyses, even those of the posterior crico-arytenoids, are usually amenable to anti-syphilitic treatment even when of considerable standing. This fact seems to indicate that the atrophy found in necrotic paralysis is not due to simple inaction of the muscle, but rather to trophic impairments of neurotic origin. Electrization may be employed when relief does not ensue from systemic medication.

Membranous webs, occluding the glottis from side to side, are divided by incision or by galvano-cautery, the edges cauterized, and readherence prevented, if possible, by frequent introduction of dilating sounds. These laryngoscopic operations are often rendered futile by insurmountable tendency to recicatrization, whereby the morbid condition is reproduced. Success in cases of this kind would seem to require exposure of the interior of the larynx by external division of the thyroid cartilage, and excision of the whole of the cicatricial tissue (Mackenzie).[1]

When syphilitic laryngitis has existed for a long time, such an amount of destruction may have taken place, and such a degree of systemic poisoning, as to render recovery impossible. The constrictions produced by the cicatrices of extensive ulcers, and the adhesions between adjoining surfaces, in cases that recover, are often such as to render tracheotomy necessary, with the permanent use of the tube; for the constrictions following syphilis are not, as a rule, amenable to dilatation.

Threatened asphyxia or unconquerable dyspnœa, from gumma, loose cartilage, morbid growth, abscess, or œdema, may necessitate tracheotomy. Tracheotomy for the purpose of conquering dyspnœa due to tumefactions in the larynx is perfectly justifiable, and usually successful. It is likewise justifiable for the mere purpose of securing rest to the organ—much more so, indeed, than in analogous conditions attending tuberculosis.

The treatment for local adhesions consists in relieving the tension as far as possible by laryngoscopic division of the constricting bands of tissue, with knife or with electric cautery, and then cauterizing and recauterizing the adjacent surfaces, to prevent fresh adhesions. These cases require careful watching and prompt attention to overcome the disposition to recurrence, which is very apt to take place in spite of all efforts. When the epiglottis

[1] Med. Times and Gaz., August 19, 1871, p. 218.

is implicated, much good can be done by teaching the patient to move the organ frequently by means of his forefinger.

In a case of stenosis due to "concentric hyperchondrosis," as a result of the hyperplastic chondro-perichondritis, Prof. Heine performed a successful resection of the anterior portion of the thyroid cartilage, splitting that structure in the middle line, separating the perichondrium and superjacent soft tissues, to the distance of one-half its surface on the two sides, with the elevator, and then removing the denuded portions by longitudinal section with bone forceps. The patient rallied so well from the operation that an artificial vocal apparatus could be substituted for the ordinary canula on the fifth day. He became able to resume work after a while; but the disease made new inroads, and he died, eleven months later, in an advanced stage of tuberculosis.

Despite the most judicious treatment, and the most satisfactory immediate results, recurrence or recrudescence takes place in many instances at variable intervals, requiring resumption of specific treatment. The most satisfactory results claimed by any writer have been in cases actively treated by Lewin with hypodermatic injections. It is advisable to keep patients under observation for many months after active treatment has been discontinued. Mercuric iodide (biniodide) in small doses, one-twentieth to one-tenth of a grain, three times daily, may judiciously be given for prolonged periods during which apparent health exists. Potassium iodide, in diminishing doses, should be administered from time to time for a few days every month until the patient begins to show susceptibility to physiological effects from small doses; and then this susceptibility should be tested from time to time at intervals of a few months. Such supervision for two years at least seems to present the best prospect for riddance from the diathesis.

It may be mentioned in conclusion that, under intercurrent attacks of erysipelas, obstinate cases of tertiary syphilis of the larynx and trachea have undergone cure after having resisted all medicinal treatment.

Stated Meeting, October 10, 1888.

THE PRESIDENT, J. SOLIS-COHEN, M.D., IN THE CHAIR.

DR. G. E. DE SCHWEINITZ presented the following paper on

ACUTE UNILATERAL OPTIC NEURITIS, WITH THE REPORT OF A CASE.

Cases of sudden failure of sight in one eye, with little or no ophthalmoscopic changes, are occasionally encountered, in which the attack is attributed to exposure to cold. Sometimes in these instances congestion of the optic disk is present, and a retro-ocular neuritis has taken place. Other cases of acute optic neuritis, sometimes monocular, sometimes double, are on record. Thus, Max Haadel[1] observed nine cases, some single and some double, with and without defects in the field of vision, usually with serious disturbance of sight, mostly with pronounced inflammation of the papilla and neighboring retina, in which exposure to a draught of air was the imputed cause. Periostitis at the foramen opticum was doubtful and the absence of syphilis, sugar, and albumen, lead, and other poisons was assured in every case. In M. Schlüter's[1] statistics, among 38 cases of neuritis and neuro-retinitis, 7 are classed as primary, while the remainder are arranged as follows: 13 of central origin, 6 from specific causes, 4 followed as the result of pathological orbital processes, 2 from abuse of alcohol and tobacco, 2 from albumen, and 1 each in connection with the puerperal state, after injury, from acute myelitis, and from hereditary reasons.

E. Schmidt,[2] in an examination of the cases of optic neuritis in the clinic of Prof. Hirschmann, at Charkow, found, among 120 cases in which the etiology was recorded with some degree of exactness, two instances of papillitis or papillo-retinitis due to cold. Voissius[3] has recorded a case of monocular optic neuritis in a man aged sixty-one, the attack coming on as the result of catching cold during a long wet drive. Recovery, with a hemiopic defect in the field of vision, was the outcome of the disorder. Roi[4] reports some examples of optic neuritis which he looked upon as rheumatic. They appeared monocular, were accompanied by a speedy diminution of visual acuity passing into amaurosis, but not, however, to the exclusion of a return to normal sharpness of sight. H. F. Hansell[5] describes two instances of acute optic neuritis of rheumatic origin, one monocular in a healthy married woman, and the other double in a man aged thirty-one. In each there was sudden loss of vision, swollen optic disks, and under treatment a rapid return to normal visual acuity. In Dr. Hansell's paper references to analogous cases are recorded, and L. W. Fox[6] has recorded an instance of acute monocular optic neuritis. Recently R. H. Derby[7] has reported a case of uniocular neuro-retinitis in a girl whose father had had syphilis, but who had no other manifestation of constitutional taint. There was at first a central scotoma, then optic neuritis. Light-perception was lost, but under mercurial inunctions and iodide of potash the swelling of the disk, which had amounted to 7 D., subsided, and fair vision was recovered.

Cases of optic neuritis without evident cause are occasionally recorded, as one by Power.[8] The patient was an anæmic lad of seventeen; the neuritis was double; albumen and syphilis were absent; the lad had had two attacks of rheumatism, and his father was gouty. Friedenwald[9] describes an instance of right optic neuritis in an otherwise healthy girl of fourteen, preceded by violent headache and other symptoms indicating grave cerebral disturbance, but in which perfect recovery followed. He classed her case with these examples of optic neuritis, referred to by Juler, occasionally met with in young girls, the cause assigned being some menstrual disturbance, the presence of which, however, careful inquiry fails to elicit. Usually the neuritis is preceded by severe head-

ache, and the prognosis is unfavorable. No further reference to the many cases of neuro-retinitis described in connection with irregularities of the menstrual functions need be made.

Hirschberg[1] has seen several instances of primary optic neuritis, whose course is very typical. The disease is divided into three stages: the first, characterized by great visual disturbance, with slight ophthalmoscopic appearances; the second, by diminution of the visual disturbance and very marked inflammation of the disk; and the third, usually by almost complete recovery, with pallor of the disk. The cases mostly occur in women, but are not connected with derangement of the sexual functions. Partaking somewhat of the nature of such cases, but not without a history of exposure as the exciting cause, is the subject of this communication.

Mrs. W., aged forty, consulted me July 11, 1888, because for a week past she had suffered from neuralgic pains in and above the eyes, most marked upon the right side. Bright light was distressing and pain followed when the eyes were rolled upward; slight tenderness was apparent when pressure was made upon the right globe. The vision in each eye was $\frac{5}{\text{VII}\frac{1}{\text{IV}}}$, the amplitude of accommodation 3.5 D.; there was high insufficiency of the internal recti, so that a divergent squint was evident when the eyes attempted to fix a point 15 cm. distant. The fundus of each revealed no gross lesions, save a slight retinal haze around the upper and lower edges of the right disk, the deeper layers of which were gray. The macules were normal and the refraction appeared to be a simple hypermetropia of 1.5 D. In the absence of any general derangement the peri-orbital pain was attributed to eye-strain, and atropia drops were ordered for the purpose of measuring the refraction error. The correcting glass proved to be + 1.5 s. and with it normal vision $\left(\frac{5}{\text{V}}\right)$ was acquired. During the application of the atropia the neuralgia disappeared. The drops were discontinued and the patient directed to return in two weeks.

During the measurement of the refractive error, the patient, on several occasions stated that although she saw the same number of letters with the right eye that she did with the left, she failed to see them with the same distinctness; but no changes at this time were present in the fundus. This indistinctness gradually assumed the appearance of a definite, dark area in the field of vision, the peri-orbital pain returned, and five days after the last ophthalmoscopic examination had failed to discover any changes in the disk or retina, she returned with the vision sunken to ability to count fingers and well-marked right-sided optic neuritis. All edges of the disk were woolly and its upper margins entirely hidden, while a flame-shaped hemorrhage was situated above and to the inner side. The apex of the swelling was + 3. D., the vessels were about normal in size, and the macula free from disease. The pupil was of medium size and acted sluggishly to light and shade. A few days before this time she had gone on an excursion with her children, became much overheated, and had afterward waded about in a neighboring brook. It was in the evening of this day that the neuralgia returned, the definite dark area appeared in the field of vision, and shooting pains attacked the deep muscles of the thighs.

Further examination proved an entire absence of any symptoms pointing to brain disorder; the heart and lungs were normal and the patient was not anæmic, there had been no suppression of the menstrual flow and this function was natural; no active uterine disease existed, except a slight prolapsus which was not then under treatment. The urine was free from albumen, sugar, and tube casts, and the last recent illness, several years before, had been an attack of peritonitis from which a good recovery had resulted. Dr. James Tyson, who saw the case in consultation, confirmed the accuracy of these examinations. Syphilitic infection and the action of lead or other poisons were carefully excluded. The vision continued to sink, and on the following day was reduced to faint quantitative light-perception and the disk, if anything, was slightly more swollen. The temple was freely leeched and the patient directed to take fifteen grains of salicylate of sodium before each meal, and seven and a half grains of iodide of potassium, with one twenty-fourth of a grain of bichloride of mercury after each meal.

Three days later, or on July 30th, the vision was slightly improved to the ability to see the hand move and the pain was distinctly better. The medicine was continued and small fly blisters ordered placed upon the temple. August 1st, the salicylate of sodium was discontinued, but the other medication continued, vision improved and large letters (Sn CC) were faintly recognized. August 6th, marked improvement, V.= $\frac{5}{\text{XXXV}}$; edges of the disk visible all around and only a faint remnant of the hemorrhage, August 20th, neuritis had practically subsided; V.= $\frac{5'}{\text{X}}$ form and color fields normal in extent; no scotomata; ordered one twenty-fourth of bichloride of mercury after each meal. September 9th, V.= $\frac{5}{\text{VII}\frac{1}{\text{IV}}}$, disk pallid, and all traces of the neuritis had disappeared.

In the absence of any symptoms pointing to cerebral disturbance, with no uterine disease save a slight prolapsus and the history of a leucorrhœa no longer active; with the menstrual functions normal; with a healthy circulatory apparatus and the urine free from albumen, sugar, and tube casts, and with the direct account of overheating and exposure, we may fairly conclude that this was an instance of genuine, acute optic neuritis.

The history shows that before any ophthalmoscopic changes were evident, and before there was any positive diminution in visual acuity, the field of vision was invested with a haze which afterward assumed a definite, dark form, probably coincident with the first appearance of the inflammation around the papilla and the loss of sight. Hence it is evident that the attack was in process of formation and was precipitated by the wetting of the feet and sudden cooling after an overheating.

Cases of optic neuritis apparently due to exposure, as has been pointed out by Leber and others, are mostly monocular; and rheumatism, perhaps upon insufficient evidence, has been cited as the cause. Gowers,[1] writing

[1] Centralbl. für Prakt. Augenheilk., Nov. 1887.

[1] Medical Ophthalmoscopy, 2d ed., p. 230.

upon this point, says: "Neuro-retinitis has been loosely ascribed to rheumatism, but only on the ground that it has sometimes appeared to be due to cold." Rheumatic inflammation at the back of the orbit, however, according to the same author, may damage the optic nerve. Michel,[1] commenting upon a reported case of acute peripheral retro-bulbar neuritis, remarks that he has never observed a "rheumatic" neuritis and considers the assertion of such as a mark of ignorance of the causes especially operative in the production of inflammation of the optic nerve. Hansell (*loc. cit.*) thinks "that a true rheumatic inflammation of the fibrous coat of the nerve between the optic foramen and the sclerotic" quite possible, but owing to the infrequent opportunity for section and examination admits that "our pathology is, at best, speculative." The central scotoma which existed in this and similar cases denotes an affection of the sheath of the nerve extending into its substance, not, as Hirschberg remarks, as would have been supposed before the macular fibres were discovered, a central inflammation extending outward.

The prognosis depends to a certain extent upon the site of the lesion and the termination may be favorable, as in the case reported, or a permanent atrophy of the disk may result. Hirschberg (*loc. cit.*), in his cases of primary optic neuritis, has found usually that the second eye is attacked; the interval may be days, or weeks, or months. Three of his cases illustrate this fact. A woman, aged forty-two, suddenly lost the sight of the right eye; in six days from the beginning of the attack this was well, but the left eye was attacked and optic neuritis developed; in three weeks recovery had taken place and the fundi were normal. In a second case a woman, aged twenty, had slight temporary loss of vision in the right eye three weeks before coming under observation for loss of vision in the left, which came on eight days before. Four months later she came with the right eye similarly affected, while the left had practically recovered. A third instance was that of a peasant girl, aged seventeen, who had her right eye attacked in 1878, recovered, and in 1884 her left eye was attacked, which also recovered.

The treatment has already been discussed. Leeching of the temple, followed by blisters, diaphoresis, together with the salicylates and iodide of potash, yield the best results. Improvement may take place before the remedies have time to take effect.

NEWS ITEMS.

The Washington Obstetrical and Gynecological Society at its annual business meeting, held October 19, 1888, elected the following officers for the ensuing term:

President.—Joseph Taber Johnson, M.D.

Vice-Presidents.—D. Webster Prentiss, M.D.; W. W. Johnston, M.D.

Treasurer.—George Byrd Harrison, M.D.

Recording Secretary.—Samuel S. Adams, M.D.

Corresponding Secretary.—G. Wythe Cook, M. D.

Corrigendum.

STERILIZED MILK.

In Dr. Baruch's note in our issue of last week, page 486, the temperature which will sterilize milk should have been stated as 266° F.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM OCTOBER 23 TO OCTOBER 29, 1888.

FORWOOD, WILLIAM H., *Major and Surgeon* (U. S. Army, Fort Snelling, Minnesota).—Is granted leave of absence for one month, on surgeon's certificate of disability.—*S. O. 100, Headquarters Department of Dakota, St. Paul, Minnesota,* October 20, 1888.

WOLVERTON, WILLIAM D., *Major and Surgeon.*—Is relieved from duty at Fort D. A. Russell, Wyoming Territory, and will report in person to the commanding officer Fort Douglas, Utah Territory, for duty at that post.—Par. 16, *S. O. 248, Headquarters of the Army, A. G. O., Washington,* October 24, 1888.

By direction of the Secretary of War, the leave of absence granted JOHN W. WILLIAMS, *Major and Surgeon,* in S. O. 209, Division of the Atlantic, October 4, 1888, is extended one month.—Par. 14, *S. O. 246, A. G. O.,* October 22, 1888.

By direction of the Secretary of War, leave of absence for one month, to take effect on the completion of his present duties, is granted EDWARD C. CARTER, *Captain and Assistant Surgeon.*—Par. 13, *S. O. 246, A. G. O.,* October 22, 1888.

BARTHOLF, JOHN H., *Major and Surgeon* (U. S. Army, Fort McIntosh, Texas).—Is granted leave of absence for one month, on surgeon's certificate of disability.—*Headquarters Department of Texas, San Antonio, Texas,* October 10, 1888.

BROWN, PAUL R., *Captain and Assistant Surgeon.*—Is relieved from duty at Fort Sidney, Nebraska, and will report in person to the commanding officer, Fort D. A. Russell, Wyoming Territory, for duty at that post.—Par. 16, *S. O. 248, Headquarters of the Army, A. G. O., Washington,* October 24, 1888.

By direction of the Secretary of War, WILLIAM A. ARTHUR, *Captain and Assistant Surgeon,* is relieved from duty at Fort Bowie, Arizona Territory, and will report in person to the commanding officer Fort Bayard, New Mexico, for duty at that post.—Par. 21, *S. O. 250, A. G. O., Washington, D. C.,* October 26, 1888.

By direction of the Secretary of War, WILLIAM C. BORDEN, *First Lieutenant and Assistant Surgeon,* is relieved from duty at San Antonio, Texas, and will report in person to the commanding officer Fort Ringgold, Texas, for duty at that post.—Par. 11, *S. O. 247, A. G. O., Washington,* October 23, 1888.

PROMOTION.

LORING, LEONARD H., *Captain and Assistant Surgeon.*—To be Surgeon, with the rank of Major, October 9, 1888, vice Meacham, deceased.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING OCTOBER 27, 1888.

SMITH, HOWARD, *Passed Assistant Surgeon.*—Detached from the "Wabash," and granted six months' leave, with permission to leave the United States.

AUZAL, E. W., *Assistant Surgeon.*—Ordered for examination preliminary for promotion to Passed Assistant Surgeon.

WIEBER, F. W. F., *Assistant Surgeon.*—Ordered for examination preliminary to promotion to Passed Assistant Surgeon.

AUZAL, E. W., *Assistant Surgeon.*—After examination, detached from Naval Academy, and ordered to Navy Yard, New York.

URIC, J. F., *Assistant Surgeon.*—Detached from the "Franklin," and ordered to the Coast Survey Steamer "Gedney."

OWENS, THOMAS, *Assistant Surgeon.*—Detached from Coast Survey Steamer "Gedney," and ordered to Coast Survey Steamer "Blake."

BERRYHILL, F. A., *Assistant Surgeon.*—Detached from Coast Survey Steamer "Blake," and ordered to Naval Academy.

HARRIS, A. N. T., *Assistant Surgeon.*—Detached from Naval Hospital, Mare Island, California, and wait orders.

HALL, JOHN H., *Passed Assistant Surgeon.*—Detached from the "Monongahela," and wait orders.

CRAWFORD, M. H., *Passed Assistant Surgeon.*—Detached from the "Vandalia," and ordered to the "Monongahela."

CONGENITAL BONY OCCLUSION OF THE POSTERIOR NARES.[1]

BY CHARLES H. KNIGHT, M.D.,
OF NEW YORK.

UNTIL recently but little attention has been paid to bony abnormality or outgrowth as a cause of nasal stenosis. Aside from what may be called acute stenosis, from traumatism or fractures involving the skeleton of the nose, bony occlusion is rare. This statement is especially true of the anterior nasal canal, the case described by Jarvis,[2] at last year's meeting of this Association, who referred also to one observed by Delstanche, and one recently reported by Dr. F. H. Potter,[3] of Buffalo, being the only cases which have been noted.

The opinion of Mackenzie,[4] of Baltimore, that "occlusion of the posterior nares is the most common of congenital naso-pharyngeal anomalies," is probably correct, but the proportion of cases in which the obstruction consists of bone is extremely small. The number of cases of congenital post-nasal occlusion, from this cause, found by Dr. Alvin A. Hubbell, and cited in his paper read two years ago before the New York State Medical Association, was then limited to thirteen, including one of his own. Six of these were bilateral (Emmert,[5] 1851; Luschka,[6] 1859; Bitot,[7] 1876; Wilkerson,[8] 1882; Schrötter,[9] 1884; Hubbell,[10] 1886). In the remaining cases the obstruction was confined to the right side in three (Wolff,[11] quoted by Fränkel, 1876; Zaufal,[12] 1876; Pomeroy,[13] 1881); to the left in three (Brandeis,[14] 1881; Sommer,[15] 1883; Zaufal,[16] 1883); and in one case the side affected was not mentioned (Gosselin,[17] 1876).

Congenital bony occlusion of the posterior nares may occur as a result of: (1) exostoses, or simple hypertrophy of the osseous structure of the turbinated body, middle or inferior; (2) a ridge, or exostosis, springing from the vomer; (3) an adventitious plate of bone developed from the floor, or the outer wall, of the nasal cavity. The bony impediment may vary in extent from a thin lamella or band, jutting into or bridging over the nasal passage, to a complete impervious wall. The former may occasion little or no manifest trouble, until, in after-life, it becomes the exciting cause of various local and reflex derangements. The latter is far more serious; and, when it exists on both sides, is almost of necessity fatal to the nursing infant.

The first variety (turbinated) is probably the most common, although true exostoses of the turbinated bone are rare, and may be congenital, or a result of disease. It is illustrated by several cases reported, more recently by a case operated on by Weir,[1] at the New York Hospital, who informs me that he has met with another similar case. Each of these was, in a measure, relieved by operation.

The dictum of certain authorities that congenital deflections of the bony septum are unknown may be true if restricted to its thicker posterior portion. While, therefore, it may not be proper to enumerate deflection of the septum among the causes of congenital post-nasal occlusion, thickening or exostosis of the vomer may exist to a degree sufficient to produce the second variety (septal) of nasal stenosis, especially if associated with abnormality of the turbinated bodies. In his work on *Post-nasal Catarrh*, p. 180, Woakes mentions exostosis and deviation of the septum as causing post-nasal obstruction, and refers to several cases, but does not speak of having met with congenital occlusion from these causes.

This condition, usually pathological, may be congenital. An instance of the former may be found in Case III., and of the latter in Case V., in Zuckerkandl's[2] classical work. In the former, the septum presented a bony prominence, which had formed an adhesion with a similar outgrowth from the middle turbinated body, evidently due to a morbid process. In the latter case, a very complicated one, there were several synechiæ, partly membranous and partly

[1] New York Medical Journal, March 12, 1887.
[2] Normale und path. Anatomie der Nasenhöhle, etc., 1882, p. 95.

osseous, due no doubt to faulty development, and not to a pathological process.

The third variety (palatal) of bony occlusion of the nares is of particular interest in connection with the case forming the basis of this paper. In the classification of the last-mentioned authority, no reference is made to it, and I have been able to find only two cases (Luschka, and Bitot) in which its existence was proved by post-mortem examination. Yet careful anterior and posterior rhinoscopy, as well as palpation, and the shape, situation, and character of the bony obstacle seem to establish the presence of this anomaly in several cases reported, as well as in my own case.

The precise origin of the bony wall is more or less a matter of speculation. It is quite probably a continuation of the free border of the horizontal plate of the palate bone, as described by Luschka, or an extension of its vertical plate, as maintained by Kundrat. In an interesting paper on "chronic nasal catarrh," based on the study of a large number of skulls, Harrison Allen[1] refers to one cranium in which the palatal bones sent up a delicate process "nearly half way on either side of the vomer at the posterior nares." He speaks of it as "strengthening the septum," but does not say to what extent it obstructed the choanæ. Possibly this may have been a modified or incipient form of Luschka's plate. In examining more than two thousand skulls, Sir Morell Mackenzie met with four instances of bony synechiæ, which he describes, but it does not appear whether the deformity in any case was congenital or acquired, or that this special form of bony abnormality was present.

The etiology of this condition is obscure. Spencer Watson[2] says that "it is probable that the late development of the bones in this region occasionally favors the formation of tumors and outgrowths in the nasal and orbital cavities, and that some of the malformations of the face are due to arrest of development of these parts during fœtal life." It is not difficult to understand the occurrence of asymmetry of the nasal chambers resulting from want of harmony in the development of the lateral half arches and the median structures, which enter into the formation of the face, as suggested by Allen. It is easy to conceive that this error of formation might proceed to even complete occlusion of the nares. But the deformity under consideration is not *necessarily* accompanied by obvious malformation or lack of development in other respects. It would seem to be rather an excess of development, an overgrowth of bone, resulting from hypernutrition.

A fourth cause of bony occlusion, though not strictly within the scope of this paper, deserves passing notice, namely, osteoma, either intranasal, or, much more commonly, projecting into the nasal passage from adjacent structures or cavities. This rare lesion has been described by Watson, Bornhaupt,[1] Tillmans,[2] and others, and recently a case of orbital osteoma, invading and blocking up the posterior nares, has been reported by Fenger.[3]

Several cases should be added to those already mentioned. Schötz[4] reports a case of a girl, sixteen years old, whose posterior nares were obstructed by diaphragms, probably bony, in consequence of which she had never been able to smell, or breathe freely through the nose. He expected to restore both the olfactory and the respiratory function by an operation. He mentions having found records of eight similar cases of double occlusion. Woltering[5] describes a case of right-sided bony occlusion, in a girl eighteen years old, which he treated with especially devised bone-cutting forceps, but with only partial success.

At the sixtieth meeting of German naturalists and physicians, Hopmann[6] described two original cases of complete bony occlusion of the right posterior naris. The first occurred in a patient eleven years old. An anæsthetic having been given, a passage was cleared by means of a chisel. In so doing the septum was broken, and fracture of the hard palate, with laceration of its mucous membrane, was produced. In consequence, the patient had considerable constitutional disturbance. Rubber tubes, increasing in size, were worn for about two months, and then discontinued. In three weeks the stenosis recurred, and a system of dilatation with Schroetter's laryngeal dilators was begun. Later, ivory plugs were used for nearly three months, being removed twice daily for cleansing. Nine months afterward there had been no narrowing of the passage.

In the second case the author describes the obstruction as being caused by a bony lamina from the free border of the septum, and by an osteoma springing from the floor of the nose. The patient was nineteen years old, and, as in the preceding case, the right choana only was affected. A similar operation was resorted to, and, as before, the vomer and hard palate were fractured. In this instance the cure seems to have been less tardy. A case observed by Schaeffer[7] is referred to, and notes of several cases of incomplete occlusion, partly membranous and partly osseous, are added.

In the discussion on Hopmann's paper, a case of total osseous occlusion *without symptoms* was referred

to by Abertüschen. Keemir reported a case in which he operated with a chisel. He then inserted a gum catheter, and afterward a silver tube. Gottstein stated that he had operated in a similar case with a dental drill, which failed to give him satisfaction.

In reporting Bitot's case to the French Academy of Medicine, Depaul[1] referred to an analogous case in his own experience. No doubt further search would discover additional examples of this interesting malformation.

Two cases of congenital, bony occlusion of the posterior nares have come under my observation, in either case the right side only being affected. One was seen but a few times, and no operation was undertaken; the other submitted to operation, and gave the following history:

G. S., female, æt. eighteen, single, consulted me in May, 1887, for enlarged tonsils, which were removed with the galvano-cautery. In the course of examination, she drew my attention to the fact that she could not breathe through her right nostril. This condition had existed as long as she could remember, but had given her no special discomfort. There was a moderate grade of chronic catarrhal rhino-pharyngitis. There was no impairment of smell, although it cannot be supposed that the right nostril shared in this function. There was no trouble in breathing through the left side of the nose, under ordinary circumstances. When the patient caught cold a discharge of watery fluid occurred from the right nostril, which at other times was entirely free from secretion. For two or three years impairment of hearing in the right ear had been observed, but it is by no means certain that hearing on that side has ever been perfect. Vision was good. The patient's mind was so occupied with her tonsils that her nose would have given her little or no uneasiness, but for the fact that she was aware of being different from other people. She was somewhat subject to headaches, which were usually explained by gastric disorder. She had no cough, and had never had any serious illness. Her general condition was not good. Her complexion was sallow, her cervical glands were enlarged, her flesh lacked firmness, and altogether she had the appearance of being poorly nourished. Her family history was good, except that a younger brother has hypertrophied tonsils.

The external contour of the nose was manifestly unsymmetrical, the right side being more prominent and "thicker," as the patient expressed it. Anterior rhinoscopy showed a very much contracted right nasal fossa, the septum being slightly deviated to the right, and presenting a ridge along the floor of the nose. The turbinated bodies seemed atrophied and their covering of mucous membrane appeared thin and dry. They were notably paler than those of the other side. A probe could be passed along the inferior meatus for two and a half inches. It traversed the middle meatus with great difficulty, on account of the deflected septum, to a similar depth, when it met with firm resistance. The left nasal cavity was unusually roomy, and the turbinated bodies, especially the lower, were large.

Posterior rhinoscopy was not easy, but after considerable training of the patient, the right choana was seen to be completely occluded by a partition, which seemed to be on a plane with the free margin of the vomer. The septum did not appear to be deflected. There was a small amount of adenoid tissue in the vault of the pharynx. The palatal arch was of average height, and nothing abnormal was seen in the oral cavity. On palpation, however, the left palate bone could be distinctly felt to extend further back by fully one-fourth of an inch than the right. By firm pressure it was possible to determine that the posterior margin of the latter was much thicker than that of its fellow. The impression given to the finger was as if the right palate bone had been bent at an obtuse angle. Pressure forward from the naso-pharynx proved the barrier to be unyielding. On pressing firmly with a large blunt probe, passed from the front along the inferior meatus, the patient complained of pain in the roof of the mouth, and during subsequent manipulations sensations were always referred to this region.

With the idea that it might be a membranous wall an attempt was made to puncture with the galvano-cautery, but it soon became evident that I had to deal with osseous tissue. No difficulty was found in perforating the obstruction with the nasal trephine attached to the electric motor. The opening thus made, about one-quarter of an inch in diameter, was subsequently enlarged by means of a revolving burr. There was not much bleeding and pain was not excessive, cocaine, in a twenty per cent. solution, having been applied anteriorly and to the naso-pharynx.

The piece of bone removed in the crown of the trephine was found to be very dense. On one side only the mucous membrane was preserved, it having been burned away anteriorly. The segment of bone measured antero-posteriorly about one-quarter of an inch at its lower, and one-eighth of an inch at its upper margin.

The after-treatment was directed to keeping the parts clean by means of a spray of Dobell's solution, and to preventing closure of the wound by daily passage of nasal bougies.

It is now more than a year since the operation, and the patient is able to breathe through her right nostril, though not always with perfect freedom. Her hearing has not improved, but her sense of smell is somewhat more acute than formerly. The question arises, Whether any other advantage has been gained? Aside from the benefit to her general health from tonic treatment, and to her pharynx following the removal of the tonsils, it must be admitted that nothing has been gained by boring a hole through her nostril. On the contrary, she is rather uncomfortable much of the time from the fact that secretions accumulate and dry in her right nostril, whereas formerly she was not annoyed in that way.

It must be confessed, therefore, that, except in the points mentioned, this patient was more com-

[1] Gaz. méd. de Paris, 1876, No. 36, p. 430. Mackenzie, Schrötter, and others refer to a case reported by "Betts." The name should be Bitot.

fortable with her nose as Nature made it than she has been since she fell a victim to science. Possibly, too, it may be said that the operation is not yet complete, since the right posterior naris is still much narrower than the left. The patient, however, is satisfied with being enabled to breathe through both nostrils, and cannot be persuaded to undergo any more drilling.

The great difficulty in these cases, namely, to keep open the newly made nasal tract, may arise from the fact that sufficient tissue has not been removed, as well as from neglect in the after-treatment. By far the best method of operating, as regards rapidity, accuracy, and thoroughness, is that with the electric trephine or drill.

Should another case of this kind offer itself to me for treatment, my plan would be, unless quite sure of the fortitude of my patient, to give an anæsthetic, and thus be allowed time enough to restore the malformed naris more nearly to its normal dimensions. Various devices have been used to obviate failure of the operation, such as the retention of flexible and of metallic tubes, and the passage of nasal bougies and dilators. In spite of all, in several cases recorded the operation has had to be many times repeated, in consequence of recurrence of obstruction.

In studying this case, two points impressed me with peculiar force. The first was the remarkable tolerance on the part of the patient of a condition involving serious interference with three important functions. In this respect the case seems to be exceptional, since the literature of the subject shows that nearly all similar cases on record had symptoms of more or less consequence, being naturally most severe in case of bilateral atresia. The amount of disturbance which would be likely to ensue from a similar *acquired* condition is in striking contrast.

The second point, a practical one, relates to the testimony gained by examination of the parts with the finger. I would not detract from the importance of rhinoscopy, but certainly, in this case at least, information was obtained by the finger which could not have been given by the mirror.

THE CLIMATE OF COLORADO AND ITS EFFECTS.[1]

By WALTER A. JAYNE, M.D.,
of Georgetown, Colorado.

In the selection of a climate for a phthisical person the great desideratum is, Where may our patients find the purest and most aseptic atmosphere, combined with the other qualities suitable to their individual wants, in which they may spend the maximum of time under the open sky safely and agreeably, and still have those comforts so necessary to an invalid? Colorado affords these conditions to an extent hardly to be found elsewhere, since not only is the climate suitable for a very large class of consumptives, but from the great combination of elevated plains and mountains an invalid may find an all the year climate of infinite variety from which to select, while the large and growing commercial interests offer inducements for a permanent residence, with the very environment proven favorable to the arrest, if not cure, of this malady, phthisis. Thousands of the population of this State, who once belonged to this invalid class, but who are to-day useful, active citizens in the enjoyment of health and strength, attest the truth of these assertions.

The climate of Colorado has been so frequently and well described that it is unnecessary for me to dwell upon it in detail, but before speaking of its effects let me recall its most prominent features, those to which the favorable results are ascribed.

Situated near the centre of the United States, far from any large body of water; extending over four degrees of latitude, and seven degrees of longitude; traversed from north to south by the great Rocky Mountain range and its numerous spurs; with open plains, more elevated plateaus—or parks surrounded by mountains—and secluded valleys at varying altitudes, it offers a most surprising diversity of climate. In summer one may choose between the heated plains and cool elevated mountains, and in winter may, if desired, almost entirely escape the rigors of snow and ice, and find a balmy air and the mild open winter of the south. The portion most interesting to us, because generally proving most favorable for the treatment of phthisis, is that lying to the eastward of the Continental Divide, and consists of open plains stretching away from the abrupt foothills at an altitude of from 4000 to 8000 feet, and the mountain parks and valleys.

The whole region is characterized by rarefaction, purity, and dryness of the air with a very large proportion of clear days and an abundance of sunshine.

The atmospheric pressure varies with the locality, since the elevation is from 4000 to 8500 feet. As in all high altitudes, the air is cool, though on the treeless plains the air in summer becomes much heated by day, but owing to rapid radiation the nights are invariably cool. In winter the mercury often sinks below zero F., but the days are bright and sunny, and though the air may be cool overcoats are often a burden, and one may frequently sit with open doors and windows, and even out-of-doors, with but little extra clothing. The temperature is not equable, but the great range of temperature, which is so marked a feature of all our meteorological tables, must not be compared with the same range in a low damp atmosphere, since, as gauged by the sensations, it is far less, and in practice is seldom found to do

[1] Read before the American Climatological Association, Washington, September 19, 1888.

injury owing to the dry, stimulating quality of the air. While great and rapid changes of temperature do take place, these extreme variations are exceptional.

The purity and aseptic character of the air are decidedly greater than at low elevations, and germs find little pabulum and few places in which to thrive. There are but few large towns, and the distances between them are great; the ranch population is scanty; and the soil is dry, gravelly, and porous to a great depth, and gives forth no noxious vapors: hence there is little chance of even slight contamination of the air by disease germs.

The air is dry. The moist winds from the Pacific are cooled by their passage over the intervening mountain ranges, and the clouds have deposited the greater part of their moisture, most of them are dissipated and few cross the last and greatest range. The annual rainfall is between fifteen and sixteen inches, and the actual humidity is less than in any other portion of the Union, except in the territories of the northern part of the United States during the winter months. The returns of the United States Signal Service show that the mean relative humidity at Denver for the past four years was (100 being saturation) 52.5, 57, 55, and 51.2 respectively; while at New York for the same years, 1884, 1885, 1886, and 1887, it was 73.3, 73, 73, and 66.5 respectively. A more certain test of the dryness of the air is the actual humidity, and from the United States Signal Service charts of the year 1882, we find that during the spring of that year the air contained an average of 1.5 grains of moisture to the cubic foot, during the summer 3.5 grains, during the autumn 1.5 grains, and during the winter but 1 grain, and the reports of subsequent years show very nearly the same averages, demonstrating the atmosphere of the region about Denver to be the dryest of any portion of the United States, with the exception noted.

The greater portion of the rainfall of the year takes place during the spring and summer months, in the daily afternoon showers, rainy days or continuous rains being exceedingly rare. The snowfall during the winter is light and the snow lies upon the ground but a short time, melting and sinking into the ground rapidly under the warm rays of the sun. Fogs and mist are almost unknown.

Winds at certain seasons of the year are common, and in towns and in those portions of the State having adobe soil, frequently raise quantities of dust. They are disagreeable and annoying, but they bear with them no peculiarly injurious effects beyond mere physical discomfort when exposed to them.

The phenomenal amount of clear, pleasant weather, with bright sunshine, especially during the winter months, is the most striking feature of the climate to a newcomer. By again examining the reports of the Signal Service for Denver for the years 1884, 1885, 1886, and 1887, we learn that there were 39, 57, 40, and 40 cloudy days respectively for these years, and it is fair to presume that on very many of these cloudy days the sun shone, since other reports compiled from the same source from the observations of fifteen years, state that there were on an average of 345 sunny days each year during this period, while the yearly average of cloudy days was 56. We also find, by referring to the same records, that the mean cloudiness is less here than elsewhere in the United States, except in Arizona during the spring, and Central California during the summer. In winter the cloudiness is less than during any other portion of the year, and the proportion of clear, sunny days is consequently greater. Owing to the clearness and dryness of the atmosphere, the sun's rays lose less heat in their passage to the earth than in low, damp climates, with the result that the open air of winter on clear days, though cool, perhaps even cold, is agreeable and comfortable with light wraps while in the sun, and pleasanter than the artificially heated atmosphere within doors.

The differences between the climate of the plains and that of the mountain parks and valleys are such as usually obtain between mountains and an open country, though more pronounced. There are few places in the mountains where meteorological records have been kept, but in comparing Georgetown, situated in the mountains, some 3300 feet greater elevation than Denver, and 8500 feet above sea-level, it is found that the mean annual temperature is from seven to eight degrees lower. For the year 1887 the mean annual temperature of Denver was 50.4° F., of Georgetown, 42.3° F. The summers are decidedly cooler, the thermometer rarely registering 85° F. in the shade during the warmest days, while at night the mercury falls to, from 65° to 60° F., and often lower. The mean temperature of Denver during the summer months of 1887 was 69.1° F., of 1888, 68.4° F.; of Georgetown, for the same periods, it was 58.3° F., and 59.1° F. respectively.

The winters in the mountains are more prolonged. The temperature on sunny days is not so high, and though the mean temperature is less the mercury does not sink to so low a point during the prevalence of northerly winds. The extremes of temperature are, therefore, not so great. During the winter months of 1886 and 1887 the mean temperature of Denver was 33.5° F., of Georgetown 27.2° F.; during the winter months last past the mean was 31.6° F. at Denver, at Georgetown 26.4° F.

The rainfall is a trifle less, and the number of cloudy days is slightly greater in the mountains than on the plains. During the year ending June 30, 1888 (the only one during which such a record was kept), there were but twelve days on which the sun

did not shine in Georgetown; four of these were during the winter months. The purity of the air is, I believe, greater in the mountains than on the plains.

I have thus briefly and imperfectly sketched the general characteristics of the climate of Colorado, those to which so many consumptives owe their lives and restoration to health, and which render the mortality of this State less than that of any other, notwithstanding the numerous deaths from phthisis of persons coming within its borders when all chance of benefit is irretrievably gone, and who reach our wondrous climate only in time to die.

In Colorado we have a remarkable combination of those climatic conditions most desirable for an invalid wishing to live as much as possible out-of-doors—a dry, bracing, stimulating atmosphere of great purity, of which rarefaction is a most important element, together with a maximum of pleasant weather and an abundance of light and sunshine, especially during the winters. Not only is it possible for an invalid to spend the whole summer and fall in camp, but when winter comes and it is desirable to be under more secure shelter, the patient is still enticed out under the open sky to engage in out-door amusements and occupations by the warm sunshine and balmy air, with a soil free from mud and dampness.

There can be no uncertainty as to the desirability of such a rare climate in phthisis; the difficulty is simply in determining and eliminating those cases not suitable for treatment at high altitudes. The class of phthisical patients deriving benefit here is a very large one, but there are some who do not improve and should never be advised to test the effects of the climate of great elevations.

After several years spent in the practice of medicine near sea-level on the Atlantic Coast, and coming to Colorado an invalid, the effects of high altitudes in health and disease have been somewhat striking, and have necessarily occupied a share of my attention during my five years' residence. My observations have been made mainly in Georgetown, a town situated in a deep mountain valley 8500 feet above sea-level, and my further remarks will relate solely to the effects of this considerable elevation.

The most marked effect of the climate of this altitude is due to the rarefaction of the air, and upon persons coming from near sea-level, while often very decided, differs greatly according to individual peculiarities, some scarcely noticing the change, while others are made decidedly ill. The most noticeable effects are slightly increased frequency of inspiration, and perhaps a feeling of insufficiency of respiration, supplemented occasionally by a sigh, with quickened pulse—generally from six to eight beats per minute—and may be a more forcible beating of the heart; but with the majority of persons there is no other inconvenience than shortness of breath after some exertion, as making an ascent, and possibly a tendency to wakefulness the first night or two after arrival. Rarely, there is a feeling of giddiness, even faintness, with headache, and a light, restless sleep at night, disturbed by troubled dreams.

If the heart is sound, and the lungs all right or but slightly affected, these organs adapt themselves to the new conditions in a few days, and the newcomer notices no effects of the increased elevation, except on considerable exertion.

In fleshy persons, or those with weak heart, the rapidity of the pulse is greater, the palpitation more marked, with perhaps a feeling of faintness, while in those of full habit the color is less fresh, may be a trifle dusky, and they recover their normal condition more slowly. Persons of a nervous, excitable temperament—particularly nervous women—in addition to the symptoms referable to the heart and lungs, complain of a feeling of unrest, nervousness, and unexplained anxiety, with sleeplessness, or, perhaps, a light sleep accompanied by disagreeable dreams. Such persons, and those with a muscularly weak heart, not infrequently faint in making excursions—even in a carriage—to a slightly higher altitude, and I have known instances of fainting even at an elevation of 8500 feet, with no disease of the heart discoverable. Dryness and harshness of the skin, with tendency to chapping of the lips and hands, is the rule with all. The kidneys are less active, the urine is higher colored, and it contains a larger proportion of solids than normal at lower elevations. Even those who have resided at a high altitude for a long time notice the lightness of the air, after an absence near sea-level of but a month or two.

The effects of this great change in altitude, as described, are rarely more than temporary, and give way to a sense of general well-being, strength, and vigor, with buoyancy of spirits. The appetite is increased, the digestive processes become more active, sleep is sound, the functions of the body become more regular, and a feeling of perfect, robust health pervades the system. On the other hand, persons of a high-strung, nervous temperament often feel depressed and exhausted, and do not succeed in shaking off the languor until a lower level is reached. Those coming from malarial districts often develop transient symptoms of malaria shortly after their arrival.

I have never known hemorrhage to occur among newcomers, except in two instances. In both it took the form of hæmoptysis, and occurred in men of sedentary habits, just from their offices near sea-level, who had come to the mountains for a brief holiday. I believe both had disease of the lungs, and one had had several hemorrhages before. One within twenty-four hours, the other within forty-eight hours after arrival, took violent exercise, and went

to an altitude of from 11,000 to 12,000 feet, and feeling exhilarated, and in buoyant spirits, declined to ride, and walked up rather steep ascents. The former spat a few mouthfuls of blood after return to his hotel; the latter some thirty-six hours after his climb, and at night after a second hard day, rowing and fishing, had a very severe attack of hæmoptysis. This man I saw a few days later. For about two months he had been in failing health, had had an annoying, hacking cough, and feverishness in the evenings, and not having his attention drawn to his lungs had attributed his troubles to malaria. When I saw him he was up and about, but had a temperature of 102° F. each evening, respiration 24, pulse 110 per minute, and I found considerable infiltration from lobular pneumonia at the apex of each lung. He returned home, and died within a year.

It may readily be supposed that such novel conditions affecting so intimately the vital processes of the body may cause illness in a person who seriously overtaxes the adaptability of the system. Let me illustrate with two of the most extreme cases I have met with:

A young man, a clerk, living near sea-level, came direct to the mountains. The following morning, noticing a prominent point of rocks overhanging the town, he scrambled up the mountain side some 2000 feet, more than 10,000 feet above sea-level, to get the view, and returned to his hotel late in the afternoon, much exhausted. Shortly after he was seized with a slight rigor, excessive shortness of breath, and severe palpitation of the heart, with cool extremities. He had a slight rise of temperature, almost gasping respiration, and a very rapid pulse. He was relieved in a few hours, and was about on the following morning, though very weak.

A young Englishman, who had always lived near sea-level, and never been to a greater elevation than 400 feet, came direct to Colorado, to an altitude of over 9000 feet. Being accustomed to active exercise, he spent entire days on foot on the mountains, and in visiting mines. After some two weeks of great and unusual exertion, he was seized with a slight febrile action, accompanied by a dry, hacking cough, shortness of breath, pain in the intercostal muscles, and palpitation of the heart, with soreness of the muscles, especially of the chest. The fever practically ceased in twenty-four hours, but the oppression of the chest, and intercostal pain, together with an amount of prostration out of proportion to the slightness of the attack, continued for ten days longer, but were promptly relieved by a short stay at a lower elevation.

What is the effect of residence at this altitude? The average expansion of the chest, as found by examinations for insurance, is greater than commonly found elsewhere, and in children the chest is proportionately larger and well developed. The skin is usually dry, though the insensible perspiration is probably greater than at lower levels in damp climates, and excessive perspiration occurs only after considerable active exercise. The urine is commonly of higher specific gravity than mentioned as normal, from 1024 to 1030.

The population of the mountains, as a whole, I have found to be an unusually healthy one, notwithstanding the fact that a large proportion of the men of this locality work in the silver mines, in bad air, in places dripping with water, and much exposed to cold draughts. The almost entire absence of bowel troubles, the infrequency of serious organic disease, of the more dangerous forms of continued fever, and freedom from all malarial diseases, give as a result a comparatively small amount of sickness. Children are especially healthy.

Occasionally cases of general debility with loss of nervous tone and sometimes with slight anæmia are met among those who have lived continuously in the mountains for a series of years, and though it is often difficult to determine the precise share the altitude may have in producing the undefined symptoms complained of, yet it is found in practice that a change to some lower elevation has a most marked and prompt remedial effect.

The trouble most frequently complained of is so-called biliousness, generally in miners, the result of continued exposure and wet, and is a slight stomach disorder. If the attack is somewhat sharp, there are general malaise and some febrile action, with headache, backache, pain in the limbs, soreness of the muscles, and heavily coated tongue. In more severe attacks the above symptoms are intensified and preceded by rigors, perhaps a slight chill; the temperature varies from 102° to 104° F.; coated tongue, nausea, and vomiting of bile, distress in the epigastric region, with tenderness of the liver, sluggish bowels and dark, offensive stools. These symptoms are usually controlled with readiness if given prompt attention, and the patient is about again in from two or three to ten days. The disease may last a week or ten days in mild form, but shows no uniformity as to duration. It is seldom or never remittent, and if a relapse does occur it does so from a definite, accidental cause.

Such febrile attacks are called mountain fever. It is a mild bilious fever with hepatic congestion.

I have known cases of fever to commence as above described and last four weeks, with no single symptom of typhoid, the temperature varying from 102° to 105° F. a great part of the time, often as high or even higher in the morning than in the evening, without delirium, tongue moist, appetite fair, even good, bowels regular and natural, but little emaciation, and the patient asking each day to be allowed to sit up, believing himself free from fever. Prolonged attacks of fever, however, usually show a few symptoms of typhoid during their course.

Typhoid fever, as I have seen it in the mountains,

has been, as a rule, very mild, lasting from two to three weeks. Commonly the only indications of a typhoid element are a few rose-colored spots about the commencement of the second week, and a transient relaxation of the bowels, with slight and temporary tenderness over the right iliac fossa. The tongue is moist, the appetite fair, and the patient often feels so well that some persuasion is necessary to keep him in bed.

I have met with two cases which proved rapidly fatal. In these the onset was unusually rapid and sharp; dry tongue and ataxic symptoms developed very early, and the fever ran very high. I have seen but few cases with ataxic symptoms and those referable to the nervous system, but these have impressed me with the belief that the occurrence of these symptoms is of far graver import than at lower altitudes.

I have never observed any material difference in the course of the exanthemata. In diphtheria death from sudden heart failure appears more common.

Pneumonia is supposed to be both common and very fatal at high altitudes. I am not of that opinion without qualification, and my experience does not lead me to believe it is of more frequent occurrence among those who are acclimated than at lower levels; indeed, I am inclined to think it less so, and under similar conditions of prudent, careful nursing, no more fatal. I have found it to be neither common nor fatal among women and children. It might be supposed that, owing to the rarefaction of the air, the diminished amount of oxygen it contains, and the increased labor thrown upon the lungs, that the proportion of deaths would be greater; but, to offset this, the air is of great purity and the health of the patient before the attack has generally been so robust that the disease finds the subject well fortified for withstanding the exhausting tendency of an acute disease. Pneumonia is, however, very fatal among those who, having been but a short time in the mountains, have been working hard, subjected to exposure under such unusual climatic conditions, in wet mines or in storms on the mountain sides at great elevations, and are seized with the disease, especially if saturated with alcohol. Living in comfortless, isolated cabins, as many men do, they have no conveniences when sick, and only the very indifferent nursing of comrades or comparative strangers, or of their families under poor surroundings. With these unfavorable conditions the disease is apt to assume a very acute and violent form, and often, when convalescent, they catch an additional cold, when the fatal result they would ordinarily have escaped promptly ensues. These circumstances would be attended by a large mortality in any climate, and here it should not properly be ascribed to the altitude but to the peculiar, rough mode of life and lack of care which were so common in the earlier history of the State, and even now in many frontier settlements and mining camps. These facts have given rise to the general impression of the fatality of this disease at high altitudes without a careful analysis of the causes contributing to the result. In acute lobar pneumonia, for the extent of lung involved, the respiration is from six to eight higher per minute. Hepatization takes place rapidly and the expectoration is usually of a fresher color than at lower elevations.

Acute plastic pleurisy is not infrequently met with, but it has not been my fortune to see a single case of pleurisy, with effusion, during my stay in the mountains. I have had one case of empyema, this as a sequel to pleuro-pneumonia. Bronchitis, in the form of ordinary "colds," is not more common than elsewhere, and seldom proves more than a temporary indisposition and does not tend to linger and become chronic.

Migraine and neuralgias are probably not more common than at sea-level. Chorea among children is rather common. Epilepsy I have but rarely met with, and have not known of the development of a single case. Enlargement of the thyroid gland among women is more frequently met with than in other places, but it never attains any great size. Exophthalmic goitre I have observed several times. Nasal and pharyngeal catarrhs are common and troublesome. Acute and follicular tonsillitis occur as elsewhere. Bowel troubles are, as I have stated, unusual, and are almost invariably promptly controlled by simple remedies. Children coming to the mountains with summer complaint usually recover quickly with little else than careful regulation of the diet. Dysenteric diarrhœas are very uncommon. Sporadic dysentery rarely occurs, and then in a subacute form. Acute dysentery with fever has come to my notice but once, and this was the result of fecal accumulation in a case of chronic constipation, and the patient had had several similar attacks before coming to Colorado. Those cases of chronic Bright's disease I have met with have been difficult to manage, though several cases of the acute form have yielded readily to treatment.

Diseases of the heart give trouble early in their course and grow worse very rapidly. To this I do not recall an exception. I have carefully watched the development and progress of several cases of valvular disease—aortic and mitral—and have noted hypertrophy, but no positive dilatation has taken place, except, possibly, in a case now under observation, it is as yet in its early stage, and has given no clear evidence of its presence. Those with fatty heart, or in whom the heart muscle is weak, are soon obliged to go to a lower altitude.

Acute diseases of an inflammatory character are more acute, as a rule, at high altitudes, and prompt measures are more necessary, while full recovery of

strength from these, and particularly from fevers, is apt to be slow, and is materially hastened by a short stay at a lower elevation.

Owing to the purity of the air and its freedom from germs and microbes, and the activity of the assimilative processes at this altitude, wounds heal by first intention more surely and with less strict attention to antisepsis than at sea level. Cases of compound fracture and extensive wounds act more kindly, granulate and cicatrize more rapidly, and suppuration is far more limited than elsewhere, even when no particular attention is paid to the thorough purification and cleansing of the parts. Traumatic fever is very slight or altogether absent. These facts are particularly apparent to a surgeon when recently from a low damp atmosphere.

A few medicines act peculiarly at high altitudes. Quinine is more active, and it is impossible to prescribe such doses as are given in the east without causing distressing symptoms of poisoning. Many women and children cannot take even the smallest quantity without distress, and I have had adults complain of cerebral excitement, nervousness, and cinchonism, after taking two doses, of two grains each, of the bisulphate at an interval of three hours. I have seen several persons wildly delirious, in whom the drug had been pushed, and the cause of the delirium not recognized. I ordinarily use larger doses of cerebral sedatives, as bromides, and smaller doses of aconite than I was accustomed to use at sea level. Veratrum viride I find comparatively little use for. Digitalis, on the other hand, may be prescribed more freely, especially in those acute diseases tending to enfeeble the heart.

The therapy of the climate of Colorado is scarcely within the scope of this paper and has been so well presented to you by the gentlemen from Colorado who have preceded me, that I will not dwell upon this portion of the subject further than to call attention to the fact, illustrated very many times in my experience, that cases of phthisis frequently do remarkably well in the mountains, at great elevations, when they have failed to improve on the plains, and had all but lost hope of deriving any benefit from that, to them, *dernier ressort*—the climate of Colorado. So many such cases have come under my observation that I am fully convinced that the timidity of advising patients to go the mountains of Colorado is largely unwarranted. Certain precautions as to clothing, exercise, and habits of life must be attended to as elsewhere in high altitudes, and these are particularly necessary in the mountains. Further, in order to reap the full benefit, the rule applicable to all parts of Colorado must be followed —*i. e.*, the stay must not be intermittent, but prolonged, until the improvement may be relied upon as more than temporary, and until the reparative process in the lungs is well advanced. Especially is this true for cases which have progressed beyond the first stage. Patients almost invariably gain the most during the winter months.

In considering the benefits consumptives derive from a residence in elevated regions, we naturally ask, To what peculiar feature may we ascribe its good effects, the purity, the rarefaction, or the dryness of the air? While I am inclined to answer that the beneficial effects are due to a happy combination of the qualities described added to the possibility of spending a large portion of the time in the open air, and believing that the importance of purity of the atmosphere cannot be over-estimated, I am of the opinion that the most potent factor is the rarefaction of the air. All portions of the lungs are fully expanded, increasing the activity of the capillary circulation of the lung and bathing the diseased parts with a dry pure air, favoring the absorption of the morbid deposits, while at the same time the stimulating qualities of the atmosphere, by improving nutrition, call into action the reserve powers of the constitution and restore the tone of the system, enabling it to cope successfully with the local disease.

There are one or two very simple rules which all consumptives coming to high altitudes should understand and observe, since, because of the unusual characteristics of the climate, they are so important that neglect of them will retard recovery, and in advanced cases may destroy the slight chance still remaining to the invalid of receiving benefit from the change, and lead to a fatal result.

1. The approach to elevated regions should be gradual and by easy stages, not in these days of Pullman coaches, to spare fatigue, but in advanced cases with limited lung space, and in those with fever and considerable activity of the disease, to avoid over-taxing the capacity of the lung to adapt itself to the rarefied atmosphere. For the same reason the invalid should, for a time after arrival, either take very moderate exercise or none at all.

2. The residence should be continuous and prolonged.

I am confident, were the first of these rules more generally followed, we should hear far less of the ill effects of high altitudes and be able to note a larger percentage of advanced cases as improved; and if the second was faithfully observed, there would be more cures and fewer relapses.

WATERMELON-SEED IN THE RIGHT BRONCHUS. OPERATION. RECOVERY.

By GREGORY ACKERMANN, M.D.,
of Wheeling, W. Va.

Carrie K., two years old, of Matamoras, Ohio, was brought to Wheeling for treatment, having swallowed a watermelon-seed which lodged in the windpipe four days previously.

The child was bright, playful, and not suffering much inconvenience from the foreign body, except that her voice was husky and she had an occasional violent paroxysm of croupy coughing, attended with attacks of suffocation. On auscultation there was found delayed inspiration over the right lung, the vesicular murmur assuming a cog-wheel-like character. This was apparently produced by the partial closure of the right bronchus.

Emetics had been tried in vain, as well as shaking and thumping the child, while holding her head downward; so the operation of tracheotomy was decided on as the only means of relief.

After the patient was removed to the Wheeling Hospital, with the kind assistance of Drs. Dickey, Schwynn, and Hildreth, I performed, under chloroform anæsthesia, inferior tracheotomy (below the thyroid isthmus). The fat neck of the child, and the numerous vessels in this locality, necessitated a careful and slow dissection down to the trachea. Making an incision about three-quarters of an inch in length, and introducing four loop ligatures through the cartilage, the aperture was held open by an assistant, while I held the child heels up, shaking it and causing expulsive coughing by irritating the trachea with a small feather. These efforts were futile, however, and recourse was had to a pair of curved slender forceps. The child lying on its back, the forceps were gently introduced through the incision, down to the extreme end of the right bronchus, where the seed, which had firmly lodged there, could be just grasped by its end and easily withdrawn. It was an ordinary sized watermelon-seed, somewhat swollen by the secretions.

The tracheal incision was closed by four sutures, and the external tissues drawn together by several sutures, a small drainage tube being inserted into the lower angle of the wound. The dressing consisted of iodoform plentifully sprinkled over the wound, and several layers of carbolated gauze loosely bandaged around the neck.

The little patient recovered quickly from the operation, and was apparently much relieved of the first mentioned symptoms. There was no elevation of temperature, the wound healed by granulations, and in ten days the child was taken home by its happy mother, perfectly well.

WHEELING, W. VA., September 15, 1888.

A CASE OF ATRESIA ANI URETHRALIS. OPERATION WITH RELIEF.[1]

BY A. T. CABOT, A.M., M.D.,
SURGEON TO THE MASSACHUSETTS GENERAL HOSPITAL AND TO THE BOSTON CHILDREN'S HOSPITAL.

THE case I have to report is one of imperforate anus, in which the rectum discharged its contents entirely through the urethra, and in which, finally, by operation, this condition was successfully corrected.

Before proceeding to the account of the case, it may be interesting to consider briefly the development of the organs involved in the deformity, and to see how the separation of the rectum from the urinary passages is accomplished during fœtal life.

In Fig. 1, which is a diagram after Kölliker, we have a representation of the manner in which the allantois folds and divides itself to form the urinary organs and the rectum. At R we see the first indi-

cations of the perineum, and the dotted lines show how this fold, as the further development goes on, pushes itself down between the rectum and the sinus urogenitalis to form finally a complete separation between them. Figs. 2 and 3 give some idea of the

FIG. 2

FIG. 3.

Fig. 2. *p* represents the rudimentary penis; *f*, the furrow from which the urethra and anus are to be formed.

Fig. 3 shows the commencing separation of the urethra from the rectum; *f*, rudimentary urethra; *a*, anal orifice.

way in which the perineum comes down and divides the external opening into an anus behind and a urethra in front. And they also indicate how the outer portion of the urethra, with the penis that encloses it, is formed by a folding of the external surface. A failure in the formation of any part of this perineal septum leaves an opening between that part of the rectum and the urethra or bladder. In woman the communication would be with the vagina.

Accordingly, Förster, in his extremely thorough monograph on malformations, makes three separate forms of this deformity. 1. Atresia ani urethralis. 2. Atresia ani vesicalis. 3. Atresia ani vaginalis.

[1] Read before the Association of Genito-urinary Surgeons, Washington, September, 1888

In all of these the anus is imperforate, and the lower end of the rectum opens into the urethra, bladder, or vagina. The opening into the vagina may be quite large and easily provide for the adequate discharge of the feces. On the other hand, however, the communication with the urethra or bladder is always by an extremely small fistulous track, which is too narrow for the sufficient escape of the contents of the bowel, and death is, therefore, a necessary result of this deformity, if not interfered with.

The fistula, when it enters the bladder, does so at the fundus. It may enter the urethra at any point in its course. Förster figures a case in which the rectum ended as a pouch, and from it a long narrow passage led forward close under the skin of the scrotum and along the under surface of the penis to open into the urethra close to the meatus. Ordinarily, however, the communication with the urethra is in the deep part, at or just in front of the membranous portion.

When a case of imperforate anus emptying through the urethra presents itself for operation, it is naturally of first importance to determine where the rectum enters the urinary passages. If this opening is into the urethra, we may hope to find the rectal pouch low down, where it is accessible to operation, and where it is less likely to be surrounded by peritoneum. To decide this point, the fecal and urinary discharges should be watched carefully. If they come separately and not mixed, it may be concluded that the communication is with the urethra in front of the compressor urethræ muscle; while if they come together, intimately mingled, it is evident that they must have become so mixed in the bladder, where they met and were stirred together before they were voided. We can also judge from the ease of the fecal discharges, and from their amount, something as to the size of the fistulous passage.

In the performance of the operation, the first difficulty is to find the end of the bowel. As its contents have been escaping through the urinary passages the rectal pouch does not form a bulging tumor as in an ordinary case of imperforate anus, but may be, as it was in the case to be reported, quite empty. Fortunately, we may be pretty sure that the cloaca lies in the middle line, and that in order to reach the urethra it must come down over the prostate. Acting upon this consideration the surgeon should have a staff in the urethra as a guide, and should take the greatest pains to adhere to the middle line in his dissection, which should be carried back toward the apex of the prostate.

The patient whose case forms the subject of this paper, was sent to me in February, 1888, by Dr. H. S. B. Smith, of Middleborough, Mass. The little boy was then five weeks old, and was a fairly well-nourished child. He showed no other deformity than the one we have to describe.

At the proper site for the anus there was only a slight dimple of the skin, perhaps one-half an inch deep, and not showing, even in its deepest part, any sign of a mucous membrane. If the finger was introduced into this depression, its presence excited a muscular contraction around it which showed the evident existence of a sphincter at that point. During the five weeks of life, all of the feces had passed through the urethra, and, as they had been always fluid, the child had suffered no apparent inconvenience from this abnormal method of defecation.

By careful watching it was found that the urine and feces never came intimately mixed, but that, if they were passed at the same time, there was first a jet of urine then an escape of feces, followed, perhaps finally, by a gush of clear urine again. Also, at times, the urine was passed without any appearance of fecal matter, or the feces appeared without any passage of urine. It was plain from this way in which urine and feces came separately that the bowel must enter the urethra in front of the cut-off muscle, and it was decided to cut down and try to establish an opening into the rectum just behind this point. This operation was done March 7, 1888.

A sound was placed in the urethra to serve as a landmark, and with the patient in the lithotomy position, an incision was made along the raphe and through the dimple which marked the proper site for the anus. After a rather deep dissection close to the prostate, the rectum was found and opened by a longitudinal incision about three-fourths of an inch in length. The edges of this opening were stitched down to the anal depression above described, care being taken to attach it within that part surrounded by the sphincter muscle. The portion of the incision behind the anus was brought together with sutures, the part in front being left open for drainage, in case any urine should leak through the wound.

Fecal matter escaped freely during the operation, and, three hours later, there was a large evacuation of liquid feces through the newly opened anus. For thirteen days all of the feces came by the anus and all of the urine by the urethra. On the thirteenth day a little gas was seen to pass the urethra, and an examination of the anus showed that the parts were almost wholly healed, and that the opening into the bowel was beginning to contract somewhat. This was easily stretched with the finger, and from this time dilatation of it was practised every second day.

Except for the rare escape of a trace of feces by the urethra, and the occasional appearance of a few drops of urine by the anus, everything now went well. After a few days, the mother was taught how to dilate the anal opening, and with instructions to do so every day or two, she was allowed to take the child home.

I heard from them again on August 6th (five months after the operation). Dr. Smith then wrote me as follows: "The anus now seems in quite a natural condition. There is much less resistance to the introduction of the finger than there was three

months ago. Most of the urine passes normally, but a little is seen now and then to pass the anus. There is an occasional stain of fecal matter by the urethra, but only when the child is constipated."

The mother writes that the baby is well and strong, and has not had a day of sickness through the summer.

Whether the communication between the rectum and urethra will finally close spontaneously cannot yet be told. It causes now no inconvenience, and can probably be closed by operation when the child is stronger and the parts larger.

TWO CASES OF GUNSHOT WOUND OF THE ABDOMEN, ILLUSTRATING THE USE OF RECTAL INSUFFLATION WITH HYDROGEN GAS AS A DIAGNOSTIC MEASURE.

By N. SENN, M.D., Ph.D.,

of Milwaukee, Wisconsin;

Attending Surgeon to the Milwaukee Hospital; Professor of Principles of Surgery and Surgical Pathology in the Rush Medical College, Chicago.

Case I.—J. J., sixteen years of age, was out hunting with some companions on Sunday, September 9, 1888, one of whom accidentally discharged his 22-calibre rifle at a distance of about one hundred and fifty feet, the bullet striking the patient in the abdomen. The injury caused but little pain, and immediately after the accident the patient walked about forty yards to a farm-house, where he was placed in bed. From there he was conveyed on a cot, in a farmer's wagon, to the Milwaukee Hospital, some six miles distant. The accident occurred about noon, and he arrived at the hospital at 3 P.M.

Examination.—Boy complains of considerable pain in the abdomen; pulse 80 and soft; his general appearance indicates no serious injury. On undressing him, a bullet wound, with omentum protruding, was found two inches to the right of the middle line, and on a level with the anterior superior spine of the ileum. Left iliac region dull on percussion; and in right, a cracked-pot sound was elicited on percussion. A rectal enema was administered, and was followed by a free fecal discharge, without admixture of blood. (On washing the feces afterward the bullet was found.)

Operation.—Ether, as an anæsthetic; thorough disinfection of abdominal wall; rectal insufflation of hydrogen gas, followed by the escape of bubbles of the gas, within a few seconds, at the wound of entrance, into which had been placed a hæmostatic forceps, the blades separated so as to render the canal patent. The gas was lighted, and after thorough cauterization of the wound by the flame, the flame was extinguished by the application of a wet sponge.

Laparotomy by median incision, eight inches in length, from pubes upward. About a pint of fluid blood in the peritoneal cavity, and hemorrhage continuing from the mesenteric veins at two points of perforation on the mesenteric side of the bowel, and to a less extent from perforations of the mesentery; arrested by ligating *en masse*. Within a distance of four feet, near the middle of the ileum, were found ten perforations, two of which were at the mesenteric border; also four perforations of the mesentery. Another perforation of the bowel was found within four inches of the ileo-cæcal valve on the convex side of the intestine, making so far eleven in all. All were closed by Czerny-Lembert sutures. At two points the perforations were so close together that it was found necessary to invert half the circumference of the bowel on the convex side, thus producing considerable narrowing of its lumen.

Two hours had been consumed in arresting the hemorrhage and closing the eleven perforations, and the patient at this time had become pulseless, and yet it was deemed absolutely necessary to determine beyond all doubt if any more perforations existed by repeating the rectal insufflation of hydrogen gas. On repeating this test it was found that gas escaped freely from the pelvic cavity, without reaching the ileo-cæcal region, showing that at least one more perforation was below this point. The sigmoid flexure was brought into the wound and compressed between the index finger and thumb. Insufflation was again followed by escape of gas, demonstrating that the perforation was below this point. Inch by inch the bowel was examined by this method in a downward direction, until a perforation was found in the anterior portion of the rectum at a point where the peritoneum covering its anterior wall is reflected upon the bladder. This perforation was rendered accessible to direct treatment by an assistant making traction on the colon and by keeping the margins of the wound well retracted by means of a pair of Hegar's retractors. It was closed by five Lembert sutures, with the greatest difficulty, on account of its deep situation and inadequate light, which was furnished by two candles.

From the perforations in the ileum there escaped pieces of green apples and intestinal contents, and from that in the rectum fluid feces.

The peritoneal cavity was freely irrigated with a one-third per cent. solution of salicylic acid. After completion of peritoneal toilet, a glass drain was introduced in such a manner that the distal open end was placed opposite the sutured rectal wound, and the abdominal incision closed in the usual manner.

Whiskey was freely administered hypodermatically during the operation and after its completion, as the patient remained pulseless for half an hour.

Time of operation two and a half hours.

The foot of the bed was elevated and dry heat applied to the extremities.

10 P.M. Temp. 99.5° F.; pulse rapid and weak. About one ounce of bloody serum withdrawn from glass drain.

Sept. 10, 8 A.M. Temp. 99° F.; pulse 126. Clear serum only in the drain; about one drachm withdrawn every three hours. During the day the patient was slightly delirious, and in the absence of the nurse he got out of bed and walked across the ward to another bed.

8 P.M. Temp. 99.8° F.; pulse 144. Some tympanites. Ordered one drachm of turpentine in half a pint of warm water, as an enema, which was followed by free discharge of feces and flatus.

11th. Temp. normal; pulse 104. Natural passage from bowels; delirium continues.

12th. Temp. normal; pulse 96; delirium disappeared. Allowed liquid food in small quantities.

13th. Pulse 72. The contents of the glass drain have a suspicious fecal odor. Glass replaced by rubber drain. Slight diarrhœa, which relieved the tympanites.

14th. A fecal fistula has formed along the track of the drainage-tube. Large rubber tube introduced through the anus, and left in rectum to allow free escape of fluid feces. Fluid injected into fistula does not flow through the rectal tube. Rectum disinfected every four hours with saturated salicylic acid solution.

9 A.M. Temp. 101° F.; pulse 126.

17th. Temp. normal; pulse 108. Free discharge of fluid feces from rectal tube and fistula.

18th. Sutures removed from the abdominal incision; only deep parts united, granulating surfaces approximated by strips of adhesive plaster over an antiseptic compress.

19th. Fluid flows freely from fistula through the rectal tube. No feces have escaped through fistula for twelve hours.

20th. Rectal tube withdrawn, followed by return of fecal discharge through fistula.

Oct. 1. The discharge of feces through the fistula has been gradually diminishing, and has now ceased.

19th. Fistulous track completely closed. Abdominal incision all healed, except a small granulating surface at lower angle.

Patient discharged cured, November 3d.

Remarks.—The subjective symptoms in this case four hours after injury, and after transporting the patient a distance of six miles, furnished no indications whatever of the extent of visceral injury which was found on exploring the abdominal cavity. The rectal insufflation of hydrogen gas at once rendered the diagnosis positive, and pointed out the necessity of treatment by abdominal section. Eleven perforations were found and sutured without much difficulty, but the last perforation in the deepest portion of the pelvis could not have been found by any other means of diagnosis short of rectal insufflation. Had this perforation been overlooked death from septic peritonitis would have been inevitable. Drainage was resorted to in this case, not only from the fact that fecal extravasation had taken place, but also for the reason that owing to the difficulty in gaining access to the rectal wound I feared that the suturing was not as perfect as it should be, and by proper drainage I wished to prevent possible extravasation into the peritoneal cavity from this cause. Subsequent events showed the propriety of this precaution.

Case II.—J. E. (case of Drs. Gudden, Steele, and Gordon, of Oshkosh), eighteen years of age, was out target-shooting with a companion, who, while raising his 22-calibre rifle to his shoulder, accidentally discharged it; the bullet struck the patient in the abdomen. He was about forty feet distant, and almost directly facing his companion. When first seen by Dr. Gudden, within half an hour after the injury was received, he was suffering severe pain in the abdomen, was pale, covered with cold, clammy perspiration, and vomited frequently. He was placed in a carriage and conveyed to his home, a distance of two miles. During the journey, the severity of the abdominal pain was so increased by the motions of the carriage as to necessitate repeated stops.

I saw the patient, with the above-named physicians, October 9th, 4 A.M., twelve hours after the accident.

Examination.—The wound of entrance was found to be at the outer margin of the left rectus about one inch below the level of the umbilicus. Abdomen dull on percussion in left iliac region, pulse 140, temperature 100° F. Penetration of the abdomen was proved by the introduction of a grooved director, which was left in place during the insufflation of the hydrogen gas.

The patient was placed under the influence of chloroform, and during the operation the narcosis was maintained with ether. The abdomen was thoroughly disinfected, and rectal insufflation of hydrogen gas practised to ascertain if any perforation of the intestine existed. Under a pressure of about a half a pound to the square inch, and the use of one-quarter of a gallon of gas, in a few minutes the gas escaped along the groove of the director, and, on applying a match, lighted as it escaped. The flame was now extinguished by a moist sponge, and the abdomen opened by a median incision, five inches in length, extending from the umbilicus to near the pubes.

On exposing the peritoneum at the lower angle of the incision, through this membrane there was observed a structure closely resembling an over distended bladder. That this structure was a distended bladder was improbable as the boy had urinated before the anæsthetic was administered. The peritoneum was carefully incised between two forceps and divided upon a grooved director to the same extent as the external incision, and it was then discovered that what appeared to be an over-distended bladder was a coil of small intestine distended with blood to twice its normal size. The whole pelvic cavity was found filled with fluid blood. On withdrawing the small intestine, five perforations near the junction of jejunum and ileum, and within a distance of three feet, were found; four occurred in pairs on the lateral aspect of the bowel, and one at the mesenteric attachment. All the perforations were disproportionately large to the size of the bullet and would easily admit the tip of the index-finger. The intestine, at the point of injury, was covered with a thick layer of recent plastic lymph, and the parietal peritoneum presented all the evidences of a beginning diffuse septic peritonitis. The intestine, which was over-distended by blood-clots for about three feet, was emptied and irrigated with a one-third per cent. solution of salicylic acid, which was used for constant irrigation during the entire time re-

quired in suturing the perforations, which were closed by Czerny-Lembert sutures.

Further examination disclosed four perforations of the mesentery, from two of which quite profuse venous hemorrhage was still going on. The hemorrhage was arrested by ligature *en masse*, by passing a needle, threaded with fine silk, through the entire thickness of the mesentery, on either side of the perforations.

Rectal insufflation of hydrogen gas was repeated so as to ascertain if any other perforations existed, and the gas after it had been gently forced beyond the highest perforation was made to traverse the balance of the entire intestinal canal by drawing forward loops of the intestine and returning them as examined without further insufflation. This procedure was found entirely satisfactory and practical, as the gas on account of its low specific gravity readily entered the highest point in the prolapsed intestinal loop.

The abdominal cavity was irrigated with salicylic acid solution, numerous coagula removed, the toilet completed, a glass drain introduced into the pelvis, and the abdomen closed.

Duration of operation two hours. Patient collapsed, pupils greatly dilated, and almost pulseless in spite of repeated hypodermatic injections of brandy, which were administered when signs of collapse became apparent, throughout the operation. Enema of a teacupful of warm water and two ounces of brandy. Foot of bed elevated and external dry heat applied.

In an hour and a half he rallied somewhat from the operation, but again sank and died at 3 P.M., eight hours after the completion of the operation.

Post-mortem eighteen hours after death (Drs. Steele, Gudden, Gordon). Circumscribed peritonitis present at time of operating, now diffuse; very little fluid in abdominal cavity; several small blood-clots in vicinity of transverse colon. The perforations were all securely closed, and the bullet was found in the soft tissues to the right of the spinal column, between the fourth and fifth lumbar vertebræ, and near the ascending colon. The bullet though only of 22-calibre was oblong and may thus explain the unusually large size of the perforations.

REMARKS.—This case compared with the foregoing furnishes a strong argument in favor of early operative interference in cases of gunshot or stab wounds of the abdomen in which the existence of visceral lesions can be demonstrated by rectal insufflation of hydrogen gas. In the first case, although twelve perforations were found and sutured, and fecal extravasation had taken place, no evidences of peritonitis were found, and the patient recovered. In this case twelve hours intervened between the time the injury was received and the treatment by laparotomy, during which time a septic peritonitis had developed, the extension of which the operation did not arrest, and from the effects of which the patient died.

MEDICAL PROGRESS.

Intra-uterine Injections of Chloride of Zinc.—FRÄNKEL (*Centralbl. für Gynäk.*, No. 37) confirms the good results obtained by Rheinstädter in the treatment of uterine leucorrhœa with injections of chloride of zinc. Especially in gonorrhœal disease of the endometrium has this method of treatment proved effective, which accords with Fritsch's recommendation of vaginal injections of zinc chloride in vulvar and vaginal gonorrhœa. In inoperable carcinoma of the uterus, also, Fränkel uses these injections, as originally recommended by Sims (solutions of 2 : 3), after curetting and applying the Paquelin cautery. After the exfoliation of the chloride of zinc crust healthy granulations usually appear, with a tendency to rapid and firm cicatrization. The main symptoms, hemorrhage, offensive discharge, and pain, are ameliorated and early recurrence prevented.—*München. medicin. Wochenschr.*, September 25, 1888.

Malarial Orchitis.—Cases of this affection have been reported by Dr. Charvot: The first feature of malarial orchitis, and one that seems to be well marked, is its occurrence only in those who have suffered severely from ague. The onset of the inflammation may be noticed during an attack of fever, often in the night, and quite apart from any injury, urethral discharge, or other exciting cause of an epididymitis spreading from the urethra. The inflammation is of an acute and severe type. In a few hours the part becomes greatly swollen, and the disease reaches its height in two or three days, and then somewhat slowly and gradually subsides and passes away. In some recorded cases the local inflammatory phenomena have undergone daily exacerbations and remissions in unison with the body temperature, but Dr. Charvot has not observed this in his cases. Both the body of the testicle and the epididymis are involved in the inflammation, and there is effusion into the tunica vaginalis. The skin of the scrotum is not implicated, and is only rarely adherent to the subjacent tissues, although there is inflammatory œdema of the cellular tissue of the scrotum. The pain is usually very severe, and radiates from the testicle up to the groin and round the loins. Under treatment the pain and inflammatory œdema quickly subside, but the absorption of the inflammatory exudation in the testicle takes place much more slowly, and is followed by more or less atrophy of the secreting substance of the gland. The disease is accompanied by malaise, headache, neuralgia, pinched face, and anæmia, all marks of severe malarial poisoning.

The treatment of this form of orchitis, happily, is not very difficult. A full dose of quinine should be given a few hours before the rise of temperature, and this should be repeated daily until the patient is continuously apyrexial. The beneficent effect of quinine is quickly seen in the fall of the temperature, the abatement of the pain, the lessening of the headache and malaise, and often in the quick subsidence of the scrotal œdema. If its influence is maintained, the swelling of the testicle shrinks, and the gland becomes smaller and softer, with loss of testicular sensibility. No special local treatment is required. The fever which is always associated with malarial orchitis is not symptomatic: it most often precedes, but is by no means in proportion to, the inflam-

mation of the gland, and it yields to treatment by quinine much more quickly than does the orchitis itself. The liability to wasting of the gland renders it important to recognize the nature of this disease as soon as the patient is attacked by it. As a rule, the diagnosis presents no grave difficulties. From gonorrhœal orchitis it is distinguished by the affection of the body of the gland as well as of its epididymis, by the character of the fever, by the history of the patient, and by the very marked influence of quinine given in full doses. It is more closely like the orchitis of mumps; but where there has been no parotid inflammation to assist in the diagnosis, the intermittent or remittent character of the fever, and the failure of the swelling to undergo rapid absorption after the fall of temperature, are sufficient to distinguish it. The effects of a single large dose of quinine are also so well marked in malarial orchitis that in any doubtful case the therapeutic test is of great value. Dr. Charvot has found more difficulty in distinguishing this form of acute orchitis from an acute tubercular affection; but in the latter the epididymis is markedly nodular, and there is a notable tendency toward suppuration. Although the disease is very little known in England, it is yet one worthy of careful study. Patients saturated with malaria often return home to this country with various manifestations of the disease; and our military surgeons, as well as many private practitioners, may find themselves called upon to treat this affection when residing or travelling in foreign climes.—*The Lancet*, Oct. 20, 1888.

Tincture of Phosphorus in Infantile Asphyxia.—Dr. Farici has obtained such excellent results in the treatment of asphyxia, occurring in the course of broncho-pneumonia in children, that he advises the use of the following formula:

R.—Cinnamon water	. .	100 grammes.
Ethereal tincture of phosphorus	. . .	8 drops.
Syrup of ether	. . .	20 grammes.—M.

The dose is a teaspoonful hourly.—*Lyon Médical*, September, 1888.

Sectio Alta Intraperitonealis.—Under this title Rydygier, of Cracow, in the *Przeglad lekarski*, describes a new method for the removal of large calculi from the bladder, which he has successfully carried out. In the high operation for stone, on the one hand is the danger of peritonitis, on the other that of urinary infiltration. The various methods to avoid the first have not proved successful; as cases of Guyon and Dittel show. Suture of the bladder, as recommended on many sides, does not always prevent the second complication; the suture gives way or the wound fails to heal by first intention and the granulations on the edges of the wound are insidiously infiltrated. The ends of the suture left protruding in the bladder in using Brenner's tobacco-pouch suture may furnish the nucleus for a new calculus. It suggested itself to Rydygier that the readiness with which peritoneal adhesions form might be availed in operations upon the bladder. In the present condition of antisepsis he proposes to open the bladder at a point where it is covered by peritoneum. A series of prefatory experiments upon dogs led to the successful performance of sectio alta peritonealis upon a thirteen year old boy in December last, and upon other older patients subsequently. Rydygier thinks the method available for neoplastic operations upon the bladder and for wounds of the lining membrane. The operative incision always unites by first intention.—*Wiener medizin. Presse*, No. 40, 1888.

Constipation with Hemorrhoids.—

R.—Glycerin	. . . .	60 parts.
Soap	. . . .	10 "
Ext. rhei fluidi	. . .	40 "
Essence of chamomile	. .	10 drops.—M.

Use as an enema three times daily.—*Revue de Thérapeutique*, October, 1888.

Tubercular Meningitis cured with Iodoform Ointment.—Five cases of this disease are reported by Warfwinge (*Arch. di Patol. Inf.*, May, 1888) as cured by this treatment. Whatever errors there may have been in diagnosis, the author thinks it hardly possible that he could have erred in all five cases, though he admits that a differential diagnosis between tubercular meningitis and the less grave variety, during life, is very difficult. In all of the cases reported the plan of treatment consisted in first shaving the hairy scalp and then rubbing in upon the skin a quantity of ointment composed of one part iodoform to five of vaseline, the head being then covered with a tarletan hood with an opening for the face. At each daily friction two grammes of this ointment were used, and the treatment was continued from nine to thirty-two days. Moleschott first advised the use of iodoform for internal diseases in 1878, and he successfully treated three out of five cases of tubercular meningitis by applications of iodoform collodion to the scalp. Nillscez and Souders have also each reported a successful case of this disease treated in the same manner.

The author offers the following suggestions based upon his experience in this connection:

1. Iodoform, which does not contain less than 96.7 per cent. of acid, is nearly insoluble in water and in blood-serum, and cannot penetrate the animal economy except through the medium of fatty substances with which it may be combined.

2. It is probable that when it is applied by friction it is received into the subcutaneous adipose tissue, which acts as a vehicle to its transmission. According to Binz, it is broken up, with the liberation of iodine, and this is absorbed and carried along by means of the organic fluids.

3. The iodine, in such cases, will act upon the protoplasm of the cells, both developing and destroying it.

4. This explanation will apply in regard to the treatment of tubercular meningitis by iodoform inunction; in accordance with which the free iodine would be carried by the lymphatics to the surface of the brain.

5. Whatever value be attached to any particular method of rubbing in the iodoform in tubercular meningitis in children, it would seem as if the subject were worthy of the serious attention of the profession.

6. Future experience may show that more rapid results may be obtained by some modification of this method than have thus far been reported. On the other hand, the prolonged use of iodoform is not followed by any accident.—*Archives of Pediatrics*, November, 1888.

The Treatment of Acne.—Dr. Isaac, before the Berlin Medical Society (*München. medicin. Wochenschr.*, No.

39, 1888), related the method of treatment of acne at the clinic of Lassar. The following ointment is applied to the affected parts with a spatula or stiff brush, remaining for a half hour or an hour:

R.—Beta-naphthol . . . 10 parts.
Sulphur. præcip. . . . 50 "
Sapo virid.,
Vaselin. flav. . . . āā 20 " —M.

On the following day, irritation and desquamation are apparent, which are completed at the end of a week. Slight irritation, which occurs at times, is relieved by the use of a drying powder. Oesterreicher has proposed a modification of this ointment which is particularly useful in obstinate cases. It consists in the addition of ten per cent. of camphor and a reduction in the amount of sapo viridis and vaseline to five per cent. This ointment should remain but a quarter of an hour. Isaac yet recommends a paste of resorcin:

R.—Resorcin . . . . 2.5 to 5 parts.
Zinc. oxid.,
Amyli . . . . āā 5 "
Vaselin. flav. . . . 12.5 " —M.

This paste may remain during the day and night, and on the following day is removed with cotton or oil. In about twenty patients thus treated no irritation occurred. The cure is speedy, occurring often in three to five days. —*Medicin. Chirurg. Rundschau*, October 1, 1888.

Salicylate of Soda in Pruritus.—Icard reports the case of a patient who had suffered nine months from intolerable itching of the skin, and had tried remedies innumerable, who was speedily cured by the internal administration of forty-five grains of salicylate of soda daily.—*La Gazette Médicale.*

Antipyrin Rashes.—Dr. C. C. Claremont, at a meeting of the Southeast Hants District Medical Society, read a paper on antipyrin rashes, in which he described two cases which had occurred in his practice during the course of enteric fever. In the first, ten doses of fifteen grains had been given in the course of ten days when the eruption appeared. It came out simultaneously on the abdomen, thorax, back, and limbs in the form of papules, darker, larger and more solid than the spots of enteric fever. There was a considerable resemblance to measles. The eruption developed into enormous erythematous blotches, with much infiltration, their vivid red color being removed by pressure, leaving faint yellow pigmentary discoloration. The rash began to subside on the sixth day, and on the tenth day was only represented by faint coppery maculæ, resembling an old syphilitic eruption. Antipyrin was omitted on the appearance of the eruption. In the second case the drug had been given in fifteen-grain doses, generally twice a day, and omitted altogether for four days. The enteric exanthem had been unusually copious. On the twentieth day of the exhibition of the drug there was a papular erythematous rash on the extensor surfaces of the arms; this spread to the flexor surfaces, and also affected the calves. The antipyrin was omitted. On the fourth day the rash had almost gone, leaving only slight redness and desquamation. The patient had a relapse of fever, and was again treated with antipyrin without suffering from a return of the eruption.

Dr. Claremont stated that antipyrin rash generally was of the papulo-erythematous type, and began on the extensor surfaces of the elbows and knees. It had been described in one case as commencing on the face, and in another as extending to the mucous membranes. Once vesicles had been present. Its most constant characters were its bilateral symmetry and its duration of about five days, irrespective of the continuance or withdrawal of the drug. The entire absence of subjective symptoms was exceptional. A scarlatiniform rash had been mentioned, but Dr. Claremont had been unable to ascertain that it was more than a transient flushing, such as is produced by belladonna.—*British Medical Journal*, October 27, 1888.

The Treatment of Gonorrhœa.—Ehrmann (*Centralbl. für die ges. Therap.*, No. 9, 1888) recommends three per cent. solutions of boric acid or resorcin as the mildest disinfectant injections in the early stage. In the case of resorcin, the injection is made every two or three hours. In general, more than three injections a day are unnecessary. The frequent application of the nozzle of the syringe excites mechanical irritation; and it is not always possible, with frequent injections, for the patient to urinate previously sufficiently to wash out the pus in the urethra. On account of its comparatively high price and its ready decomposition, resorcin is rarely used. Most frequently sulpho-carbolate of zinc is ordered, which exists in colorless, transparent, tabular crystals, efflorescent in the air and slightly soluble in water and alcohol. Though the sulpho-carbolate is a weak astringent and disinfectant, strong solutions are not begun with. As soon, however, as the second portion of urine passed is clear, a solution of sulpho-carbolate of zinc, one part in two hundred, is used. From week to week this is increased to four or five parts in two hundred. Rarely is it necessary to use six or seven parts. This method of treatment has furnished excellent results.—*Medicin. Chirurg. Rundschau*, October 1, 1888.

Treatment of Dyspepsia.—Dujardin-Beaumetz divides dyspepsia into three classes: that caused by excessive secretion of gastric juice, that caused by a deficiency of secretion, and that depending on sympathetic troubles. In that where secretion is deficient, he gives pepsin, toasted bread, *bouillon*, powdered beef, and hydrochloric acid:

R.—Acidi hydrochlorici . . . 4 parts.
Water . . . . . 1000 "
A wineglassful at the ending of meals.

When the secretion of the gastric juice is excessive, the diet is principally vegetable, though slightly cooked eggs are allowed.

In dyspepsia due to sympathetic troubles the diet is strictly vegetable.—*Révue de Thérapeutique*, October 15, 1888.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, NOVEMBER 10, 1888.

GLYCERINE CLYSTERS.

IT is now about a year since glycerine, which has been employed by internal administration for a long time with more or less effect for the relief of constipation, was first recommended for this purpose in the form of enema. Anacker's so-called minimalclysmata (*Deutsche med. Wochenschr.*, p. 823, 1887) and Unger's microclysmata (*Pharmaceut. Centralhalle*, Berlin, 1887, 42), described nearly at the same time, immediately attracted the attention of practising physicians throughout the world. Numerous clinicians have reported the results of their use of glycerine in this manner in hospital and private practice. It is obvious that a condition so influenced as is constipation by individual peculiarities, habit, mode of life, diet, drink, and exercise; a condition frequently in itself a symptom of constitutional or of local disease, is sure to yield uncertain results when subjected to investigation by the numerical method. We may, therefore, reasonably demand more than mere statistics of successes and failures following the administration of minimal clysters of glycerine from those who, as von Vamossy, Seifert, Reisinger, Boas, and Mayer, of Wilkesbarre, have published accounts of their experience with this treatment.

Ullmann, of Vienna (*Centralblatt für die Gesammte Therapie*, August, 1888), has investigated this method of treating constipation with regard to the following points: 1, the general condition of the patient, with special reference to the disease from which he suffered, the state of the digestion, the presence or absence of habitual constipation and the objective phenomena relating to the intestinal canal; 2, the dejections, as regards amount and consistence; 3, the time elapsing between the administration of the enema and the effect; 4, the subjective sensations of the patient, as regards abdominal pain, local irritation, and increase of previous pain; 5, unusual manifestations, as colic, mucus or blood in the dejections; and, finally, 6, the time and consistence of the next following spontaneous evacuation.

Regarding quantity, the result was variable. After 226 injections, the discharge in 71, or 34.4 per cent., was abundant; in 103, or 45.5 per cent., it was incomplete; in 52, or 23.1 per cent., there was either no result or a mere scanty intestinal secretion mixed with the injected glycerine. It was further found that in females and in persons suffering from a tendency to habitual constipation and after repetitions of the treatment the result was in general less satisfactory than in the case of males, in mere transient constipation, as, for example, that occurring in fevers, and in single or infrequently repeated administrations of the glycerine.

The consistence of the discharge was, in 145, or 83 per cent., of the 174 cases in which the treatment was effective, hard, the stools being either formed or composed of masses of scybala; in 22 cases, or 13 per cent., the stools were mushy and unformed; in only 7 cases, or 4 per cent., were they watery. The last occurred in patients subject to diarrhœa.

Subsequent constipation lasting, when untreated, five or six days, occurred in 68 of the 174 instances, 39 per cent. Subsequent diarrhœa occurred in 6 cases, 3 per cent. These were individuals suffering from visceral tuberculosis. And in 3 of them, *post-mortem* examination revealed the existence of tuberculosis of the intestines.

Painful sensations before, during, or immediately after defecation were complained of in only 5 instances—3 cases of recent parametritis, 1 of retroversion of the uterus, and 1 of chronic tuberculous peritonitis. Careful inquiry, however, elicited the fact that a trifling burning sensation in the anus was not infrequent after defecation, but that it usually subsided in a few minutes.

The infrequency of borborygmi, which were spoken of by only 9, or 4 per cent., of the patients, Ullmann ascribes to the same cause as the non-escape of flatus,

namely, the failure of the intestine above the rectum to participate in the response to the activity of the glycerine.

It is in this connection worthy of note that in a majority of the cases in which the glycerine enemata failed, rectal examination and abdominal palpation showed on the one hand a relaxed and atonic condition of the lower bowel; on the other hand, an upper portion of the intestinal tract to be the seat of the fecal accumulation.

In such cases large enemata of water or purgatives administered by the mouth were followed by more or less copious evacuations. The failure of glycerine is explained by the peculiarities of its action. This Anacker ascribes to the powerful irritating effect of the glycerine, due to its avidity for water, upon the mucous membrane of the rectum. This irritation causes a local hyperæmia with fluxion to the mucous membrane and reflex intestinal peristalsis. Reisinger, who found that other substances having avidity for water, as, for example, concentrated saline solutions, gave negative results, concludes that it is not this property of glycerine, but some other peculiar chemical attribute of that substance to which its efficacy in this respect must be ascribed. Unger holds the opinion that the glycerine produces its effects by reason of the profuse hypersecretion which it provokes; and in this opinion Ullmann coincides. The last observer, however, believes that the peristalsis excited is restricted to the lower portions of the large intestine. This opinion is based upon the almost invariable failure of the administration when the rectum is either empty or relaxed, upon the absence of borborygmi, upon the rare occurrence of flatus or colic, upon the immediate cessation of tenesmus so soon as the glycerine has been voided, and, finally, upon the infrequency of repeated liquid evacuations.

As a rule, the action of glycerine is prompt, the result following, in the large majority of instances, in from three or four to fifteen minutes. The dose administered varies from 3 to 6 grammes (that is, from 45 to 90 minims). Ullmann concludes that glycerine thus administered exerts a specific action upon the lower bowel, an action unattended by unpleasant sensations or unfavorable influences; that it is especially available when it is desirable to evacuate the lower bowel promptly, as before surgical operations, in accouchement, for purposes of rectal and vaginal investigations and the like. This method is also available when it is desirable to empty the lower bowel without exciting extensive peristalsis, as in cases of internal hemorrhage, hæmoptysis, painful affections of the abdomen, or when, for any reason, it is undesirable to change the position of the patient in bed. In intestinal obstruction or fecal accumulations in the small intestine or in the upper part of the large intestine, or where constipation is due to acute or chronic catarrhal processes in the small intestine, or to obstruction by gall-stones, glycerine injections are without effect. They are, by reason of the pain which in such conditions they occasion, contraindicated in ulceration of the rectum and painful inflammatory affections of adjacent parts, as acute prostatitis, parametritis, cystitis, and analogous processes.

In habitual constipation, glycerine injections are to be used for occasional relief, never habitually. The amount of irritation which they occasion, as shown by copious serous and mucous discharges containing numerous epithelial cells, indicates a danger that their too frequent use may cause local inflammation or ulceration.

We may add that we have thus employed glycerine with equally satisfactory results in the case both of infants and adults in hollow suppositories of cocoa butter—a more convenient method.

THE DISINFECTION OF INSTRUMENTS AND APPARATUS.

Each succeeding day renders more palpably true the tenet that the fate of a wound, whether it progresses to cure in the natural, ideal manner or wreaks from least to greatest injury upon its unfortunate host, undoubtedly depends, in almost all instances, upon the knowledge, actions, and precautions of the surgeon who may happen to have it in his care. The conscientious surgeon will, therefore, never consider that he has arrived at a millennium of wound treatment until every wound under his hands pursues the most desirable course.

Of the various means at our command for this most invaluable attainment the employment of absolutely sterile instruments and appliances is of import secondary to none. The most complete series of experiments to ascertain the best methods of rendering instruments surgically clean and innocuous are those which have recently appeared in the *Berliner klinische Wochenschrift*, No 35, 1888, from the pen of Hugo Davidsohn. But whilst the deductions which are corroborated by these valuable experiments have long been familiar to us, still they possess especial merit and value in positively deducing

by the only true and scientific method an absolutely reliable, yet safe and simple, process of rendering our appliances free from all varieties of living bacteria and spores.

After experimenting upon an extensive scale and in a most thorough and careful manner, Davidsohn comes to the conclusion that moist heat is by far the simplest, safest, and most certain of microbe- and spore-destroying agencies within our present reach and knowledge. By its application to instruments infected in every conceivable manner he has found that they were invariably rendered sterile in a very short time. In fact, he has proved that all forms of bacteria and spores, no matter where situated—including the hard-dying anthrax bacilli—are invariably deprived of life and harmfulness by simple exposure to moist heat of 212° F. for five minutes. This degree of heat is best obtained by boiling the instruments, apparatus, etc., in a closed vessel—that is, one with a fairly snug-fitting lid, so that the temperature of all portions within may be maintained at an even 212° throughout; for if this precaution is neglected, the upper strata of water will be cooler than those lower down, and only the water actually upon the bottom of the vessel will reach the desired and necessary temperature. Such boiling, if continued for five minutes, he finds amply sufficient for thorough disinfection of even complicated instruments, canulas, catheters, etc., provided that the water fills all canals and hollows and comes in contact with every part.

The perfected process thus evolved which he would recommend for general adoption is as follows: After operation all instruments are to be rinsed well in cold water and scrubbed, and hollow instruments are to be injected and left filled with water. They are then to be actively boiled for five minutes in a closed vessel, care being exercised that no portions project above the surface. Finally, they are to be dried with a sterilized towel and put away in an aseptic place. Before being used again they should be boiled under precisely similar conditions, and used direct from the water when it has become sufficiently cooled. Davidsohn has been unable to discover the slightest harm which this method inflicts upon properly constructed instruments.

THE Boylston medical prize of four hundred and fifty dollars has been awarded by Harvard University to Dr. George H. F. Nuttall, of San Francisco, for a dissertation entitled, *A Contribution to the Study of Immunity*.

THE American Academy of Medicine will hold its twelfth annual meeting at the New York Hospital, 8 West Sixteenth Street, New York, Tuesday and Wednesday, November 13th and 14th.

THE Cincinnati Polyclinic was organized October 31st, with Dr. Charles A. L. Reed, as Dean of the Faculty; Dr. Longstreet Taylor, Secretary, and Dr. R. B. Hall, Treasurer. The Faculty is made up as follows: General Medicine, Drs. Andrew C. Kemper and E. W. Mitchell; Diseases of Children, Dr. H. W. Rover; Diseases of Women, Drs. Rufus B. Hall, Charles A. L. Reed, and Edwin Ricketts; Diseases of the Eye, Dr. Robert Sattler; Diseases of the Throat, Drs. A. B. Thrasher and J. H. Boylan; Diseases of the Skin, Drs. A. Ravogli and Merril Ricketts; Surgery, Drs. Longstreet Taylor and Wallace Neff. The Faculty are almost entirely identified with the three medical colleges, and many of them with the various hospitals of the city. A large clinic has already been built up.

OVER two hundred cases of sickness, caused by eating cheese, have been reported to the Ohio State Board of Health, within a few months, the towns of Urbana and Mansfield contributing about fifty cases each. Grave symptoms, even to complete syncope, appeared in some cases, but there were no deaths.

DR. JAMES CRANE died in Brooklyn, October 13st, aged seventy years, of apoplexy, supervening upon four years of cerebral disease, which had necessitated retirement from professional life for that length of time. He was a native of Newark, N. J., a graduate of Princeton College, a pupil of Dr. George McClellan, and a graduate of Jefferson Medical College in 1839. His medical career was successful and honorable. He was one of the foremost of the health officials of his time, very many of the reforms in the health administration of Brooklyn taking place during his incumbency at the health board. He was twice Commissioner of Health, first holding office in 1866, in the famous and efficient Metropolitan Board which was called into being by the cholera epidemic of that time, and which was the first genuine impulse toward sanitary reform in New York City and vicinity. Forcible and fearless in his official work, he initiated measures for the repression of infectious disease which he lived to see adopted or imitated in many other cities; and his name will be remembered by those who have to deal with the problems of preventive medicine.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, November 1, 1888.

THE PRESIDENT, A. JACOBI, M.D., IN THE CHAIR.

DR. J. LEWIS SMITH read a paper on

SUDDEN HEART FAILURE IN DIPHTHERIA; ITS PATHOLOGY AND TREATMENT.

There is no other disease, he said, in which sudden, unforeseen, and fatal attacks of heart failure occur so frequently as in diphtheria, and no other disease in which physicians (largely on account of these unexpected attacks of weakness of the heart) are so frequently deceived in their prognosis. In most cases of this kind death speedily occurs even when the medical attendant has made a favorable prognosis a few hours previously. The pulse becomes feeble, and abnormally slow or rapid. It is at first usually slow and subsequently rapid; while the respiration is superficial, and the surface becomes pallid and perhaps slightly cyanotic. In the more favorable cases the patient may rally by active stimulation, and, perhaps, eventually recover, or, after some hours or a day or two of comparative comfort he will succumb to a return of heart failure.

In order to give a clear and accurate idea of the clinical history of sudden heart failure in diphtheria, Dr. Smith quoted, with comments of his own, a number of typical cases occurring in the hospital service of M. de Gassicourt, which he said he had related on account of the completeness of the latter's records. In some of these the heart failure occurred early in the course of the disease, and in others during its later stages. M. de Gassicourt met with one recovery to fourteen deaths, and the case which recovered was of special interest from the fact that the heart failure preceded the palatal and other forms of paralysis, instead of being preceded by them, as is ordinarily the case.

Dr. Smith then proceeded to discuss the cause of this sudden loss of power in the heart in diphtheria. Bouchut and Lagrange attributed it to endocarditis; a hypothesis based on the appearance of the free edge of the mitral valve, and sometimes of the aortic valves in addition, which seem to be roughened as if from the presence of minute vegetations. It is a fact, however, that it is very seldom that a bruit or heart signs indicative of endocarditis are observed during life; while after death the surface of the valves and the endocardial surface are usually found to have undergone no appreciable change, such as endocarditis would be likely to cause.

Moreover, the roughened condition of the edges of the mitral and aortic valves upon which this theory was based, has been found with equal frequency in children who have perished with other diseases, and the late Prof. Parrot had expressed the decided conviction that this condition does not have an inflammatory origin, but is an anatomical peculiarity, which originates in fœtal development. De Gassicourt arrived at the conclusion that "diphtheritic endocarditis is extremely rare, as pathological anatomy and clinical observation alike demonstrate," and Dr. Smith therefore believed this theory to be untenable.

Weakening of the heart's action in diphtheria, and sudden death as a consequence, he went on to say, had with more probability been attributed to granulo-fatty degeneration of the muscular fibres of the heart, consequent upon a prolonged and severe attack of the disease; and he quoted Oertel in support of this hypothesis. Such degenerative changes, if occurring in a considerable proportion of the muscular fibres of the heart, would, he said, inevitably render the contractile power of the organ feeble and perhaps inadequate. Still, if we regarded it as a cause of sudden heart failure, it was such probably in certain cases only; for in most instances the weakening of the power of the heart was sudden and during convalescence, at a period, therefore, when degenerative changes were most likely to occur. In most of the recorded cases the contractile power of the heart did not appear to have been notably weakened previously to the attack of heart failure, as probably would have been the case were degenerative changes in the myocardium the sole or chief cause. Furthermore, in typical cases of sudden heart failure the microscope sometimes revealed a perfectly healthy myocardium after death.

The accident had also been attributed to cardiac thrombosis, and among the most strenuous advocates of this theory was Dr. Beverly Robinson, whose thesis on this subject, published in 1871 in Paris, was alluded to by nearly all recent French writers on this subject. But, as several observers had pointed out, the heart clots were identical in appearance and kind with those found in the heart after death from other diseases; there was every reason for the belief that they occurred during the death struggle, and were not the primary cause of the heart failure, but secondary to it. The opinion of most pathologists was, he thought, explained by de Gassicourt in his clinical treatise, "I have often shown you these clots, and I have enabled you to see that they occur equally in children dead of diphtheria and in those who have succumbed to other maladies, in subjects struck with sudden death, and in those who have not been attacked by any sudden casualty. This objection is in itself conclusive. You have been able to see also that the constitution of these clots does not have any of the characters which the most competent authors have assigned to clots formed during life. They are the clots of the agony."

The theory of deficient innervation, or a true cardiac paralysis, Dr. Smith thought the most tenable. It appeared to be applicable to the largest number of cases and afforded the most satisfactory explanation of those cases in which death occurred during apparent convalescence, when the symptoms were fast disappearing with the exception of the palatal or other paralysis, as well as the most satisfactory explanation, also of the occurrence of those obscure cases in which the post-mortem examination had shown an apparently healthy state of the heart. The theory of an arrested or deficient innervation of the heart, furthermore, furnished an explanation of the occurrence of concomitant symptoms in cases of sudden heart failure, such as vomiting, epigastric pain, and dyspnœa or irregular respiration, since the heart derived its innervation from the same source as the lungs and stomach, viz., through the pneumogastric. He felt justified, therefore, in his classification of the forms of diphtheritic paralysis in making a distinct class

having the designation cardiac paralysis, or, to adopt the French expression, cardio-pulmonary paralysis.

He then went on to speak of the etiology of cardiac paralysis. It was, as had been seen, with few exceptions, associated with, and preceded by other forms of paralysis, and it was probable that, in most cases, it had the same pathology and cause. What was true in reference to the cause and nature of palatal and multiple paralysis, and even of abolition of the tendon reflexes, was probably true of cardiac paralysis. Gubler, in his memoir published in 1860–61, attributed paralysis of the velum and palate to disease of the terminal nerves produced by contiguity, or propagation from the inflamed fauces; but this theory was short-lived, for physicians soon perceived that it was inadequate to explain the occurrence of paralysis at a distance from the inflamed surfaces, while palatal paralysis sometimes occurred after cutaneous and other forms of diphtheritic inflammation in which both the fauces and nares remained entirely healthy. Trousseau considered that the real cause of diphtheritic paralysis was the poisoning of the system by the morbific principle which generated the malady, and believed it doubtful whether its mode of action in producing the paralysis would ever be discovered. The microscopic examinations of Charcot, Vulpian, Roger, Damaschino, Buhl, Pierret, Déjeunè, Oertel, and others, established the fact that the peripheral nerves distributed to paralyzed muscles had, in certain instances, at least, undergone degenerative changes. Pathologists had attributed these lesions to a neuritis, and hence the widely accepted theory that the cause of diphtheritic paralysis is a peripheral neuritis. But anatomical changes equally great had been discovered in the spinal cord, especially in its gray matter, and in the roots of the spinal nerves; so that in some cases it was a fact that central lesions occurred, which were quite as extensive and marked as those in the peripheral nerves. Dr. A. Jacobi, seeing the inadequacy of the various theories to explain all cases or forms of diphtheritic paralysis, wrote, in 1860, "It may be positively asserted that diphtheritic paralysis does not in any case depend on one and the same cause."

Dr. Smith then went on to examine, by the light obtained from clinical experience, the prevailing theory that diphtheritic paralysis results from anatomical changes, peripheral or central, or both, in the nervous system, and to inquire whether it was adequate to explain the paralysis as it commonly occurs, whether cardiac paralysis, or the other forms. The following were some of the objections to it:

1. Cases occur in which carefully conducted microscopic examinations reveal an apparently normal state of the nerves supplying the paralyzed part, and of that part of the cerebro-spinal axis from which the nerves arise. Thus, in three cases of typical cardiac paralysis reported by M. de Gassicourt, which had been described in the early part of the paper, the pneumogastric and its bronchus, examined in one case, appeared normal, and in the three cases no lesion sufficient to cause paralysis was found in a careful examination of the medulla oblongata, the central organ of innervation of the heart.

2. Palatal paralysis sometimes occurs as early as the second or third day of diphtheria, and loss of the tendon reflexes as early as the first day; and it seems improbable that a peripheral neuritis, or anatomical changes in the cerebro-spinal axis, such as to cause paralysis, should occur at so early a date.

3. In its commencement, diphtheritic paralysis often exhibits what Trousseau designates mutability, suddenly shifting from one group of muscles to another. It would seem impossible that there should be a sudden recovery from the paralysis, and then, perhaps, on the following day a recurrence of it, if it resulted from degenerative nerve changes, either central or peripheral. A persistent cause should produce a continuous effect.

4. Some of the microscopists who discovered degenerative changes in the peripheral nerves which supply paralyzed muscles, state that some nerve-fibres have undergone complete or nearly complete degeneration, and others partial degeneration, while others still seem to be intact, a condition which would hardly account for the complete paralysis which often exists, for instance, in the velum palati.

5. It has been noted, by both Drs. Sass and William H. Thomson, that diphtheritic paralysis, both motor and sensory, is frequently limited to the parts supplied by a single branch of a nerve, while all the other branches have their normal function. This fact, of not infrequent occurrence, is not, of course, antagonistic to the theory that peripheral nerve lesions cause the paralysis; but it affords a strong, if not conclusive, argument against the theory that central nerve lesions are the cause.

Notwithstanding such objections as these, however, when the lesions referred to are found after death, whether peripheral or central, we naturally inferred that they had a tendency to increase and prolong the paralysis. The present theory relating to the etiology of diphtheria which is gaining acceptance throughout the world, is that the specific germ of the disease acts only locally upon the surface, and that systemic infection occurs through ptomaines, which are produced upon the surface by the agency of the microbes, and enter the system through the lymphatics, or bloodvessels. Even Oertel, who stated, twenty years ago, that he found the micrococcus of the disease in the kidneys and other internal organs, now asserts that he does not find microbes in the interior of the body, but only upon and in the inflamed surfaces in typical cases. If this theory is true, we must attribute anatomical changes in the interior of the body, in the peripheral nerves as well as the cerebro-spinal axis, to the agency of ptomaines, and the ptomaine must be the causal agent, acting directly or indirectly, in diphtheritic paralysis. Dr. William H. Thomson, in his recent paper on diphtheritic paralysis, wrote, "It is quite conceivable that a ptomaine may follow upon the changes which the diphtheritic process sets up in the organism, and thus produce all of its characteristic symptoms. The special tendency of diphtheritic inflammation to cause necrotic and gangrenous lesions lends further support to this surmise."

The ptomaines, Dr. Smith said, sprang into existence suddenly and unexpectedly under favoring conditions, as is seen in the cheese or milk ptomaine, tyrotoxicon; and chemistry, brought to the aid of microscopy, may yet reveal the fact that the common cause of diphtheritic paralysis is a chemical agent acting in some respects, in manner, though not degree, like curare. Clinical facts appear to harmonize best that a ptomaine is the direct cause of the paralysis, especially in cases occurring early and quickly cured; but it would be idle to argue that the

marked degenerative peripheral and central nerve lesions which are so frequently present in those who have died with diphtheritic paralysis, do not prolong and intensify the paralysis, and are in some instances its primary cause.

In speaking of the treatment of cardiac paralysis, Dr. Smith said that it was evident from the nature of the trouble that it must be combated promptly and with the most active remedies. The patient should be kept quiet in bed, with the head low, and alcoholic stimulants administered at once. In sudden seizures hypodermatic injections of brandy act most promptly in sustaining the heart's action. Ammonia, camphor, musk, and electricity are also of service, as well as predigested beef preparations, peptonized milk, and other concentrated foods designed for those with feeble digestion. If the urgent symptoms are relieved by those measures, such remedies should be employed as are useful in other formr of diphtheritic paralysis. In addition to the beef extracts, concentrated foods and alcoholic stimulants, iron and quinine, in moderate doses, are indicated. The use of electricity is suggested by the nature of the attack, though some physicians consider it of doubtful efficacy. If there be reason from the symptoms to suspect the presence of lesions in the central nervous system, the galvanic current, in short sittings, has been recommended in preference to the faradic; while, in ordinary cases, either the direct or indirect current may be employed. Strychnia, however, is regarded by good observers as the most efficacious nerve stimulant in the various forms of diphtheritic paralysis, and he referred to the testimony of Reinhard, Gerasimon, and Henock in its favor. Still, it is a fact that some physicians of experience state that they have not observed any marked benefit from this agent.

The President said that there were several questions of great interest suggested by the paper which he trusted would receive attention in the discussion. Thus, Is the heart failure, which occurs early in the disease, identical with and dependent on the same cause or causes as that occurring in its later stages? Again, Are the cases in which a slow pulse is noted of the same nature as those in which the pulse is quick? Still, again, Is there any difference between those cases of heart failure, which precede and those which follow general paralysis?

Dr. A. L. Loomis said that his experience with heart failure in diphtheria was limited to two cases. Both the cases were well on in convalescence, the trouble occurring on the twentieth day, if he remembered rightly, and in both death took place almost instantaneously. In one of these no autopsy was made, but in the other post-mortem examination showed that the heart cavities were distended with pretty firmly organized clots, while the walls of the heart were in a granulo-fatty condition. There was no appreciable change in the medulla oblongata, and the peripheral nerves were not examined. From his observation and reading he had supposed that diphtheritic paralysis and heart failure are not always dependent upon the some cause or causes. In the early stages of diphtheria it had seemed to him that heart failure is due to the direct action of the poison in the system, whatever that might be; as is, no doubt, the case in other diseases, especially typhus fever, in which sudden death not infrequently occurs from this cause. On the other hand, he had been inclined to believe (although there was not, perhaps, sufficient ground for justifying such an assumption), that in the advanced stages of diphtheria heart failure, when it occurs, was due to a peripheral neurosis.

Dr. A. Caillé spoke of the importance of keeping all patients suffering from diphtheria strictly confined to bed. He said that formerly he had believed that such patients should be encouraged to get up and go into the fresh air if they were strong enongh to do so, but his later experience had convinced him of the great danger of such a course; and he related one of his cases to illustrate this point. In another case which he mentioned, one of diphtheria following measles, heart failure resulting in sudden death was apparently induced by an error in diet. In the absence of her attendants the child partook of a meal of fried clams and cabbage. He also spoke of the importance of sufficient stimulus in every case of diphtheria, as one of the most efficient preventives of heart failure.

Dr. Beverly Robinson said that, so far as he was able to judge, cardiac failure in acute cases, in the majority of instances, is connected with the ante-mortem formation of clots in the heart (especially the right heart), depending on granulo-fatty degeneration of the walls of the organ. When a hospital interne in Paris he had made a large number of autopsies in such cases, and he had never found any lesions of the peripheric nerves. He believed that the condition of the heart, to which he had referred, could be frequently detected during life in acute cases, if properly looked for. Dr. J. Forsyth Meigs, of Philadelphia, was the first to call attention to this feature of diphtheria. In his experience death did not always occur rapidly; the symptoms of heart-failure often continuing for a considerable time before the fatal termination. After death there would almost invariably be found fibrinous clots, particularly in the right heart, and from their character he believed that they were formed ante-mortem and were to a greater or less extent the direct cause of death. In some instances the condition was associated with more or less broncho-pneumonia, and in others not. Altogether, it seemed to him a sufficient explanation of the phenomena noted. In conclusion, Dr. Robinson said that it was his impression that tincture of chloride of iron, in the large doses in which it is frequently given in diphtheria, has a direct effect in the formation of these heart-clots.

Dr. Fruitnight said that he was inclined to believe that the agency of ptomaines, as suggested by Dr. Smith, offers the most plausible explanation of the heart-failure. The condition present is practically a toxæmia, and the treatment must, therefore, be preservative, as well as curative. He differed from Dr. Robinson in his opinion as to the effect of tincture of chloride of iron, and believed it one of the most useful remedies at our command in diphtheria. As it is a medicine given so constantly in this disease, it seemed to him that if it really is the cause of the formation of clots with resulting heart-failure, we should find heart-failure a much more frequent complication than is now the case. It is in the experience of all, he thought, a comparatively rare condition.

Dr. Seibert said that he thought a differentiation ought to be made between heart-failure occurring in the early stages of diphtheria, which he believed to be due

to the direct action of the poison of the disease on the central nervous system, and that occurring in the later stages, which he believed to be brought about by pathological changes in the heart-muscle. He then related some cases of death from heart-failure, and stated that all the patients died from the attempt to make some exertion.

Dr. S. H. Dessau said that he had been accustomed to think that the heart-failure was due to various causes, and it seemed to him probable that when it occurred in acute cases it was due to cardiac thrombosis. As regards the matter of treatment, he thought strychnia was a dangerous remedy on account of the special susceptibility of children to its effects, and he had known of one instance in which this agent was apparently the cause of death.

Dr. Loomis said that Dr. Robinson seemed to be of the opinion that it was the heart-clot that killed. He himself, however, did not believe it was possible to have a clot without antecedent heart-failure. It was the heart-failure that caused death, and the formation of a clot was simply the last act, resulting from the slowing of the blood-flow. As to the alleged effect of the tincture of chloride of iron, he could hardly understand how any remedy whatever could increase the coagulability of the blood beyond which it reached naturally in various diseases.

Dr. Robinson said his personal experience compelled him to differ from Dr. Loomis as regards the formation of clots, and as he had formerly made a special study of this subject, he felt justified in the views which he held. It was a fact that the heart-clot in diphtheria differed absolutely from every other. It was completely fibrinous and formed in layers, and he thought there could be no possible doubt that it existed a long time before death. He did not believe, from his own observation or from any evidence that had been presented to that effect, that heart-failure occurred before the formation of the clot. Direct experimentation had also shown that these clots might be found without any change whatever in the heart structure.

The President said that in the case of Dr. Loomis in which an autopsy was made, death probably resulted from fatty degeneration of the heart. Or, it was possible, that the child had died simply of syncope, the result of sudden anæmia of the brain, brought about by exertion. In pneumonia it is well known that patients sometimes die suddenly from such syncope. Fatty degeneration of the heart, however, is always a sufficient cause of sudden death. There is one peculiar condition that may be mistaken for heart-failure in the later stages of diphtheria, viz.: Paralysis of the muscles of respiration. This condition usually follows the other forms of diphtheritic paralysis; the paralysis, as a rule, affecting first the throat, then the muscles of accommodation, then the extremities, and, finally, the respiratory muscles. Paralysis of the latter is characterized by shallow respiration, with a great deal of resulting dyspnœa and rapidity of the heart's action. In such cases electricity, repeatedly applied, and strychnia in full doses, are very beneficial. The strychnia should be given hypodermatically, the one-hundredth of a grain of the sulphate every one, two, three, four, or five hours, according to circumstances. Such a case as that referred to by Dr. Dessau he did not think should prevent our using this remedy, as there is always more or less danger connected with the use of any poisonous agent, and some individuals are peculiarly susceptible to the action of special drugs.

It is impossible to say which of our diphtheritic patients are going to die of heart-failure; but we do know that in diphtheria there is such a tendency, and hence it is our duty, in every instance, to do all that we can to prevent such an accident. The indications are to save the strength of the patient by feeding and tonics, and especially to fortify the heart by means of alcohol and such agents as digitalis, sparteine, and strophanthus. In every case of diphtheria we have to deal with sepsis, and alcohol is, therefore, of the highest possible advantage. He believes that no case of this disease can be injured by alcohol, and even the most courageous practitioners often err in giving too little of this invaluable agent. If the choice were given him between alcohol and all other remedies in diphtheria, he would undoubtedly select the former as offering the best chances for the patient. In brief, then, the indications are to save the strength, combat sepsis, and fortify the heart.

Dr. Smith said, in bringing the discussion to a close, that since the stomach and lungs, as well as the heart, are affected, the inference is that the cause of the trouble is some affection of the nerve supplying these three organs, the pneumogastric. It is a fact that a certain proportion of patients attacked with heart-failure recover, and that in some of those who died there is for a time an amelioration of the symptoms; and it seemed to him that this would not be possible if the trouble were due to heart-clot, which would undoubtedly be a permanent condition, unaffected by any treatment that could be adopted. It was also a fact that paralysis of some form almost invariably precedes the heart-failure, and this would seem to indicate that the latter is due to the same cause as the paralysis.

PHILADELPHIA ACADEMY OF SURGERY.

Stated Meeting, October 1, 1888.

R. J. Levis, M.D., in the Chair.

Dr. J. Ewing Mears reported the following case of

RADICAL CURE OF INGUINAL HERNIA.

James B., aged forty years, laborer, was brought to the hospital June 4th suffering from strangulated inguinal hernia. Had had hernia since he was six years of age. Had always worn a truss, removing it every Saturday evening and reapplying it Monday morning. Removed truss June 2d as usual, with resulting protrusion, which he failed to reduce. A physician was called in, and after making taxis for a few minutes, failed to reduce. He recommended the patient to St. Mary's Hospital for operation. Dr. Mears was summoned, and after employing taxis succeeded in partially reducing the hernia. There was slight vomiting after this (not stercoraceous).

7 P.M. Patient covered with sweat; temp. 101° F., pulse 100; has a great deal of pain. There was a good deal of swelling in inguinal region, due either to inflammation or recurrence of the hernia; most likely the latter.

Dr. Mears examined the patient, and decided to operate.

An oblique incision about three inches in length was made, the various layers divided, and the contents, as diagnosticated (omental), exposed. The constriction at

the internal ring was divided by the hernia knife, the omentum drawn down and ligated in six equal segments with carbolized silk; the last ligature, after ligating its own segment, was passed around the entire mass. The omentum was next divided, and what was esteemed to be one-quarter of it was removed. The stump was then dropped back into the cavity of the abdomen. The sac was next dissected up from its adhesions, ligated in two places and divided; the upper part was transfixed into the ring by means of a harelip pin, the lower part was dropped into the scrotum. In tearing the sac from its adhesions there escaped about f℥j of clear straw-colored serum. The operation was strictly antiseptic. Only two wire sutures and three of catgut were needed to close the wound. There was slight tympany in the evening.

The wound healed with great promptness, and the sutures were removed on the fifth and sixth days. An attack of diarrhœa delayed the convalescence slightly. Two weeks and a half after the operation the patient sat up, and was discharged six days later. Dissection of the hernia, at the time of the operation, showed it to be congenital in character and the method of dealing with the sac, by double ligature and section, provided a vaginal tunic for the testicle. The proximal stump of the divided sac was twisted and transfixed by a long pin, and this secured in position in the internal ring, forming a barrier to further omental or intestinal descent. As is usual in these cases, a small knuckle of intestine accompanied the mass of omentum.

Dr. William Hunt said that in these cases some time must elapse to decide whether the cure is permanent. There is no doubt about the dense and strong union of *serous* surfaces, and based upon this, he made a suggestion as to a radical cure for hernia. He did not know whether it was new or had ever been tried. In these days of laparotomy upon both sexes, it is reasonable to suppose that a patient might come under the surgeon's hands who is at the same time a subject of hernia. Let the surgeon then take the opportunity of pulling the hernia in from the inside and stitch the broad serous surfaces at the hernial opening together, taking care of the cord, if the hernia is at that point. The result might develop whether it would be justifiable to do this operation for its own sake.

Dr. C. B. Nancrede thought that in these operations for the radical cure of hernia, it would be advisable to unite the parts with something that will remain permanently, such as silkworm-gut. This is non-absorbent and non-absorbable. A few months ago, in operating for a ventral hernia, where it would have been impossible to get anything like a plug of inflammatory matter, he closed the opening with three silkworm-gut sutures. The result was perfect. He thought this would be better than simply trusting to deposit of inflammatory matter.

In regard to the use of a truss after these operations, there was published some six months ago a *résumé* of a large number of operations, and the conclusion reached was that a truss had better be dispensed with.

Dr. R. J. Levis said that as far back as twenty years ago the operation for the radical cure of hernia was quite a subject of discussion. He performed quite a number of operations by the invagination plan, in which peculiar instruments were employed. All of these cases proved failures. In this operation a plug from the surrounding tissue, perhaps the size of the end of a finger, was introduced into the ring and the plug closed in. He also operated in other ways, employing both the operation of Wutzer, Wood, and of McDougal. Our operations are now performed on a different plan. If there were any difficulty in bringing the columns of the ring together, he did not see any objection to freeing them from their lateral attachments in order that they may be approximated. His confidence would be in some means of holding the parts together until united.

Dr. Mears said that operations for hernia have taken a new departure since the work of Macewen and of Ball, of Dublin. He thought that we may now say that our operative work in regard to hernia is almost perfect, whether we adopt the method of Macewen or that which he carried out in this case. In a case presented to the Academy recently, and operated on by Macewen's method, in which the ring was carefully sutured, the hernia returned. What is needed and what is endeavored to be accomplished by the injection of infusion of oak bark in Heaton's method, is a mass of lymph to plug the opening and form a barrier to the descent of the hernia. Macewen plugs up the opening by tucking up the sac. In the method employed in this patient, the important point is to pull the sac down until you get that which is loose, and the finger may be used to loosen it around the ring. Then by transfixing this and fastening it in the opening a plug is secured. Different views have been entertained as to the advisability of removing the redundant portion of the sac or allowing it to remain. In the case presented, the hernia being congenital, the lower part of the sac was allowed to remain, forming a tunica vaginalis.

In this case he directed the patient to wear a Spica bandage with a compress after the operation. A truss, especially where it makes strong pressure, has a tendency to cause absorption of the inflammatory mass. All that is required is a simple support for a short time. This may be furnished either by a light truss with a broad pad or by a bandage.

MONTREAL MEDICO-CHIRURGICAL SOCIETY.

Stated Meeting, October 19, 1888.

The President, William Gardner, M.D., in the Chair.

Drs. George Ross and F. J. Shepherd reported a case of

PERFORATING APPENDICITIS

in which laparotomy was performed.

Dr. Ross gave the following history of the case: On the 4th inst., first saw the patient in consultation with his attending physician, who had first visited him three days previously. The patient was a healthy lad, aged seventeen. He had always enjoyed good health with the exception of some three or four attacks of so-called colic which had occurred within the past two years. These attacks were all very similar, and consisted of a somewhat sudden pain in the lower part of the abdomen and in the *left* side, not very severe and always soon relieved by a hot application and a mild anodyne. The attacks were attended by vomiting. The following day a dose of castor oil was given, and then the boy appeared quite well again. He was never away from his work on account of these attacks for more than two days. In the

intervals he suffered from no digestive disturbance of any kind, the fecal evacuations being quite normal.

Early in the morning of the first he awoke suffering from violent pain across the belly, chiefly in the middle zone and toward the *left* iliac fossa. Vomiting soon came on and was several times repeated during the day. The attack was looked upon as similar to those previously suffered from and was treated in the same way. Opium and poultices were prescribed by the medical attendant.

Dr. Ross first saw the patient four days later. At that time the face had the characteristic abdominal expression, but was not specially anxious-looking. Color good. He complained of great pain in the lower part of the abdomen and on the *left* side; no pain on right side. Flatulence was considerable and the belly was moderately distended, chiefly in its lower half; parietes very firm and resisting; tenderness not great, but well marked, chiefly in the hypogastric, umbilical, and *left* iliac regions. Pressure was better borne in the right iliac fossa than in almost any other part, and palpation of that region failed to detect any deep-seated fulness or resistance. Vomiting was frequent. The evening previous the bowels had been moved by an enema. Pulse 120 and weak, temperature 98°.

The diagnosis lay between an acute obstruction and an acute peritonitis, the latter view being favored by Dr. Ross. The cause of the peritonitis was the difficult point to decide; the sudden onset and rapid progress of the case suggested perforating appendicitis, and this was considered probable. The history gave some support to this idea, the difficulty being that the pain had always been referred to the left side, and on this side was also the greatest degree of tenderness. The ultimate diagnosis was acute purulent peritonitis depending on some previous disease in the lower part of the abdomen and that this might be an appendicitis, but the evidence on this point was inconclusive.

Dr. Ross gave it as his opinion that the boy would not live twenty-four hours if unrelieved, and strongly advised laparotomy. He fully realized the fact that four days had already elapsed and that the peritonitis was very extensive, and that in consequence the chances of relief by operation was very small. The boy was removed to the General Hospital and, after consultation with Drs. Shepherd and Bed, laparotomy was decided on.

Dr. Shepherd said that when he saw the case with Dr. Ross, the patient was in a very helpless condition; he had a pulse of 150 and of much volume; vomiting was continuous. There was no tenderness on deep pressure in the iliac region, nor was there any fulness. The only very painful point was a little below and to the left of the umbilicus. It was decided to give the patient the very small chance offered by operation.

An incision some two inches long was made in the median line below the umbilicus and two fingers introduced; nothing could be felt but distended intestines, and the cæcum could not be reached, so the incision was enlarged and the hand introduced; no collapsed intestine could be felt, but quantities of lymph covered the intestines, and some fetid pus escaped from the wound; the left iliac region was explored, the appendix was felt hanging over the brim of the pelvis, and was apparently normal, though somewhat distended. For purposes of further exploration some of the intestines were drawn out of the abdomen and the cavity washed out with hot water. A large quantity of pus and lymph was evacuated from the bottom of the pelvis. In order to return the distended intestine an incision was made in it to allow the gas to escape; this incision was closed by Lembert sutures. The abdominal wound was now closed, a glass drainage tube being left at the lower end. At the end of the operation the boy was much collapsed and his pulse had failed markedly. He rallied somewhat but died next morning. After the operation there was no more vomiting.

An autopsy was made by Dr. Lafleur, who found that the cause of peritonitis was a perforation of the appendix. This appendix was found hanging over the brim of the pelvis, and it was in a gangrenous condition. It was folded up on itself, the perforation was situated within the fold and could not be seen until the parts were dissected out; to the feel, the appendix was normal. There was a great quantity of lymph on the intestines, and in the true pelvis the folds of intestines were glued together in every direction.

Dr. Shepherd remarked that, although he had examined the appendix at the time of the operation with his fingers he had not seen it, and that this case taught him that in cases of general peritonitis the appendix should always be examined by sight, even if the history and symptoms of the case do not point to this part as being the origin of the affection. If the cæcum and appendix cannot be brought to the surface at the median incision, they should be examined through an incision made in the left iliac fossa. The position of the appendix, viz., pendent in the cavity of the pelvis, explained in this case the absence of local symptoms; although the pelvis was examined before operation per rectum, nothing was made out. Dr. Shepherd also remarked that in these cases of perforating appendicitis in which the peritonitis was diffuse from the first operation, gave much less hope of cure than when there was from the outset a distinctively localized area of inflammation, characterized by the existence of a tumor.

Dr. Ross urged strongly the importance of early laparotomy in these cases, and said that operation should not be postponed beyond the third day. In this case, operation was not undertaken until the end of the fourth day, and consequently but little good could be expected from it.

Dr. Roddick asked Dr. Shepherd whether, if he had recognized the lesion in the appendix, he would have excised it, and would the result have been different.

Dr. Mills said that the position of the appendix was peculiar and might have caused a diminished circulation and finally strangulation; there was no doubt that the position favored the necrotic process.

In reply to Dr. Roddick, Dr. Shepherd said that if he had made out the gangrenous condition of the appendix he would have excised it, but that he did not think this would have had any influence on the result.

Dr. Harvey, of Calcutta, made a few remarks on the objections to laparotomy prevalent among the natives of India, and said that it was very rare to get a native to consent to any new operation. He related a case which had come under his observation, of perforation of the appendix due to a lemon seed.

Dr. Wm. Gardner related a case in which he had lately performed

ABDOMINAL SECTION

at the request of Drs. Rodger and England. The patient was a lad aged sixteen, who suffered from severe abdominal pain and vomiting a few days before; this was relieved by morphia, and in a day or two he was able to return to his work. When seen by Dr. Gardner he had very severe abdominal pain, vomiting, constipation, and marked distention of the abdomen. There was also an elastic swelling the size of a duck's egg in the region of the right inguinal canal. On examining the scrotum only one testicle (the left) was found. There had been a suspicion of strangulation with peritonitis, and the patient had been put under ether without result. So it was decided to open the abdomen, and this was accordingly done.

An incision was made long enough to admit two fingers; on incising the peritoneum a quantity of turbid serum escaped. All the ordinary hernia regions were examined and nothing found. The swelling in the inguinal canal was in the abdominal wall and extra-peritoneal; nothing else being found, the wound was closed.

The symptoms were much relieved for three or four days, then the abdominal distention began to increase and became very marked on the eighth day. However, the bowels began to act freely and the boy rapidly recovered, and was now quite well; the swelling in the groin had completely disappeared.

DR. BELL exhibited specimens from a

CASE OF SEVERE SYPHILIS

which had died from tuberculosis of the lung. The syphilitic disease in this case was very destructive, causing extensive ulceration of palate and larynx. The nose had disappeared. In the brain were spots of softening, due probably to thrombosis. The patient first contracted syphilis in 1886, and never commenced treatment until 1888.

DR. RODDICK exhibited two specimens of

CANCER OF THE LOWER JAW.

The first had occurred in a man aged forty-five. The growth commenced in the gum near the first molar tooth some months before, and rapidly spread to the bone and cheek. Half the lower jaw and a portion of the cheek were removed. The glands were only slightly enlarged and not infiltrated; the growth was epithelioma.

The second case occurred in a man aged sixty-five. The disease first appeared on the lower lip some eighteen months before, and rapidly involved all the soft tissues as far as the chin; the growth was adherent to the bone and of great density and hardness. The affection was never painful. The submaxillary lymphatic glands were involved. The growth and the portion of lower jaw to which it was adherent were removed. The growth proved to be epithelioma.

EXCISION OF KIDNEY.

DR. GARDNER exhibited a tumor, which he believed to be the left kidney, removed some days before by abdominal section from an unmarried woman of twenty-eight years, who had first noticed the tumor two and a half years previously. It had grown slowly, and had been moderately painful. On examination it appeared to be the size of a child's head, was hard, nodular, painless, and was so movable that it could be shifted to any part of the abdominal cavity from its ordinary position on the left side. When the patient was on her back the lower end of the tumor could be felt through the vagina. It could not be felt or pressed into the left lumbar region. Percussion showed it to be surrounded by intestine. The tympanitic note over it was unmistakable in the left loin. The patient was watched for eight days before operation. Pus was constantly present in the urine; she had night-sweats, but no rise of temperature.

At the operation the tumor was found to be behind the mesocolon, and the descending colon was over its outer aspect. The peritoneum over the tumor was incised, and the tumor was then easily shelled out. The attachments were at its upper end, and seemed to be the blood-vessels and ureter. The operation was completed by gathering the edges of the capsule together, and including them in the abdominal sutures. A glass drainage tube was inserted at the lower end of the wound; this was removed at the end of forty-eight hours. Her progress was uneventful, and now, at the ninth day, recovery is assured.

The tumor on section was found to be moderately firm, the surface grayish-white and fibrous. The growth was loculated; some loculi contained pus, others a yellowish transparent fluid. Urine was secreted plentifully from the first; the first two specimens contained blood, but no pus; since then there had been a little pus in the urine. Dr. Gardner thought that the absence of pus from the urine after the operation was conclusive evidence that the tumor was the kidney.

DR. RODDICK asked Dr. Gardner whether he would have performed the median incision if the diagnosis of kidney tumor had been made before operation.

DR. SMITH congratulated Dr. Gardner on the success of this operation, and said he was glad to see the gynecologist wresting further territory from the surgeon.

DR. SHEPHERD asked Dr. Gardner if it was not usual, in cases of removal of kidney by median abdominal incision, to drain through the loin. From the description given by the reader of the paper, the kidney removed appeared rather an anomalous one. All the vessels entered its upper end, and the ureter could not be distinctly made out. The tumor, if kidney, was apparently functionless.

DR. GARDNER, in reply, said that for such a tumor the abdominal incision was the best, the tumor was so movable and it could not be felt at all from the lumbar region. He was aware that some surgeons recommended draining through the loin in such cases, but he thought where the enveloping peritoneum was so loose, as in this case, and could so easily be brought to the surface and drained through the abdominal wound, the method adopted by him was preferable. He had handed the tumor over to Dr. Lafleur for examination and report.

DR. RUTTAN exhibited for Dr. deW. Smith, of British Columbia,

A LARGE GALL-STONE

which had been removed from the intestines after death, having produced fatal obstruction. The stone must have ulcerated through the gall-bladder into the duodenum as its size precluded the possibility of its passing successfully through the common duct. There had been no previous history of gall-stone.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, October 10, 1888.

THE PRESIDENT, J. SOLIS-COHEN, M.D., IN THE CHAIR.

DR. JAMES K. YOUNG exhibited the

MORTON OPHTHALMOSCOPE,

which presents some new features of interest. It is made by Pickard & Curry, London, and as an instrument is well balanced, fits the eye well, and as a piece of mechanism is perfection itself. It is a modification of the Gower's ophthalmoscope, as are all modern English instruments, but in the position and movement of the lenses differs from this and all others. The Rekoss disk is there replaced by an elliptical trough containing the lenses. These are simply confined in the channel, are unattached to each other, and are moved by a wheel below, and pass around a wheel above.

In this respect it resembles the Couper instrument, in which the lenses are attached to one another as an endless chain, but is an improvement in the right direction. It has, in all, thirty-three lenses. In the trough are eighteen concave lenses from —0.5 to 30 D. Eleven convex lenses from +0.5 to 12 D., and on the disk has four additional lenses, a — 10 D. and — 50 D., and a +0.5 and + 20 D. These admit of as many combinations as any instrument he was familiar with.

It has three mirrors, a small concave mirror of about 6 cm. focal length, fastened to a collar, a large concave mirror of about 29 cm. focal length, and a plane one. These are all attached, and the apertures come readily over the sight-hole. It has below the index dial a pupillometer, which adds to the usefulness of the instrument. It fits accurately into a rosewood case, and has a convex lens for the indirect method.

NEWS ITEMS.

The Origin of the Yellow Fever Epidemic.—At the meeting of the Virginia State Medical Society, held at Norfolk last week, Surgeon-General Hamilton, of the Marine-Hospital Service, gave the following account of the manner in which the now-prevailing epidemic of yellow fever was introduced into this country, the details of which, he said, had been secured at great cost to the Government and which have not as yet been published:

Last year the yellow fever appeared in Key West in the family of a restaurant keeper by the name of Baker. It appears that a family of Bolios, who had kept a hotel in Havana in various places, the last being called the Quinta-Avenida (Fifth Avenue) Hotel, unfortunately for Florida, emigrated to Key West. Their household effects, under the regulations governing the regular line of steamers, could not be shipped by them, so they shipped these effects, consisting of bedding and various articles of furniture, by an irregular "tramp," not now running, called the "Cochran." There was no objection officially made at Key West, as there was neither Government nor local quarantine, and the articles were landed and stored above Baker's restaurant. The Baker family died of the fever, and thus the fever started, and rapidly became epidemic.

The Government, under the operation of that section of the statutes forbidding interference with local authorities, did nothing except that, on request of the Governor to aid the local board, they established a dispensary and paid the expenses of the city hospital. To assist in the speedy depopulation of the city a refuge camp was established at Egmont Key, at the mouth of Tampa Bay. No case from Egmont communicated the disease. The first cases in Tampa were kept secret from August to October 21st. A family of Italians by the name of Turk, fruit-dealers, brought the fever into Tampa. The steamers had refused, under orders from the Hillsborough County Board of Health, to bring fruit from Havana or Key West. These Italians finding it impossible to continue in business, set up a smuggling line and brought fruit by way of Punta Gorda Bay and overland to Tampa. For this purpose the man Turk and his assistant Peep, or "Pete," made frequent surreptitious visits to Key West while the disease was there epidemic, and blankets were purchased in the infected city and used while on the overland trip, and brought to Tampa. It is a significant fact that the whole family of the Italians were the first taken sick, and that they were not publicly known to have been out of the town, although the fact is now known. The measures taken by the Government were simply to conform to the wishes of the Governor to aid the Hillsborough County Board of Health.

The duty of preventing the spread of the disease was undertaken by the Florida State Protective Association, an organization consisting of one representative from each County Board of Health, under the presidency of Dr. King Wyley, of Sandford. In December the Association raised the quarantine against Tampa. The County Board of Health asserted that the disease had disappeared, but unfortunately the disease had not been stamped out, and although the cases of fever lingered all winter in Tampa, its existence there was bitterly denied. From Tampa the disease spread to Plant City, Manatee, and other places, and it is now believed that the fever was at Jacksonville as early as February. Dr. Guitéras, of the Marine-Hospital Service, an acknowledged expert, says that in his judgment at least two of the cases of "society" fever, of which there were over thirty reported in Jacksonville in that month, had the well-marked clinical history of yellow fever. Nine of these cases died. Dr. Potts treated cases in Bay Street in June, and there were probably cases continuously until the formal announcement was made. He said that so-called isolated cases had been reported at Jacksonville after the case in Bay Street had been treated in June by Dr. Potts, but that the local authorities denied the presence of an epidemic, and placed a guard around each case. This state of things existed until August 16th, when the spread of the disease in Jacksonville became so great, cases springing up at various points in the city, that could not be traced to any of the so-called isolated cases, that the authorities had to declare the disease epidemic.

Dr. Hamilton said that the disease had been introduced in Decatur, Ala., by a man who had gone from Jacksonville while all of the cases in that city had been reported under guard. His ticket had been from some point outside of the infected city, and consequently he was not denied admittance. The doctor said the fever had been introduced into Gainesville and Fernandina by baseball players, who had played a game of ball in Jacksonville before the epidemic nature of the disease had been declared, and then returned to these cities.

Dr. Hamilton went on to explain the Government work at Camp Perry, and said that since its establishment there had been only one death from yellow fever in the fever hospital at the camp. He said that the experience of the physicians at the camp went to show that five days was the incubative period, and that when persons had been in the camp for that length of time and did not develop the disease, there was no danger of their having it. No person having spent ten days in the camp had developed the fever after leaving the station.

He spoke of the lack of local inspection at Tampa, where the disease first appeared this season, and said that if the first cases had been reported there would probably have been no epidemic, and he also said that he had proof to show that when the case of McCormack was reported as the first in Jacksonville, that the fever was then epidemic.

He also stated that while the fever was raging at Key West he, at the request of several health officers, had prepared a bill providing for the establishment of a State Board of Health, but it was laid on the table by the Florida Legislature through motives of false economy. He concluded by saying that the inspection of Florida cities, ordered by the Government, had developed the fact that the yellow fever was epidemic in both Enterprise and Fernandina.

Fatal Accident to a Physician.—Dr. R. Leonard, of Mauch Chunk, a prominent physician of Carbon County, while walking home from a visit to a patient, early on the morning of the 26th ult., was struck by a passing train and killed. Dr. Leonard was active in the local medical societies, was President of the Lehigh Valley Medical Association in 1884, and a member of both the State and National Society.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM OCTOBER 30 TO NOVEMBER 5, 1888.

BAILEY, ELISHA J., *Colonel and Surgeon.*—Detailed for duty on the Army Retiring Board, to meet at San Francisco, California, for the examination of such officers as may be ordered before it.—Par. 3, *S. O. 253, A. G. O., Washington,* October 30, 1888.

COCHRAN, JOHN J., *Captain and Assistant Surgeon.*—Detailed for duty on Army Retiring Board, to meet in San Francisco, California, for the examination of such officers as may be ordered before it.—Par. 3, *S. O. 253, A.G. O., Washington,* October 30, 1888.

NORRIS, BASIL, *Lieutenant and Assistant Surgeon.*—Will be relieved from duty in the Department of the Columbia, by the commanding general of that Department, and will report in person on or before November 14, 1888, to the commanding general Division of the Paeific, for duty as Medical Director of that Division and of the Department of California.—Par. 14, *S. O. 255, A. G. O., Washington,* November 1, 1888.

By direction of the Secretary of War, EDWARD P. VOLLUM, *Lieutenant-Colonel and Surgeon,* on being relieved from duty as Medical Director Department of Texas, by Lieutenant Colonel Joseph C. Baily, Assistant Medical Purveyor, under War Department Order dated October 31, 1888, S. O. 255, A. G. O., will repair to New York City, assume the duties of Acting Assistant Medical Purveyor, and take charge of the medical purveying department at that place.—Par. 2, *S. O. 255, A. G. O., Washington,* November 1, 1888.

ALEXANDER CHARLES T., *Lieutenant-Colonel and Surgeon.*—Is relieved from further duty in the Department of Dakota, and will report in person to the commanding general Department of the Columbia, for duty as Medical Director of that Department.—Par. 14, *S. O. 255, A. G. O., Washington,* November 1, 1888.

BAILY, JOSEPH C., *Lieutenant-Colonel and Assistant Medical Purveyor.*—Is, at his own request, relieved from the charge of the medical purveying depot in New York City, and is, by direction of the President, under the provisions of the Act of Congress approved June 23, 1874, assigned to duty as Surgeon in the Medical Department. He will report in person to the commanding general Department of Texas, for assignment to duty as Medical Director of that Department, to relieve Lieutenant-Colonel and Surgeon E. P. Vollum.—Par. 1, *S. O. 255, A. G. O., Washington,* November 1, 1888.

By direction of the Secretary of War, leave of absence for two months, to take effect on the completion of his present duties, is granted to HENRY MCELDERY, *Major and Surgeon* (U. S. Army).—Par. 3, *S. O. 256, A. G. O., Washington, D. C.,* November 2, 1888.

WEISER, DANIEL, *Captain and Assistant Surgeon* (U. S. Army).—Died at Fort Sill, Indian Territory, October 30, 1888.

HOFF, J. VAN R., *Captain and Assistant Surgeon.*—Is granted leave of absence for one month, with permission to apply for an extension of one month.—*S. O. 134, Headquarters Department of the Missouri, Fort Leavenworth, Kansas,* November 1, 1888.

By direction of the Secretary of War, JOHN J. COCHRAN, *Captain and Assistant Surgeon,* is relieved from temporary duty at Headquarters Division of the Pacific, and will report in person to the commanding officer Fort Adams, Rhode Island, for duty at that post.—Par. 2, *S. O. 256, A. G. O., Washington,* November 2, 1888.

By direction of the Secretary of War, NORTON STRONG, *Captain and Assistant Surgeon,* is relieved from duty in the Department of Arizona, and will report in person to the commanding officer Fort Schuyler, New York, for duty at that post, and by letter to the commanding general Division of the Atlantic.—Par. 4, *S. O. 255, A. G. O., Washington,* November 1, 1888.

OWEN, W. O., Jr., *Captain and Assistant Surgeon* (Fort Leavenworth, Kansas).—Will proceed at once to Fort Sill, Indian Territory, and report to the commanding officer, for temporary duty at that post.—Par 1, *S O. 133, Headquarters Department of the Missouri, Fort Leavenworth, Kansas,* October 30, 1888.

GLENNAN, JAMES D.—Appointed Assistant Surgeon (U. S. Army), with rank of First Lieutenant, to rank from October 29, 1888.

BRADLEY, ALFRED E.—Appointed Assistant Surgeon (U. S Army), with rank of First Lieutenant, to rank from October 29, 1888.

By direction of the Secretary of War, JAMES D. GLENNAN, *First Lieutenant and Assistant Surgeon,* recently appointed, will repair from this city to Willett's Point, New York, and report in person to the commanding officer of that post for duty.—Par. 3, *S. O. 255, A. G. O., Washington,* November 1, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING NOVEMBER 3, 1888.

GIHON, A L., *Medical Director.*—Ordered to Naval Hospital, Brooklyn, New York.

TAYLOR, JOHN Y., *Medical Director.*—Detached from Naval Hospital, New York, and ordered to Examining Board.

HUDSON, ADRIAN, *Medical Inspector.*—Promoted to Medical Director.

BRADLEY, MICHAEL, *Medical Inspector.*—Promoted to Medical Director.

BATES, NEWTON L., *Medical Inspector.*—Promoted to Medical Director.

WOOLVERTON, I., *Surgeon.*—Promoted to Medical Inspector.

WHITE, C. H., *Surgeon.*—Promoted to Medical Inspector.

WOODS, G. W., *Surgeon.*—Promoted to Medical Inspector.

DUBOIS, F. L., *Surgeon.*—Promoted to Medical Inspector.

COOKE, G. H., *Surgeon.*—Promoted to Medical Inspector.

WELLS, HOWARD, *Passed Assistant Surgeon.*—Premoted to Surgeon.

BERTOLETTE, D. N., *Passed Assistant Surgeon.*—Promoted to Surgeon.

GAINES, J. H., *Passed Assistant Surgeon.*—Promoted to Surgeon.

DERR, EZRA J., *Passed Assistant Surgeon.*—Promoted to Surgeon.

STEPHENSON, F. B., *Passed Assistant Surgeon.*—Promoted to Surgeon.

ORIGINAL ARTICLES.

THE RELATION OF ALBUMINURIA TO LIFE ASSURANCE.[1]

BY JAMES TYSON, M.D.,

PROFESSOR OF GENERAL PATHOLOGY AND MORBID ANATOMY IN THE UNIVERSITY OF PENNSYLVANIA, ONE OF THE PHYSICIANS TO THE PHILADELPHIA HOSPITAL, ETC.

IT is not unusual to hear that medical examiners of life insurance companies have passed candidates who are the subjects of well-established and, it would seem, easily recognized kidney disease; but it may occasion surprise to hear it asserted that a certain number of good risks are lost to companies by the indiscriminate rejection of all cases of albuminuria. This, however, I believe to be strictly true, and it is the object of this paper to point out these, and to discuss the question as to whether it is possible to save them. The importance of such discrimination is manifest, since it will be admitted by every one that no system of life insurance is perfect which does not include all who are essentially healthy, as well as exclude those who are not.

The terms normal or physiological albuminuria, functional, intermittent, cyclical, and alimentary albuminuria have become familiar to every reader of medical literature. They all refer to an albuminuria which is associated with an otherwise apparently healthy organism. No one of them conveys an accurate notion of what is meant, but the term I prefer is *functional* albuminuria.

The words "normal albuminuria" literally mean that the albuminuria itself is normal, which is not intended. The term "intermittent" implies an intermission, which does not always occur, while an albuminuria acknowledged to be abnormal may also be intermittent. The term "cyclical" supposes a periodicity in the intermissions which often occurs, but is by no means constant. Alimentary albuminuria represents a single class of cases in which the albuminuria succeeds the ingestion of food.

Functional albuminuria, on the other hand, simply means that there is somewhere a functional derangement, as the result of which, without structural alteration in the kidney, albumin transudes through its vessel walls along with the normal urine constituents. Of the immediate cause of this I believe it may be safely said we are ignorant, and to speculate upon it is foreign to my present purpose; but I am inclined to believe it is either some quality of the albumin which favors its transudation, or some excess of it in the blood as the result of which it, so to speak, overflows its banks.

I may allude also, in passing, to certain observations of Ralfe, Noel-Paton, and Oliver, as the result of which it is reasonable to suppose that where albuminuria succeeds the ingestion of proteids it is due to an over-stimulation of the red blood-disk destroying office of the liver whereby these bodies are too rapidly destroyed to permit the resulting albumin to be converted into urea, whence again the blood becomes overcharged and the albumin escapes.[1]

For the present we cannot get nearer the truth than this, but this much is now generally admitted, that the person thus affected is essentially healthy. Let me narrate briefly two cases under my observation which illustrate precisely what I mean.

CASE I.—On March 3, 1883, I first examined, at the request of Dr. W. W. Keen, of Philadelphia, the urine of a gentleman, then aged thirty. It had been passed in the morning on rising, and was essentially normal, containing neither albumin, sugar, nor casts. It had 34.5 grammes of urea to the litre. The evening urine contained one-fifteenth of its bulk of albumin but no casts, and there were 21.6 grammes of urea to the litre. Five days later a volumetric examination of the twenty-four hours' fluid discovered 29.8 grammes of urea, the average of two analyses. In addition to the fact that there was no albuminuria on rising, it was also noted that while exercise had the effect of increasing the albumin, massage had not. The most striking symptom was pain in the muscles of his legs, accompanied by a "tired" feeling, in seeking for the cause of which Dr. Keen discovered the albuminuria.

In June, 1884, the patient consulted Prof. T. Grainger Stewart, of Edinburgh, who gave the following opinion: "I have to-day completed the study of ——'s urine. He suffers from intermittent albuminuria, occurring chiefly after food and exertion. He has no evidence of Bright's disease, his urine being of good specific gravity, and containing upward of 400 grains of urea in the twenty-four hours. There is also no trace of sugar. There is no change in the heart or vessels, or in any organ,

Noel-Paton: Relation of Urea-formation to Bile Secretion, Journal of Anatomy and Physiology, October, 1885, January, 1886. Oliver, Thomas: Relation of Urea to Certain Diseased Processes, British Medical Journal, November 27, 1886.

and I regard his albuminuria of the functional kind which has been named 'alimentary albuminuria.'"

At Dr. Stewart's suggestion the patient took a long sea voyage. Six months after his return he came under my care. On January 18, 1886, he brought with him, at his first visit, eight specimens all passed on one day. These I examined with the following result: 7.45 A.M., no albumin; 9 A.M., half an hour after breakfast, one-fifteenth bulk; 10 A.M., an hour after breakfast, one-twentieth to one-fifteenth; 1.30 P.M., after rest, one-twentieth to one-fifteenth; 6.30 P.M., after exercise, one-fifteenth; 8 P.M., after supper, one-fifteenth; 10 P.M. *a trace.* I find also the following note: "Mr. C. has no symptoms, except that he becomes easily tired, but he allows his mind to rest a good deal on his albuminuria, and is in the habit of testing his own urine, and says there is much less albumin than there was, that he feels better when at rest, and on the ocean."

In March, Mr. C. again consulted Dr. Stewart, at Edinburgh. Dr. Stewart reported his condition about the same, "no better, no worse." He recommended a milk diet, suggesting eight ounces of pure milk and an unlimited amount of skimmed milk or buttermilk. On April 4th, under my directions, he began the milk diet, weighing at the time one hundred and twenty-five and three-quarters pounds. He took forty-eight ounces the first day, gradually increasing the amount until, on April 19th, he was taking four quarts a day. This was continued until April 25th, when I ordered a gradual return to a mixed diet. He first lost weight rather rapidly, losing two and a quarter pounds in six days. But as the quantity of milk was increased he gained, and when he returned to a mixed diet he weighed within a quarter of a pound of what he did at the start. At no time during this period of twenty days was the urine free from albumin, and although the proportion was less, yet it is to be remembered that the quantity of liquid ingested was very large, and that, therefore, the absolute quantity in the twenty-four hours was probably in no degree diminished.

From this time on until my last note, dated May 7, 1888, the albumin diminished gradually but irregularly so that more frequently at different times of the day there would be none whatever, being always absent on rising; it would oftener be absent after meals, while the average quantity of all examinations was less. His life is always one of considerable activity, and in summer he is extremely active all day long on a country place. At the last examination, at 9.30, after breakfast there was one-twentieth bulk; at 1 P.M., after exercise but not violent, one-fifth; 3 P.M., after dinner none; at 4.30 P.M., after rest, none; 7 P.M., after driving, a trace; 9.20 P.M., after supper and rest, one-thirtieth. With slight drawbacks his general health steadily improved, and, early in 1887, he married. *Casts were never found.*

As to the determining causes of increased albuminuria, my own study of the case added nothing to the conclusion already arrived at by Prof. Stewart, that food and exercise both tended to increase it, except that possibly exercise exerts a somewhat more potent influence than food.

CASE II., illustrating the class I desire to portray, is that of a gentleman, now forty-one years old. For fifteen years his mother has been passing uric acid gravel. Two maternal uncles died when about fifty-eight years old, having had gout since they were forty. The only suggestion of gout shown by him is an occasional tenderness or stiffness about the small joints, with slight lateral swellings.

From 1880 to 1883 I repeatedly examined his urine, finding nothing abnormal, except a slight hyper-acidity, until August, 1883, when I found a trace of albumin by the picric acid test. On each occasion there had been vague tenderness over the region of the right kidney, probably muscular. He is disposed to headache when constipated, on account of which takes care to keep his bowels free. On November 29, 1883, he called upon me complaining of discomfort, rather than pain, in the region of the right kidney, already referred to, a sensation he found difficult to describe. A portion of the past twenty-fours' urine was acid, had a specific gravity of 1.018, was a pale yellow, and contained neither albumin nor casts.

On January 13th, he was examined for life insurance. The medical examiner after his own examination brought me a specimen of urine, perfectly clear, specific gravity 1.020, in which I discovered a mere trace of albumin by the contact method with picric acid, and by the heat and acid test. On the 18th of the same month, the patient himself brought me a specimen, which also contained a trace of albumin by heat and acid, but which did not respond to nitric acid alone. The quantity on subsidence was decidedly less than that in the urine brought me by the life insurance examiner. On January 20th the urine responded to neither test. *None of these specimens contained casts*, but considerable uric acid appeared some time after the urine was passed.

On January 25th, my patient brought two specimens of urine, one voided in the evening just after tea, the other on rising Saturday morning. Neither contained albumin. On Saturday evening he went to a dinner party, ate freely of rich food, and drank champagne. After dinner he played on the violin for two hours, music requiring much expression and concentration. The urine passed the same night on retiring contained one-tenth bulk of albumin, and that brought to me had a copious sediment of urates. In that of the next morning there was a trace of albumin, but the most careful examination failed to discover casts. Urine passed Sunday evening after a supper of crackers, coffee, and preserves furnished a trace, as also did that of Monday morning. A portion of the twenty-four hours' urine also contained a trace.

Two days later, on rising, the urine was absolutely free from albumin; but after a breakfast of tripe, bread, and milk I found one-tenth its bulk. At 2.15 P.M., having attended a board meeting from 12 to 1.30, there was a mere trace. At 5.30 P.M., dinner and office business intervening, there was no albumin; nor was there any at bedtime.

The next day on rising there was absolutely none. That passed at 10 A.M., the first passed after breakfast consisting of a chop, oatmeal, and cream fol-

lowed by pepsin and a railroad journey of forty miles, was without albumin. After one and a half hours in court testifying, no albumin. After dinner consisting of chicken, bread, milk, and potatoes, none. That passed on returning to Philadelphia contained none. After a tea of oysters and milk-toast there was a trace, and at 12.30, after a visit, also a trace, rather more than after tea.

Such notes as these were made from day to day, and may be regarded as fair samples of the average condition. Always, with the exceptions named, the urine was without albumin on rising, but it was impossible to discover any law followed by the albuminuria at other times. At one time after breakfast, although at home writing quietly, there was one-tenth of albumin; at another there was none. On one day there would be a trace at each examination; at another, although more rarely, there would be none. This important fact was, however, ascertained, although the urine passed on rising contained no albumin, that passed at 9.30 A.M., *but before any food had been taken*, contained one-seventh its bulk. Urine passed at 11.05 A.M. the same day, one and a half hours after breakfast, contained a *trace;* that passed at 2.30 P.M. contained a mere trace; at 4.45 P.M., two hours after dinner, none; and at 6 P.M. none; that passed after tea contained none; at 11.45 P.M., after a lunch of roasted oysters, weak coffee, bread, and a teaspoonful of sherry wine, a trace. The last urine had a specific gravity of 1.030. This day's observations showed that the albuminuria did not, at least, necessarily depend on food; but rather that exercise was responsible for it. At other times, however, after exercise and after food there was no albumin. It was observed that there was almost invariably a tendency to increase after breakfast under any circumstances, almost as invariable as there was absence on rising. Next to the absence of albumin on rising, absence was noted more frequently between 4 and 6 P.M. More commonly there was albumin when the specific gravity was high, yet I note that at least once with specific gravity of 1.036 there was none.

In this case the albumin also became gradually less, and ultimately disappeared. Quite an important observation was this, that the use of "beef-tea" or "beef-essence," as prepared at home, invariably increased the albuminuria.

Contrasting these cases I would call attention to the fact that although in the matter of family history and age the second case would be regarded as the more unfavorable, yet in it the albumin disappeared altogether, while in the first it is still intermittently present.

These cases I regard as illustrating a class in which, although there is albuminuria, its subjects have not renal disease and are insurable risks. Such conclusion is, however, based upon a study of the cases extending over months in the one instance, and years in the other, a study which is seldom, if ever, possible to the ordinary medical examiner. There can be no doubt, however, that could a set of rules be laid down for his guidance the well-trained examiner might save to his company a certain number of risks which are now lost by it. Unfortunately from necessity perhaps, at the present day, the majority of medical examiners are neither well educated nor well trained. Supposing, however, that these important desiderata are attained, as it is reasonable to believe they will at no distant day, are there any conditions which if observed will enable the companies to secure these risks which are now rejected? I believe there are and I submit them to your consideration.

First. It is scarcely necessary to say that the applicant must in all other respects present the signs of good health.

Second. The albuminuria should be unaccompanied by tube casts. However perfect may appear the health of an applicant with albuminuria, the presence of casts in his urine must effectually close the gates of life insurance against him. Casts and albumin conjoined can receive only one interpretation—structural change in the kidney either acute or chronic. Here, however, let me say I have known men with good medical education say that casts were passed in a given specimen when there were none; certain granular aggregations having been mistaken for them.

Third. If the quantity of albumin is large, the applicant should be rejected irrespective of the presence of casts. The term large albuminuria admits, of course, of considerable latitude in its application; but I should say that an albuminuria is large in which the albumin habitually exceeds one-fifth the bulk of the specimen examined.

Fourth. A consideration which goes far toward establishing the functional character of an albuminuria, although not essential to this end, is the absence of albumin on rising in the morning. Nor dare it, of course, be said that such an albuminuria precludes the existence of organic disease. It must be taken in connection with the other considerations mentioned.

A *fifth* point of importance is specific gravity, meaning thereby the specific gravity of the twenty-four hours' urine, or what my friend Dr. Charles W. Purdy, of Chicago, calls the "real" specific gravity. The specific gravity of any portion of the twenty-four hours' urine, or the "apparent" specific gravity, is of limited value, varying greatly with the time of day and relation to meals. If we regard the specific gravity of a normal twenty-four hours' urine (say 50 oz.) as 1.020, the following may be laid down: *albuminuria is least significant when the specific gravity is high*, throwing out, of course, the consideration of sugar. The specific gravity is a direct measure of the solids, which in health are strikingly constant for each twenty-four hours, while the same is true in a less degree of the watery part of the secretion. Hence, the specific gravity of the twenty-four hours' urine is tolerably constant.

In all forms of renal disease the solids are diminished, and in all except acute nephritis and cyanotic induration the specific gravity is lowered. In these two it is lowered because in them the quantity of urine is also markedly less, and, in consequence, the specific gravity is increased to 1.028 and even higher. In acute nephritis the presence of blood may also contribute to such specific gravity. Strictly speaking, acute nephritis may be ignored, because no one ill of it is likely ever to apply for life insurance. In functional albuminuria the specific gravity remains normal. Dr. Purdy even says that his observations in many of these cases show a specific gravity above the normal standard, reaching 1.022 to 1.030.

Whenever, therefore, in addition to the absence of other symptoms and signs alluded to, the "real" specific gravity is above 1.020, another most important fact is in evidence against the presence of organic disease and in favor of the view that the albuminuria is functional. On the other hand, if the real specific gravity of the urine be 1.012, 1.010, 1.008, or even less, as it sometimes is, it would be hazardous to accept such a case of albuminuria, however good may be the apparent health of the applicant and even in the absence of casts. To judge unfavorably from the specific gravity of any portion of the twenty-four hours would be exceedingly unfair to the candidate.

Sixth. The signs of hypertrophy of the left ventricle and of high vascular tension associated with albuminuria are conclusive symptoms of renal disease and should exclude the candidate. High vascular tension may sometimes be shown to exist by the sphygmograph, even when not appreciable to the touch.

Seventh. A highly important consideration is the age of the candidate. Albuminuria is much less apt to be of the functional kind in persons over forty years of age than in those who are younger, especially between the ages of twenty-one and thirty-five. It is questionable whether any person with seemingly functional albuminuria who has reached the age of forty should be accepted unless he has been long under the observation of a competent and conscientious observer.

Eighth. The presence of true gout in any shape precludes admission to life insurance, because gout is always sooner or later followed by interstitial nephritis.

Finally. The retinal symptoms so commonly associated with chronic Bright's disease, although usually late in their appearance, do sometimes form the earliest noted sign of this affection, and whether or not conjoined with albuminuria must effectually exclude the candidate from its advantages.

These, in brief, are the conditions which, if observed, appear to me to enable one to establish conclusively the functional character of an albuminuria, the presence of which should not exclude a candidate from life assurance. They might have been further elaborated, but I prefer to leave them to be discussed as presented. It is to be remembered, however, that observations should extend over a considerable period of time, also that there is reasonable doubt as to whether the requisite knowledge and training are sufficiently general to secure intelligent recognition of the conditions. Take, for example, so simple a matter as examining for tube casts, which may be regarded as almost the easiest sort of microscopical work. Yet, how few medical examiners are competent to make such examinations. Most of them have no microscopes, and many who have them use them so rarely that their opinion whether positive or negative as to the presence of casts cannot be relied upon. On the other hand, there are those who are competent to apply these conditions, and it is reasonable to suppose that this number will gradually increase.

I conclude, therefore, that life assurance associations should recognize a condition of functional albuminuria out of consideration of their own interests, as well as in justice to a class which is coming to be recognized as more numerous as our knowledge increases, and who are blindly excluded from benefits to which they are entitled.

CHRONIC INTERSTITIAL NEPHRITIS AND ANGINA PECTORIS.[1]

By SAMUEL C. CHEW, M.D.,
PROFESSOR OF THE PRACTICE OF MEDICINE, UNIVERSITY OF MARYLAND, BALTIMORE.

The subject which I propose to consider in this paper is the relation between certain symptoms referable to the kidneys, and certain other painful and oppressive symptoms relating to the heart.

The former of these two groups of symptoms consists of the occasional presence of albumin in the urine, the occasional occurrence of tube-casts, commonly of a fine granular or hyaline character, and, in general, a low specific gravity of the urine; signs pointing to that form of Bright's disease which is pathologically a chronic interstitial nephritis. The latter group is made up of a feeling of constriction in the chest more or less constantly present, sometimes in moderate degree and sometimes so greatly intensified as to be an acute agony, or an anguish even deeper than that, "a sense of ruin which is worse than pain, a masterful negation and collapse," a feeling of impending dissolution; the condition, in a word, to which the term angina pectoris is commonly applied, and with the emotional as well as the sensory phenomena belonging to that dire disease.

[1] Read before the Association of American Physicians, Washington, 1888.

Each one of these groups of symptoms is, taken by itself, almost a commonplace of medical experience; but their association with each other is perhaps not very frequently met with, and yet must be occasionally encountered by physicians in general practice. How are they correlated with each other? Is the connection merely an incidental one, so that the anginoid symptoms might have occurred in any given case even had there been no renal disease? Is the condition indicated by the signs referable to the kidneys the direct cause of the cardiac symptoms? Or is there anything in the state of a heart laboring under such symptoms which may directly or indirectly determine albuminuria?

It is well known that some forms of Bright's disease are likely to cause, or at least to be associated with organic changes in the heart, and the manner in which such cardiac changes are brought about has been the subject of much ingenious speculation and able argument, as instanced most recently in the thoughtful and suggestive Middleton-Goldsmith lecture of Professor DaCosta.

It is equally true that an organic change in the heart resulting in dilatation of the organ and general venous stasis may determine secondary disease of the kidneys. But the cases which I have in view would not seem to belong to either of these categories. They may occur without any hypertrophy of the heart ascribable to the renal disease, if it be admitted that the latter can cause such cardiac change, and they may occur also without any such dilatation of the heart as could of itself have produced passive renal congestion. Are both groups of symptoms the results of a common cause acting upon both of the involved organs? I ask the question, but I propose to consider the subject chiefly from a clinical point of view, narrating some of the cases in which I have observed these conjoint symptoms, suggesting perhaps some explanation of them, but trusting that they may receive from others a more complete pathological interpretation than I am myself able to offer.

In the first place I would state that, so far as my reading goes, there is no express mention of a relation between these maladies in any systematic treatise upon the subjects.

Heberden, who first described angina pectoris and gave it the name by which it has been known since his day, states that he had seen nearly a hundred persons suffering with the disease, yet he makes no reference to dropsical symptoms as ever attending it. This he would probably have done had he observed them, though, of course, without associating them with kidney disease, as his observations were anterior to the existence of renal pathology.

In Dr. John Blackall's report of cases of angina pectoris appended to his work on *Dropsies*, which was published before the year 1820, he quotes an account of the case of Lord Clarendon, who died of angina pectoris occurring with symptoms which, as Dr. Blackall says, "rendered probable the existence of some disorder of the urinary organs." These symptoms were great frequency of micturition occurring without pain in the urinary organs themselves, but with intense pain in the left arm. "The circumstances" says Blackall, "have been scarce heard of before, and the causes are not yet understood by any physician."[1] It would seem not unlikely that in this case the morbid state of the urinary organs unattended with pain was chronic interstitial nephritis which is so often accompanied with increased frequency of micturition.

To come to a somewhat later time we find no mention of the combination of the heart and kidney symptoms in Sir John Forbes's masterly article on angina pectoris in the *Cyclopædia of Practical Medicine*.

Professor Gairdner, in his very elaborate and able discussion of angina in Reynolds's *System of Medicine*, merely remarks that "renal disease forms a very serious and often unmanageable complication" of angina;[2] as it certainly does, especially if it give rise to pulmonary œdema; but he does not refer to any pathological connection between the renal and cardiac changes. Nor does any systematic writer, so far as I have been able to ascertain. And yet in several authors there are observations which might have led to the thought of a connection between the two diseases. Thus Gairdner remarks that Lauder Brunton's case in which the value of nitrite of amyl in angina was first made known, "shows a correlation of some kind between angina-like paroxysms and increased arterial tension;" and it is well known that increased arterial tension is common in Bright's disease. Indeed, Brunton himself, in his statement of the therapeutic applications of nitroglycerine, after referring to its use in angina pectoris, says that "it is useful when the heart is weak, or when the tension is abnormally high, as in Bright's disease."[3]

The consideration of the therapeutic fact that the same agent is beneficial in the two diseases, and in the same way apparently—that is, by lessening arterial tension, might suggest a relation of some kind between them. Still nearer the mark is an observation of Strümpell, in his account of the chronic contracted kidney, that "the long-known asthma of renal disease, often termed, without reason, 'uræmic asthma,' does not always have the same origin. It usually depends upon cardiac weakness, and is a genuine cardiac asthma, *corresponding precisely* to angina pectoris in its different

[1] Blackall on Dropsies, p. 255.
[2] Reynolds's, vol. iv. p. 546.
[3] Brunton's Therapeutics, p. 669.

symptoms."[1] But he does not attempt to trace a pathological connection between the diseases.

One case of coexistence of angina pectoris and Bright's disease, closely resembling those I have myself observed, is reported by Dr. Von Russdorf, of Berlin.[2]

I have selected from my note-book the following cases as illustrative of the combination of diseases to which this paper refers:

Case I.—G. A., female, seventy-one years old, had for more than a year been failing in strength and appetite, becoming pallid in hue and troubled with a feeling of constriction and oppression in the chest, especially referred to the cardiac region. Occasionally there was slight swelling about the ankles, transient in duration, and disappearing entirely at intervals. On auscultation, there was no evidence of pulmonary trouble of any kind, nor did the heart show any sign of valvular disease, but its action was habitually and markedly weak. The urine showed at times slight traces of albumin, which again would entirely disappear, and there were occasional fine granular and hyaline casts—never abundant, and often absent or not discoverable even when a rigid search was made for them. The specific gravity of the urine ranged from 1.012 to 1.015. The diagnosis was that of chronic contracted kidney.

The distressing sense of constriction in the chest increased in degree and persistence, until the 23d of March, 1886, when I was urgently summoned to the patient, and found her suffering with agonizing pain in the region of the heart, extending down the left arm. The expression and color of the face were characteristic of angina pectoris. This pain was promptly relieved by a hypodermatic injection of morphia; but at various times it occurred, though with less violence than at first, while the sense of constriction and oppression in the chest, which had been felt for several months before the severe attack, became more constant. This form of suffering was, however, controlled to a considerable degree by the administration of nitroglycerine in the dose of $\frac{1}{100}$ of a grain three or four times a day. In order to test the value of this remedy, after administering it for two or three days in succession, and until the patient had been apparently relieved entirely of the constrictive pain in the chest, I would withdraw it, when, in a day or sometime in two days, she would request its use again. "Give me my little pills," she would say, and again would experience the desired relief from them. She was provided also with pearls of nitrite of amyl in case of the recurrence of an attack of great severity, and occasionally had recourse to them. And so the contest with two mortal maladies went on, in which, in view of the patient's age and the nature of the diseases, little could be done beyond relieving suffering and endeavoring to promote euthanasia, when, on November 19th, or about seven months and a half after the first acute paroxysm, the patient, on walking from her bed to a chair, sank into it and expired.

In this case the symptoms of angina pectoris were classically marked, as were those of Bright's disease in the form, apparently, of the chronic contracted kidney, as shown by the intermittent occurrence of albumin in the urine, the occasional presence and frequent absence of tube-casts, and the small amount of dropsy. There was no opportunity of making a post-mortem examination.

Case II.—N. B., sixty-four years old, a merchant by occupation, consulted me in November, 1887, for oppressed breathing and a painful sense of constriction in the chest, extending to the left arm, and felt, in general, only when walking, especially when walking up hill or up stairs. Auscultation showed no valvular change in the heart, but its action was weak, and at that time there was no sign of pulmonary disease. Examination of the urine gave a negative response as to the existence of disease in the kidneys, but a few weeks later it showed a cloudy trace of albumin and scanty hyaline and fine granular casts. Later repeated examinations showed sometimes the presence and sometimes the absence of these signs, as is common in chronic interstitial nephritis. The patient was troubled with constipation, and was often imprudent in eating; and the regulation of the bowels, together with restriction for a time to a milk diet, produced a marked improvement in the breathing and a lessening of the constrictive pain in walking. At the same time he was put upon the use of $\frac{1}{20}$ of a grain of arseniate of iron three times a day. In January, 1888, anasarca appeared in the lower limbs as well as slight effusion in the pleural sacs and patches of pulmonary œdema. These symptoms abated under the influence of digitalis and tincture of the chloride of iron.

The weather in Baltimore being at that season very unfavorable for one in the patient's condition, he went, by my advice, to the milder climate of Thomasville, Georgia, where he consulted Professor John T. Metcalfe. This gentleman wrote to me that he detected in the patient's lungs the presence still of some œdema in scattered spots, and he stated that he had frequently met with this patchy sort of œdema in Bright's disease, and thought it somewhat characteristic of the malady. I believe it often is so, and perhaps it is analogous to another localized form of dropsy occurring in the same disease, that, viz., in the lower eyelids. In April the patient returned from Georgia, and in the drier and warmer weather of the spring and summer he has somewhat improved; the effusion in the pleural cavities, the lungs, and the lower extremities has disappeared; but the chemical and microscopical signs of renal disease still exist, and he still suffers occasionally with attacks of angina. On July 19, 1888, albumin was present in the urine to the amount of two per cent. by volume; there were a few hyaline casts, and the specific gravity was 1.015. On August 18th, there was three per cent. of albumin by volume, no casts, and a specific gravity of 1.011.

In this case, again, the coexistence of the symptoms of angina pectoris and of chronic contracted kidney is plainly shown.

[2] Deutsche Klinik, vol. xviii. p. 375.

Case III. — J. W., sixty-three years of age, a physician by profession, was able to appreciate the full significance of all the symptoms belonging to his mortal maladies and to meet them with fortitude. He had been failing in health and growing weak and anæmic for many months, when in February, 1888, I was invited by his attendant physician to see him in consultation. The most prominent symptoms then existing were great oppression and sense of weight in the cardiac region, with attacks of acute pain in the same situation so severe as to render the hypodermatic use of morphia necessary, and also the inhalation of nitrite of amyl, from which temporary relief was gotten. The administration of nitroglycerine was without effect. Dyspnœa was frequently urgent, but was not dependent upon any change in the lungs or heart discoverable by auscultation. Anasarca in moderate degree sometimes appeared in the lower limbs, but was transient in duration. The urine was examined many times, often presenting nothing abnormal, but occasionally showing slight cloudiness when tested for albumin, and sparse hyaline casts under the microscope. Yet the presence of these at all, though infrequent, taken in connection with the character of the breathing and the anasarca, pointed to the existence of chronic contracted kidney, while the breast pang showed angina pectoris. No remedies stayed the progress of his organic disease; but little and only temporary relief could be given to the attendant pain and difficult breathing, and on the 8th of April he died.

At the *post-mortem* examination the kidneys were found to be diminished in size, chiefly at the expense of the cortical portion, and their capsules somewhat adherent, though not to so great an extent as is usual in a more advanced stage of atrophic change. The heart was distended by coagula, giving it the appearance of being enlarged before it was opened, but the ventricular walls were attenuated and large fibroid patches were found under the endocardium of the left ventricle. The coronary arteries were both in a state of fibroid degeneration; the right artery being completely occluded by softened fibrous and atheromatous material, and the left so much obstructed that it was only slightly pervious. This degree of obstruction must necessarily have caused great cardiac ischæmia. An aneurismal dilatation of the aorta of the size of a large egg, with atheromatous walls was found just below the cœliac axis.

Of the three cases here reported, in the first no post-mortem examination could be made. The second is that of a patient still living. In the third the diagnosis of the condition of the kidneys made in life was confirmed by the post-mortem examination, which also showed changes in the heart not positively diagnosticable, but entirely in accordance with the cardiac symptoms observed, and perfectly explaining them.

It seems a fairly probable inference that inasmuch as Cases I. and II. corresponded in the combination of their symptoms closely with Case III., the same or closely similar changes to those found in Case III. existed in Case I., and exist now in Case II.

There would certainly be no reason for regarding the changes in the heart belonging to Case III., and probably belonging also to Case I. and II., as in any way causative of the diseased state of the kidneys. And, on the other hand, there would be no reason for regarding the kidney disease in Case III. as productive of the cardiac symptoms through uræmic poisoning or any merely functional disturbance, when positive organic change fully accounting for the cardiac symptoms was found. If uræmia acting on the heart ganglia were the source of trouble in the same way that it occasions such disturbances as convulsions and coma by its influence on other nervous centres, then these heart symptoms might be expected to be as frequent as are the cerebral symptoms of Bright's disease, which they certainly are not. Nor, again, is it easy to see how the kidney disease could have been the direct cause of the organic change in the heart and the symptoms due to it. Bright's disease may, it is true, give rise to endocardial inflammation and to consequent changes in the cardiac valves: but in the cases referred to no such changes existed, and, therefore, the kidney disease could not have held a causal relation to the angina by producing such valvular lesions.

The morbid changes most commonly found in connection with angina pectoris are obstruction of the coronary arteries, insufficiency of the aortic valves, or rigidity of the aorta, possibly interfering with the filling of the coronaries, and fatty or fibroid degeneration of the heart. Any one of these pathological conditions may give rise to cardiac ischæmia, which is most probably the immediate cause on which the angina depends. Cardiac ischæmia is more directly brought about by obstructive disease of the coronaries than by any other lesion, though atheroma or sclerosis of the aorta may accomplish the same result, as may also endo-arteritis or peri-arteritis of the heart arterioles by preventing sufficient blood from entering the myocardium, even though there may be no coronary obstruction. According to the statistics of Sir John Forbes, coronary disease was found in seventeen out of forty-five cases, or more than one-third.[1] Lussana gives twenty-one cases of coronary obstruction in thirty-six fatal cases of angina;[2] and Liegeois, whose researches are later and probably comprise a larger number of cases, states that three-fourths of all cases may be attributed to atheroma or sclerosis of the coronaries or aorta, or both.[3]

Now all these are degenerative changes, and ap-

[1] Cyclopædia of Practice of Medicine, vol. i. p. 107.

[2] Virchow's Handbuch, vol. ii. p. 422.

[3] Bull. Med. des Vosges.

parently they cannot be directly attributable to any renal disease. It would seem more probable, therefore, that the change in the heart giving rise to the symptoms of angina is, as is ably maintained by Professor Da Costa in reference to the cardiac hypertrophy of Bright's disease, not the direct consequence of that disease, but a part of a general degenerative change, of which one expression is manifested in the heart and another in the kidney. As Russdorf remarks in the report of his case, "the renal change is the last stage of a slow process of disease, of which the beginning was in the heart."

And, perhaps, if we are inclined to believe with Dr. Da Costa and Dr. Longstreth, that "it is in the nervous system that we are to search for the original source of the malady," we may think that some further probability is lent to this view by the pathological fact of the increased arterial tension found both in Bright's disease and in angina pectoris, and due to a change in the vaso-motor system, and possibly in the cervical ganglion, and the further therapeutic fact that nitroglycerine, which lessens this tension, has proved beneficial in both affections.

IMAGINARY LINGUAL ULCERATION.[1]

By GEORGE M. LEFFERTS, A.M., M.D.,
PROFESSOR OF LARYNGOSCOPY AND DISEASES OF THE THROAT IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

"Imaginary lingual ulceration," with its demoralizing pain and indefinite terrors, is very real to the sufferer, while to the physician the almost utter futility of his present therapeutic resources for its relief renders the affection one of more than passing interest and importance.

These two reasons alone, even if others did not exist, would justify my bringing the subject briefly before you for discussion, which I now do, in the hope and belief that light may be shed, especially upon the vexed questions of etiology and therapeusis.

"Imaginary lingual ulceration" — recently so named by Verneuil—although a comparatively rare affection, is doubtless well known by some name or under some form to many of you. It presents no complex symptoms; its local lesions, if any exist, are often indefinite; still the diagnosis usually admits of no doubt, and the clinical history, taken alone, is distinctive.

A patient, male or female, as the case may be, for the affection occurs with equal frequency in the sexes, and from thirty-five to fifty years of age, presents himself complaining of intense pain, usually of a lancinating or darting character, limited to one-half of the tongue, usually the left, and extending from its base, just opposite and below the tonsil forward to its tip, or the pain may be more circumscribed and limited to the junction of the posterior with the middle third of the organ, at or near the location of the posterior lenticular papilla. It is more or less intermittent, rarely constant; is aggravated by movements of the tongue, although these are free; is often increased by the act of mastication and excited by hot or irritating articles of food. Its effect upon the patient is demoralizing, his imagination plays him false, his terrors are aroused, and injudicious medical or surgical interference and advice, instead of allaying both mental and physical disturbance, not infrequently excite them; the fear of cancer, and the belief, which remains unshaken, that ulceration actually exists, constitute an integral part and important factor in this curious affection.

Such patients, however, are not invariably hypochondriacal, as has been asserted; on the contrary, the affection is met with in those who present no evidences of a neurotic or even nervous temperament; it is occasionally seen in individuals possessing and presenting all the signs of robust health, and the mistake has been made, and is made to-day, of ascribing alone to the imaginative fears of the patient what actually exists as an undoubted, if not always demonstrable, physical and painful fact.

Subjective symptoms, other than the pain as described and occasionally slight salivation, if it be excessive, do not exist.

Careful physical examination reveals but little or nothing to guide us to a diagnosis, especially if the tongue, at its affected point, has not been tampered with by local and irritant applications. If drawn forth from the mouth and extended to the opposite side from that on which the local point of pain is complained of, it usually presents a normal appearance; the surgeon's attention being directed, as it always is, by the patient to a point on the line of demarcation between the roughened epithelium of the dorsum of the organ and the smooth mucous membrane below, a lateral line, which is marked near the tonsil by the invariable presence of a few delicate papillæ. These will be found of natural number, size, and color, subject to normal variations in different individuals. If irritation has been caused, these papillæ will be seen swollen, reddened, and associated with lateral inflammatory enlargement of the tongue to a greater or less extent, pain is increased and constantly aggravated by the swollen tongue being impinged upon by the teeth during mastication. Lesions of a catarrhal nature, which commonly coexist in naso-pharynx, pharynx, and perhaps larynx or tonsils, are not of such a character or grade, as a rule, as to influence a part so remote and indirectly connected, nor are they such as to excite a plausible suspicion as to a possible reflex character of the tongue disturbance.

Such is a brief physical sketch of the affection

[1] A paper read at the Tenth Annual Meeting of the American Laryngological Association.

which we have named "imaginary lingual ulceration." A fanciful term, perhaps, as ulceration rarely if ever exists, but certainly descriptive enough from our, and truthfully exact from the patient's, point of view, to warrant its being retained.

In passing to the question of causation, we are at once involved in a multitude of hypotheses, bewildered by more or less plausible explanations, and confronted by a variety of views. No unanimity of opinion exists. From the little that is found in literature concerning the affection, I select the following, first recording my own opinion, based upon experience, that to regard it and to dismiss it at once as a fanciful conceit on the part of the patient, is a grave mistake, and that relief of the real suffering that undoubtedly often exists—granted that this may be in part mental—is not and cannot be attained by such a course.

Verneuil (*Acad. de Méd. de Paris*, July 27 and October 4, 1887), and I believe Labbé, regard the disease as a purely neuralgic affection of the tongue, and compare it to an affection of the breast, described by Velpeau under the name of imaginary tumor of the breast, which, like the above-named disease, is also characterized by intense local pain without any appreciable lesion.

Fournier, Lollé, Hardy, Luys, and Magitot all agree to regard the symptoms as hypochondriacal.

Poyet (*Journ. des Conn. Méd.*, October 20, 1887), from whom I quote, says that the delusion may almost always be referred to one of four causes. In the first class of cases there is a neuralgia of the tongue, and the pain leads the sufferer to believe that ulceration exists. In the second class are patients who have read or heard of some person afflicted with cancer, and have been led thereby to examine their own tongues. They notice, perhaps, a somewhat prominent papilla, and their fears lead them to the conclusion that it is the edge of an ulcer or a commencing cancer. Others are hypochondriacs, pure and simple, and are so convinced that there is an ulcer present, that no amount of argument or demonstration can convince them of their error. Finally, certain patients, with lingual psoriasis, discover the white patch on their tongue and think that ulceration is present.

These old-time views, representing but one side of the question, I present, for the moment, without comment.

Albert (*Wiener med. Presse*, Nos. 1 to 6, 1885) ascribes the pain to the presence of "irritable papillæ in the *regio foliata*." But cases are certainly met with in which none of these hypotheses covers the diagnostic ground. Cases such as I have described above, not neurotic, not imaginative, of good general physical condition, cases in which all possible or probable sources of local irritation have been removed, such as decayed, irregular, or ragged teeth which press upon the tongue, teeth filled with amalgam, which possibly chemically affect it, diseases of the gums, which have been claimed by recent writers to be efficient cause for reflex neuroses of distant parts, but still pain persists. *Why*, is the question that we must ask ourselves. Are general causes at work of which we at present know nothing? Can a rheumatic or gouty diathesis with such local manifestations be at fault? Doubtless such cases exist. I have seen and treated them successfully; but they are limited in number. Must we then be driven, by our etiological uncertainty, into that indefinite and unsatisfactory but comfortable diagnostic haven of "neuralgia?"

I have alluded to the common plan of treatment: the patient is classed as hypochondriacal, nervous, fanciful; his sufferings regarded as unreal and possessing actuality in his imagination alone, and as a *placebo* local applications of a caustic nature are made to the lingual papillæ, whether these be enlarged or not, in the hope of curing the supposed growth. The results are such as to increase rather than alleviate pain, and only serve to confirm the patient in his delusion, should this exist. Still more, these results of injudicious treatment may pass, as I have seen, beyond the limit of mere irritation into a stage of actual ulceration, suspicious induration, and dangerous extension, with glandular involvement.

To such a vulnerable organ as the tongue, the danger of such a course cannot be overestimated, nor its adoption too strongly condemned. That it is unscientific and ineffectual requires no demonstration.

Applications of cocaine or of aconite sometimes succeed, often fail; and the same is true of the various treatments with which we are familiar, usually pursued in neuralgias of other parts of the body. Electricity is usually of service. Hypodermatic injections of analgesic drugs have been recommended. More radical procedures have their advocates in cases in which milder means have failed. Cauterization with the thermo-cautery and destruction of the calciform papillæ sometimes, not always, found upon the tongue in such cases. Poyet recommends such a course, or some other painful application, solely for its moral effect; the danger and futility of such a procedure we have seen.

Neurotomy must be discarded, not alone on account of the difficulty attending such an operation in this particular locality, but mainly because of the impossibility of proving whether the lingual or the glosso-pharyngeal nerve is the one at fault.

While thus criticising my own treatment, with its few successes and many failures, and reviewing that of others, I regret that experience has taught me nothing that is uniformly successful in its results to recommend, and my intention has been, in bringing this rare and curious affection before you for discus-

sion, to place it in what I regard as its true light and to profit by your therapeutical experience in its treatment.

Ample room exists to-day for improvement in our methods, and increase in our means directed toward this end.

TWO CASES OF EPILEPSIA PROCURSIVA.

By H. A. HARE, M.D.

DEMONSTRATOR OF THERAPEUTICS AND INSTRUCTOR IN PHYSICAL DIAGNOSIS IN THE UNIVERSITY OF PENNSYLVANIA.

RUNNING epilepsy is so rarely seen even by neurologists that the following cases may be of interest and are certainly worthy of record:

CASE I. was as follows: Girl, aged eight years, the child of healthy parents, was brought to me by her mother who stated that the child would give a scream and then suddenly dart out of the house into the crowded street and run one or two hundred yards, when she would return to herself dazed and unable to find her home, rather because of her surprise at her new surroundings than an absolute lack of intelligence. At the time I saw the case the attacks were so frequent as to prevent the mother from performing her work, because of the constant watching necessary. In other words, the attacks occurred several times a day. If held so that escape was impossible, the girl struggled to get away, but there were no fits of the ordinary character at any time. There was never any coma after the attacks, no incontinence of urine or feces. There was no history of any cause of the disease so far as could be discovered. The mother was told to bring the child back in one week, but failed to do so and all trace was lost of the case.

CASE II. is as follows: Jesse ——, aged fourteen years, is a strong and apparently healthy boy, of healthy parents. He is a remarkably well-built and manly looking fellow of more than the usual height and weight and is well proportioned. His complexion and color are good and he is notorious at school for his brightness and acuteness in learning his lessons. He is not one of those typically "bright boys" who look as if highly strung, but is perfectly normal so far as his appearance is concerned. He was entirely devoid of any morbid condition until just one year ago, when the first fit took place. The history of his life gives no record which can be, in any way, considered as a cause of his present trouble, save that when he was about six years of age he was struck on the back of the head by another boy who was much larger than himself with a heavy club. No unconsciousness was produced, but blood flowed freely from the wound, the scar of which is still to be seen about two centimetres downward and to the right of the occipital protuberance. No secondary effects ensued from this stroke, but exactly two years ago he was struck while at play on the head within two centimetres of the former scar. The blow felled him to the ground and produced unconsciousness lasting for some minutes.

One year ago, almost on the anniversary of this last blow, he was down in the cellar of his father's house and suddenly rushed up stairs and sat on the kitchen table, muttering, and moving his legs, and apparently unconscious of his surroundings. There was no coma, nor headache after this attack and he seemed perfectly well. The other attacks have since occurred either once or twice a week or even less frequently at certain times. When they occur in the daytime they invariably consist in a sudden run across the room ending sometimes in a fall to the floor, but there are no spasms when he falls. One week ago he was sent to a store for some nails. He entered, asked for the nails, and then suddenly darted out into the street, throwing his money away as he ran. The distance traversed before he was caught was about one hundred yards. When stopped by the storekeeper who followed him, he strove to escape, but a moment after regained consciousness and was absolutely ignorant of how he reached his new surroundings.

Up to this time the writer had never seen him in an attack but on the day this was written, while he was being taken up stairs in the University Hospital in order to be shown to the class, he was seized with a paroxysm in which the following symptoms were noted. The head was drawn slightly to the left, the right shoulder thrown forward and upward and he assumed the position of one about to start on a foot race. He was seized instantly but used the utmost effort to escape, the efforts being ineffectual chiefly because they were lacking in intelligence, but the movements of the legs, although he was held, were running movements finally deteriorating into struggles such as those of an angry child trying to break away from a parent. The entire attack was accompanied by muttering and at the beginning of it the saliva poured from his mouth. The aura in this attack was distinctly visual and consisted in total blindness. Indeed, at the first part of the attack he groped blindly about for something to clutch. This condition of blindness has formed the aura in every fit, so far as can be learned from the boy and his parents. There was no incontinence of urine or feces. The transient stage from unconsciousness to intellection was but momentary and could not have lasted over sixty seconds. The mental clouding after the attack was so slight and transient as to be scarcely noticeable. He has had several nocturnal attacks consisting in turning and twisting in the bed with muttering but no running movements. An interesting fact in regard to the case is that while ten grains of bromide of potash three times a day failed to control the attacks, antifebrin in doses of five grains three times a day produced an intermission of one week which might have been much longer had not the fright of going before a class precipitated an attack.

Unfortunately this case, like its predecessor, promised to return for an ocular examination but failed to appear, and frequent requests have been so persistently disregarded that I have given up all hope of obtaining it as the parents do not seem to regard the disease as being more than a slight annoyance.

CHEYNE-STOKES RESPIRATION.

A Report of Three Cases, with Remarks.

BY WILLIAM O. STILLMAN, A.M., M.D.,
OF ALBANY, NEW YORK.

CASE I.—On December 11th last, I received a telephone message to call upon Mr. C. S., white, married, American-born, aged forty-seven. About 5.30 that same morning, while engaged in wheeling a loaded wheelbarrow on a scaffolding, a portion of the structure fell with him, and caused the barrow to fall upon him striking him in the abdomen. The fall was not over three feet, and he was able to pick himself up almost immediately and extricate himself and his load. Despite considerable shock, he was able to work until late in the afternoon. About 3 P. M. he complained of headache and nausea, grew faint, and for a couple of hours felt unable to attend to his duties, but succeeded in walking to his home, a quarter of a mile away. I saw him about 7 P. M., and found him lying in bed; his mind was somewhat confused, his pulse was about 95, rather hard and full, and his respirations of the Cheyne-Stokes description; the period of breathing and of apnœa occupying the same intervals, some twenty to twenty-five seconds, the number of respirations during each series being fifteen to twenty. The pupil was contracted (slightly) during the period of rest, but dilated during the respiratory paroxysm. Muscular power and movement of every description (arms, limbs, tongue, head, and trunk) were retained.

On being roused he complained bitterly of pain in the epigastrium, where he claimed the barrow struck him, and also of bruises on his legs and right hip. He was able to give an account, interrupted by lapses from which it was necessary to rouse him, of his accident and subsequent conduct. His head (the whole of it he claimed) ached slightly, but he was not conscious of having hit it, nor was any bruise of the scalp discernible. His kidneys worked freely, and there appeared no indications of uræmia, and he had no rigor.

The following day his condition was much the same, except that the peculiar respiration was more marked and the apnœic intervals longer. He partook of nourishment (there was no nausea or vomiting), his bowels were moved freely, his mind was more sluggish, but he did not recognize his wife, although able to answer questions intelligently. At the end of about eight days the Cheyne-Stokes respiration had gradually disappeared, and his condition was much improved. At the end of seven weeks he was able to be out of doors, and at this time (February 26, 1888) he is at work,[1] though feeling somewhat weak and "short of wind." He still suffers a little pain in the epigastrium, and claims a diminished power in the right hand and leg. This last was scarcely noticeable during the first week in bed, and was not a marked symptom at any time. His heart is quite weak in its impulse, evidently from excessive use of tobacco, and the pulse is very compressible. There is no indication of atheroma or valvular disease. Has always been thin and not vigorous. I have presented the symptoms in the order in which they claimed attention. The diagnosis was serous effusion particularly affecting the base and anterior vertex of the brain; but I am inclined to think that there was a small hemorrhage in the vicinity of the left ascending frontal convolution.

CASE II.—On December 31, 1887, I was called to see Mrs. A. U. L., white, married, American-born, aged about seventy-six. She was unconscious, and presented the unmistakable symptoms and history of cerebral hemorrhage; there being complete loss of power in right arm and leg. The medulla was evidently already affected, the breathing puffy. Cheyne-Stokes respiration was present, the periods of breathing and apnœa being about equally divided in regard to time, and the respiratory series being about thirty each time in number. The pulse beats numbered about 84, and remained about the same during my call. I had previously attended Mrs. L. for heart difficulty, there being marked evidence of fatty degeneration (atheromatous arteries, arcus senilis, attacks of difficult breathing, etc.). There seemed to be no marked valvular trouble. She had also suffered from a slight cerebral apoplexy a few weeks previous, with a very slight disturbance of motility on the side later affected. She died on the morning of January 3, 1888, there having been no particular change in her general condition, except that the intervals between the breathing spells gradually lengthened, the respiration became more stertorous, and there was a progressive loss of strength.

CASE III.—Early on the morning of January 1, 1888, I was summoned in consultation in the case of F. C. F., male, white, unmarried, American-born, aged twenty-seven. The patient had been in apparent health the day before, when, although somewhat inactive, he had walked some distance, played upon a piano, and seemed to be in a cheerful frame of mind. About 11 o'clock in the evening he had complained to a friend of severe pain in the back of his head; a physician was called and a small amount of anodyne administered. He retired between 11 and 12 P. M. At 3 A. M. his room-mate was aroused by his heavy breathing and he was found to be unconscious. The family physician was at once called, and at 5 o'clock I was sent for. Subsequently the physician who had first seen him arrived. Cheyne-Stokes respiration was well marked when the family physician arrived, and continued so up to the time of death, which occurred at about 10 o'clock the same morning. When I first saw him the interval of apnœa was longer than the breathing period, and this condition continued with slight fluctuations and a tendency toward increased apnœa, until his death. His extremities were cold, his pulse rather small but of somewhat increased tension, and frequently the pupils were strongly contracted and varied but slightly in calibre; he was completely unconscious. There were no indications of organic heart disease, but the heart's action was very feeble. He belonged to a somewhat neurotic family, was slight in build, and was an excessive cigarette-smoker. A diagnosis of cerebral meningitis was made and concurred in by all present. Subsequently it was learned that he

[1] He is now, August 18, 1888, in his usual health.

had received a sharp blow on the head by running against a telegraph pole while trying to catch a train the day before he was taken ill.

I have not attempted to give the symptoms or histories of these cases with any great minuteness, as that is not necessary for my purpose, which is simply to call attention to the accepted explanation of the causes of Cheyne-Stokes respiration. It seems to me that the classical theory of its causation is defective in certain respects, which I will explain later.

Dr. Cheyne first called attention to this peculiar alteration of the rhythm of respiration in 1818, and described it with great accuracy. In his case it was associated with fatty disease of the heart. Little attention was paid to the symptom until 1846. Dr. Stokes urged its significance as a sign of fatty degeneration of the heart, believing that it was a pathognomonic symptom of this affection, and that its presence indicated a fatal and speedy termination. Dr. Seaton Reid soon demonstrated that it might depend on valvular incompetency only, and Dr. Hayden has shown that it is probably present in about one-third of the cases of fatty degeneration of the heart (presumably those resulting in death are meant). He considered that atheroma of the aorta was the cause of its presence.

Later observers, with wider opportunities, have shown that this symptom is occasionally found in a considerable variety of diseases, relatively most often (it is asserted) in those diseases of the brain which give rise to compression in the neighborhood of the medulla oblongata. Thus it is found in cerebral hemorrhage, exudation, and tumors; it also occurs in uræmia, and in various cardiac diseases, including fatty degeneration, sclerosis of the coronary arteries, stenosis of the aortic or mitral valves; and may complicate abscess and congestion of the brain. Fräntzel, Leube, and Bernheim have reported cases in which it appeared after the administration of morphine; Biot after the use of bromide of potassium; and O'Neill after chloral. Fräntzel's case furnished Traube with the data for his classical remarks on the *rationale* of its causation. His theory is, that lack of arterial blood supply to the respiratory tract in the medulla (a characteristic common to these affections it is claimed) diminishes its irritability to such an extent that a much larger accumulation of carbonic acid in the blood than usual becomes necessary to excite the inspiratory stimulus, and that thus an interval occurs which is compensated for by increased action.

Traube's theory has two great faults; it does not show why the Cheyne-Stakes respiration should not be present in all cases which at times may produce it, and it does not explain why spasmodic compensatory activity of respiration should occur only in these cases of carbonic acid poisoning and under these special circumstances. Filehne, recognizing these deficiencies, extended Traube's hypothesis, and formulated the commonly accepted theory of its causation. He claimed that the vaso-motor centre must be more easily excited than the respiratory centre, and that the symptoms were caused as follows: "At the end of the respiratory pause there is a large disappearance of oxygen from the blood, carbonic acid has accumulated, the vaso-motor centre is thereby stimulated, and the arteries (the cerebral artery among the rest) at once contract; this produces a gradually increased anæmia of the respiratory centre, and inspiration becomes deeper; this, however, supplies the wanted oxygen to the blood; the arterial spasm is relieved, the anæmia of the respiratory centre passes off, and with it the exaggerated impulse to respiration and breathing once more becomes superficial," and with the cessation of the arterial spasm the stage of apnœa is again reached.

Filehne's theory is very ingenious, but I do not see that this explanation has relieved us from our embarrassment. First, he claims increased vaso-motor irritability. Does not this exist normally, as much as it can be demonstrated to exist in these special cases? Does not the sympathetic system (the heart being under its control), as a rule, persist longer in a condition of irritability than the voluntary system, or the semi-voluntary, which controls the lungs (it being the voluntary muscles which are concerned in respiration)? As an instance, the heart of a person asphyxiated by hanging continues to beat for some time after *efforts* at respiration have ceased. Second. He does not explain why a special cause for the symptom exists in some cases and not in others of the same disease. Why should not all cases of cerebral apoplexy or opium poisoning exhibit the Cheyne-Stokes respiration? It seems to me that the missing link, or rather the starting-point in the chain of causation is found in the equilibrium between the respiration and circulation being always disturbed by a relatively weak heart. In all the early cases cardiac degeneration or incompetency was noted. In all of those which I have been able to study personally or through notes, the heart has seemed to be the disturbing factor, even when the disease which has produced the special illness affected other parts. Cerebral hemorrhage, with which this variety of respiration is specially associated, naturally suggests a degenerated vascular system. Since the heart is found to be affected in so large a number of cases of this description, does not this fact offer a reasonable explanation of why certain cases of drug exhibition may or may not show it?

Without discussing the cases which I have instanced in detail, I may say that I believe that they all sustain this view of the situation, although two of them still further disprove the early claim of fatty degeneration of the heart being necessarily present. They seem also interesting as illustrating the range

of age and disease which may furnish this still not fully understood symptom. I am not aware that any one has hitherto pointed out this apparent connection between a *merely weak heart* and the Cheyne-Stokes respiration.

MEDICAL PROGRESS.

The Mortality of Abdominal Section.—At a late meeting of the Royal Medical and Chirurgical Society, Mr. W. A. Meredith (*Lancet*, October 27, 1888) read a paper, the purpose of which was to draw attention to certain points affecting the present death-rate after abdominal section, and with this view operations for ovarian growths were chosen, as being to some extent representative of the entire subject under consideration. As a basis for the inquiry, the results of the author's own work in this connection, amounting to 126 operations, were examined with regard to the chief causes influencing the mortality, special reference being made to the ten deaths which occurred in the series of 104 completed ovariotomies. All the operations were performed with strict antiseptic precautions, including the use of the carbolized spray. He was now less inclined than formerly to look upon the latter as an absolute essential to the safeguards of antiseptic abdominal surgery, but he still considered it valuable as the most convenient and effectual means of antiseptic irrigation at our disposal when dealing with the peritoneal cavity. Both ovaries were removed in seventeen cases, two of which terminated fatally, but in neither instance was the result in any way attributable to the removal of the second ovary. Complete enucleation was performed in five cases, all successful, the resulting rent in the broad ligament being closed by means of a continuous silk suture. He advocated the use of the drainage tube in all cases of ruptured or inflamed cysts, in any case in which irritating or septic fluid had escaped into the peritoneum, in all operations complicated by serious injury to bowel or urinary bladder, in every instance in which washing out had been resorted to, and in all cases of severe operation in middle-aged or elderly women. For washing out the peritoneum, where necessary, he advocated the use of plain, recently boiled water, cooled as required by the addition of a saturated solution of boric acid.

Discussing the mortality, he was inclined to believe that in a large series of cases the average death-rate would never be less than five or six per cent. Of the ten deaths in his series, two were from septicæmia, one from intestinal obstruction, one from hemorrhage, one from dysenteric diarrhœa, two from chest complications, and three from exhaustion; three of these deaths were from preventable causes. Twelve successful operations for the removal of the diseased uterine appendages were next reviewed. In seven patients, in whom both appendages were removed, complete arrest of menstruation followed. He had found that in cases of chronic ovarian mischief about ninety per cent. were the subjects of obstinate constipation, and in them tonic purgative treatment, by lessening pelvic congestion and preventing the formation of scybala, was followed by marked relief of symptoms. Included in a series of ten exploratory operations were two incomplete ovariotomies. Both patients had been tapped, and the death of one was directly due to the difficulties encountered in the attempt to separate universal adhesions which had resulted from this treatment.

In conclusion, it was shown that the increased success of abdominal section for ovarian disease during the past ten years was chiefly attributable to the diminution in the number of deaths from septicæmia. For purposes of comparison he took three successive groups of operations, which represented three separate periods during the last twelve years, and gave their average death-rate from septicæmia alone. In 100 consecutive cases taken from Sir Spencer Wells's work, when the clamp was used and before the employment of antiseptics, the mortality was ten, or one to every ten patients. In 150 cases recorded by Mr. Thornton in the sixty-fourth volume of the *Medical and Chirurgical Transactions*, which were treated antiseptically and with intra-peritoneal ligature of the pedicle, there were five deaths, or one to every thirty patients. In his own series of 104 cases there were two deaths, or one to every fifty-two patients. The chief factors which had contributed to this increased success, he thought, were as follows: (1) The general adoption of the intra-peritoneal treatment of the ovarian pedicle; (2) the application of the antiseptic system to abdominal surgery; (3) the gradual abandonment of the practice of tapping adbominal cysts; (4) the increase in our knowledge respecting the proper use and management of the drainage tube; (5) the recent introduction of the plan of freely washing out the peritoneal cavity in cases complicated by the extravasation of blood or other fluid.

Mr. Alban Doran had seen great advantages follow both the antiseptic and the non-antiseptic systems of treatment. He thus summed up the influences which he thought contributed to lessening the mortality after ovariotomy: The skill and experience of the operator; early operation; a good hospital and efficient nurses, amongst the latter emulation being a great factor in favor of good results; the use of antiseptics, not only for their own value, but because they drilled the operator into habits of forethought; drainage, when the tube was frequently pumped out; and gently flushing the peritoneum with a great bulk of warm fluid, which checked hemorrhage, washed out clots, and prevented shock by keeping the peritoneum warm. He condemned the use of a ward nail-brush, which he believed to be a frequent carrier of infection.

Mr. Knowsley Thornton objected to stitching up the rent in the peritoneal capsule after enucleation. A number of small vessels were torn; hemorrhage or serous effusion might occur into the sac, which led to tension, nerve disturbance, inflammation, and suppuration. If the rent was left open, the case did much better, as the fluid flowed into the peritoneum and was rapidly absorbed. Tapping of cysts should not be resorted to, the escape of fluid in some cases leading to infection of the peritoneum. Ruptured cysts rarely needed drainage if carefully sponged out. He thought that flushing often acted by breaking up septic material into tiny particles, which were unable to defend themselves against the power of the peritoneum. He maintained that efficiently performed oöphorectomies always stopped menstruation. In cases of ovarian disease it was only necessary to remove the troubled ovary or tube—not both. It was sufficient to empty the drainage tube once in twelve hours under the antiseptic method, but to do so every hour was not too often where no antiseptic was used.

Mr. Meredith replied that he did not consider the opening made in the broad ligament to enucleate a cyst was comparable with the peritoneal wound made in the removal of a kidney. Women at the menopause were passing through a critical time, when kidney trouble often developed, which would hinder ready absorption of peritoneal fluid; he was, therefore, inclined to extend the advantages of drainage to them. Flushing out the peritoneum not only checked hemorrhage, but also avoided the undue irritation of the membrane caused by excessive sponging.

For Enteritis in Infants.—

Camphoric Acid in Inflammation of the Mucous Membranes.—Mosler, an assistant at the Medical Clinic at Greifswald, reports (*Deutsche med. Wochenschr.*) the results of the use of camphoric acid in the various catarrhs. Camphoric acid is an oxidation product prepared by the action of nitric acid on camphor; it crystallizes in colorless needles; it is with difficulty soluble in water, but readily in alcohol and ether; the taste is acid, astringent, and somewhat disagreeable. It is innocuous in small doses, and is only irritant to the gastric mucous membrane in large doses. Among the indications for its internal administration are the night-sweats of phthisis. In all of the seven cases observed by the author the influence was prompt and encouraged further investigation. Fifteen to thirty grains of the powdered, crystalline acid were given at night. Based upon its disinfecting and astringent action, camphoric acid was successfully used in a case of acute cystitis for three weeks (seven and a half grains, thrice daily); the large amounts of pus present in the urine almost entirely disappeared and the subjective condition remained satisfactory. Milder attacks of catarrh of the larynx and of the nose submitted after one to two weeks' application with a brush and a spray of one-half to one per cent. solutions (at first made with glycerin, but subsequently in bicarbonate of sodium). Inhalations of the one per cent. alkaline solution in phthisis and chronic bronchitis were followed by diminution of the irritation and expectoration, and rendered the expectoration easier. Washing out the bladder with a twenty per cent. alcoholic solution, diluted with lukewarm water to a half to one per cent., answered admirably in chronic cystitis.—*Wiener medizin. Presse*, No. 42, 1888.

Creolin.—The utility of creolin as an all-round remedy is summed up by Dr. Lichtwitz as follows: It is an antiseptic of high powers, a disinfectant, hemostatic, and non-poisonous, as large a dose as 120 grains having been taken with no bad results. In cases of tænia solium and oxyuris vermicularis, in 15 grain doses in capsules, it has proved beneficial; and in parasitic skin troubles and eczema, given in soap liniments, its action is especially efficacious. Internally it is recommended for all troubles of the digestive tube accompanied by fermentative processes, and when the stomach is the seat of cancer. In diseases of the larynx and trachea it may be given with advantage by inhalations, or the powder applied directly to the morbid tissues. There are many cases of ulcerative keratitis which it alleviates, but some in which it has no appreciable effect.—*Les Nouveaux Remèdes*, October, 1888.

Chromic Acid in Excessive Sweating.—A circular has been sent to all the Prussian Army medical officers, advocating chromic acid as an economical and efficient means of checking excessive perspiration. In hyperhidrosis of the feet the application of a ten per cent. solution, repeated every three or six weeks, is sufficient to prevent any inconvenience from this source.—*Medical Press*, October 24, 1888.

Impetigo.—The contagious nature of impetigo induces M. Eloy to insist upon the isolation of patients affected with it, and where this is impracticable, to have towels and brushes specially set aside for their use. The patient should bathe frequently in antiseptic water and apply the following ointment:

R.—Boric acid . . . . . gr. xv.
Vigo's ointment . . . . ℈iv.
Vaseline . . . . . ℥j.—M.

To be spread on fine linen and applied to the diseased surface.

Successful Splenectomy.—A successful splenectomy was performed on August 2d last, at the Charity Hospital, New Orleans, by Dr. G. B. Lawrason. The patient was a woman, aged thirty-one years, who had been under treatment for uterine fibroids. She presented a large tumor of the abdomen to the left of the median line, which was diagnosticated as an enlarged spleen. It was entirely unconnected with the uterus, and was very movable, and could be pushed upward under the left ribs, and as there seemed to be periodicity in the paroxysms of pain large doses of quinine were ordered to prevent them. The pains becoming more continuous, hypodermatic injections of strychnine and codeia were made twice daily in the spleen.

The patient obtained no benefit from the treatment and strongly begged to have the tumor removed. After some hesitation, on account of the great pain which it was causing and the comparatively favorable prognosis from the fact of its being a floating spleen, extirpation was decided upon. On August 2d the patient was chloroformed, and with the assistance of Drs. Souchon and Logan and members of the Hospital staff, the operation was performed. An incision was made in the median line, extending from about an inch above the umbilicus toward the symphysis, about seven inches in length. The spleen was found under the incision and removed by slipping it sideways. The pedicle proved to be about eight inches in length, and was very much twisted. The return circulation was so impeded that the veins were dilated to the size of intestines. Two ligatures were applied about

an inch apart and the pedicle divided between them, leaving a stump about six inches in length. The arteries and veins were tied separately in the stump as an additional safeguard against hemorrhage. No blood was lost, so the peritoneal cavity was closed immediately with fourteen sutures. The spleen weighed 54¼ ounces, measured 12½ inches in length, 7 inches transversely, and almost 4 inches at its thickest point.

On being drained of its blood it shrank nearly to normal size. On microscopic examination nothing abnormal was found. The recovery of the patient was uninterrupted until the 14th, the temperature not having risen above 99⅗°. On that date she had a severe chill, the temperature rose to 101°, and there was great pain referred to the left side. This was all easily controlled by quinine. On the 16th the patient was allowed to get up, the temperature and pulse were normal, and the appetite very good, but not exaggerated. The patient returned home the first of October, feeling perfectly well. During the operation after opening the abdominal cavity the pulse became very weak and rapid, but after removing the spleen it resumed its normal strength immediately. During the treatment three hypodermatic injections were given to produce rest; each time an abscess was formed at the seat of puncture.—*New Orleans Medical and Surgical Journal*, November, 1888.

For the Green Diarrhœa of Children.—For the diarrhœas of children, particularly for the green, undigested evacuations containing casein particles, Zinnis (*Union Méd.*) enjoins the withdrawal of all starchy food with the following prescription:

℞.—Aquæ fœnic. . . . . 75 parts.
Liquor. calcis . . . . 6 "
Bismuthi subnitrat. . . . 3 "
Syrup. aurantii flor. . . . 15 "—M.

S.—A dessertspoonful every two hours.—*Deutsche med. Wochenschrift*, September 6, 1888.

Management of Cerebral Hemorrhage.—Dr. Liégeois treats light attacks by absolute rest in bed in a shaded room, the head of the patient being elevated and all constriction removed. If the case is severe, he bleeds at the arm, whether the pulse is free or weak, and gives, later on, iodide of potassium internally. Counter-irritation in the form of sinapisms and vesicants, is applied to the chest and extremities, and cold dressings are used on the head every three or four hours. If the onset of the disease has followed a hearty meal, he gives an emetic of ipecacuanha.

When internal stimulation is desired, Hoffman's anodyne, ammonia, or ether, hypodermatically, are found the most reliable agents. For the two weeks following the apoplexy he regulates the diet, and if paralysis results he treats it by massage and electricity. For the more remote effects he relies on the iodide of lithium or sodium, and as the action of these drugs is debilitating to some patients, he adds a tonic of arsenious acid.—*Revue Générale de Chirurgie et de Thérapeutique.*

Intermittent Hemoptysis in Phthisical Subjects.—Dr. J. Lowenthal, of Frankfurt on Main, in No. 39 of the *Centralbl. für klin. Med.*, describes two cases of intermittent hemoptysis in phthisical patients, one of which had already been reported by Silber-Schmidt. In the first case there was no hereditary predisposition. There were dulness at the left apex and a cavern at the right. The sputum contained large numbers of bacilli tuberculosis. The liver and spleen were not enlarged. There were night-sweats and intermittent fever. On May 27th, at noon, an attack of cough and blood-spitting set in, some ten ounces of blood being lost. On June 1st, at about noon, two pints of blood were lost, and on June 2d there were several minor attacks, in which about one pint was lost. On June 3d, twelve ounces were lost. The spleen was now found to be perceptibly enlarged. From 10 A. M., June 6th, to 11 A. M., June 7th, seven ounces of blood were lost. The spleen was yet enlarged. From 10 A. M., June 10th, slight hemoptysis continued. At this stage, Gerhardt made the diagnosis of intermittent hemoptysis and ordered quinine, fifteen grains, morning and evening, until June 20th, during which time no blood appeared in the expectoration. On June 20th, the spleen was no longer enlarged.

The second case was that of a man who had already had bloody expectoration. Creasote was administered, improving the general condition. From July 14th to 17th, at intervals of eighteen hours, the patient spat blood. The spleen was somewhat enlarged. Upon the administration of quinine the expectoration of blood ceased, and on July 26th, the spleen was no longer enlarged. The sputum contained bacilli. From the regularity of interval of the recurring attack, from the enlargement of the spleen, and from the efficacy of quinine, the author diagnosticated a masked intermittent. He explains the occurrence of the intermittent hemoptysis by the fact that in cases of masked intermittent the concentration of the malarial poison is not sufficient to cause a typical attack of fever, but that the poison operates upon some point, the normal resistance of which is diminished. The progress of the disease is attended with erosion of a vessel, which ruptures from the increased blood pressure caused by the influence of the malarial poison.—*Wiener medizin. Presse*, No. 42, 1888.

Phenic Acid in Skin Diseases.—The internal use of phenic acid in pruriginous affections is highly thought of by Dr. Augagneur, and is especially efficient in eczema and psoriasis. He gives it in the following combination:

℞.—Phenic acid crystals . . . gr. vij.
Syr. aurantii . . . . ℥vj.
M. Glycerine q. s. to dissolve acid.

The dose for an adult is two teaspoonfuls daily.—*Revue Générale de Clinique et de Therapeutique.*

Balsam of Peru for Idiopathic Leukoplaques and other Disorders of the Buccal Mucous Membrane.—Many remedies, both medical and surgical, have been used in the treatment of the so-called idiopathic leukoplaques or psoriasis of the buccal cavity. The use of the galvano- and thermo-cauteries and the sharp curette are rational enough, but the condition is apt to recur. Medicinally, nitrate of silver has been applied locally, and alkaline mouth washes have been used. Corrosive sublimate is efficient only in cases of specific origin. Chromic acid, tincture of iodine, iodoform-ether, and iodoform-alcohol are unreliable. Lactic acid is an excellent remedy, but it has the disadvantage of injuring the teeth, no matter

how carefully applied. The same objection applies to salicylate of sodium. Recently, papayotin, in five to ten per cent. solutions, has been recommended; but the preparation is often unreliable, decomposes readily, is expensive, and only exercises a pain-relieving influence and forms a covering for the denuded surfaces, not influencing the disease process. After numerous trials, ROSENBERG (*Therapeutische Monatshefte*, October, 1888) recommends the balsam of Peru applied with a brush. Two points should be borne in mind: the remedy must be used for a long period; and the preparation must be a good one. The application is followed by slight burning and increased salivary secretion, and is made one to three times daily by the patient himself. It is also thought that in mercurial stomatitis this method of treatment not only diminishes the pain but also the salivation, and that it shortens the duration of the disease. There seems to be no reason why the utility of balsam of Peru should be confined to affections of the mucous membrane of the mouth. The remedy should also prove useful in disorders of other mucous membranes, particularly of those of the urethra, the rectum, and the female genito-urinary tract. The author concludes as follows:

1. Balsam of Peru has an analgesic influence upon painful conditions of the buccal mucous membrane dependent on tissue changes.

2. It hastens granulation and repair of lost tissue.

3. It causes the disappearance of epithelial opacities, in case of old leukoplaques, however, often only after protracted treatment.

When to take Medicines.—Alkaline medicaments should be given before meals. Iodine and its preparations should be given during fasting, when they become rapidly absorbed in their own forms and do not undergo the changes caused by the presence in the stomach of food acids and starchy materials. Acids are best taken midway between meals, when they become rapidly diffused. If, however, it is desired to limit the production of gastric juice, they are given just preceding a meal. Arsenic, copper, and like irritants come after meals, likewise, cod-liver oil, phosphates, and malt preparations. —*Journal de Méd. de Paris.*

Chloroform Water as a Hæmostatic.—ULBRICH (*Präg. med. Wochenschrift*, No. 32) recommends chloroform water (1 : 10 well shaken together) as an effective hæmostatic in bleeding from the gums after the extraction of teeth. Chloroform water is not only a hæmostatic, but also an antiseptic and anodyne in painful and mycotic affections of the mouth. It has also been used for the severe stomach pains of neurasthenia.

℞.—Aquæ chloroformi . . . 100 parts.
Aquæ aurantii corticis,
Aquæ menthæ piper. . āā 50 parts.—M.

S.—Take tablespoonful, three times a day.—*Deutsche med. Wochenschrift*, September 6, 1888.

The Results of the Surgical Treatment of Diffuse Purulent Peritonitis and of Peritoneal Sepsis.—WITZELL, of Bonn, before the Surgical Section of the Sixty-first Congress of Naturalists, discussed this subject:

Though the peritoneum, under certain circumstances, bears well the presence of extremely irritating, infectious matters (as in the reposition of the injured and soiled intestine), although surgical operations for diffuse peritonitis are successful, sometimes in spite of doubtful cleansing of the abdominal cavity, still the method of operation in peritonitis must be improved in the direction of thoroughly, and with safety, cleansing and disinfecting the cavity. The methods hitherto used (removing the intestines or filling the abdominal cavity with antiseptic fluid, evacuated by turning the patient on his side) expose the patient to severe shock without sufficient warrant of entire success. As a result of numerous experiments with animals, Witzel recommends making numerous perforations in the peritoneum, the introduction of long drainage tubes in various directions and passing through these a warm solution of common salt. That this method is also capable of removing the products of inflammation was demonstrated by three cases thus treated—demonstrated at the autopsy, it is true, for, on account of the severity and duration of the existing condition, the operation was powerless to prevent death. It is important to distinguish between peritoneal sepsis and diffuse peritonitis. In the former an enormous development of septic irritant matter occurs in a cavity, the absorbing power of which remains unchanged; the septic products are not prevented entering the system through the large lymph spaces. In purulent peritonitis, however, there exists an inflammatory condition of the serosa, and the lymph spaces are early occluded. Thus, in peritoneal sepsis, therapeutics is hopeless. In the transition forms of purulent-putrid peritonitis, the degree of general infection determines the result. Some successes have been had from the surgical treatment of such cases (Krönlein, Mikulicz, etc.); also, without finding and suturing the perforations in the stomach or intestine has a cure been effected by incision and drainage (Lücke). In true purulent peritonitis, not the result of perforation, we have in its progress, so to speak, to do with a more or less simple abscess; for this reason, surgical measures promise much better results. The progress is equally favorable in cases of so-called idiopathic and in true puerperal peritonitis; in metastatic puerperal pyæmia temporary relief, at least, may be secured by evacuation of the large exudate. In the discussion, Krönlein reported that he had operated in six cases of diffuse purulent-putrid peritonitis, with success in but one. He prefers the median incision and disinfection from this point to multiple incisions.—*Berlin. klin. Wochenschr.*, Oct. 15, 1888.

Pastels for the Sick-room.—

℞.—Iodine . . . . . 1 part.
Acidi salicylic. . . . . 2 parts.
Paraffine . . . . . q. s.

These ingredients are mixed, a wick supplied, and then burned at a candle. The salicylic acid is changed into phenic, and the iodine set free in its own state.—*Revue de Thérapeutique.*

Acne.—For two years LASSAR has successfully treated acne by the application of an ointment of naphthol, 10 in 100. This is washed off in an hour and reapplied on the second day, when desquamation occurs without any cicatrix remaining. In more obstinate cases a camphor salve is also added.—*Lyons Médicale.*

MENINGITIS IN TYPHOID FEVER.

THE more closely the clinical history of typhoid fever is studied, the more important do its complications appear. Betke, from an analysis of a series of 1420 cases in the hospital at Basle, found only 672 free from complications, whereas 748, or 52 per cent., showed complications of a more or less marked character. It is obvious that no hard and fast line can be drawn between the complications of an acute febrile disease and the mere intensification of certain processes with corresponding prominence of local symptoms. We agree with those who place intestinal hemorrhage, perforation, and peritonitis among the complications. To the same category it seems proper to refer such results of parenchymatous degeneration as atrophy of muscles, abscess of muscles, parotitis, and nephritis. The category to which hypostasis, œdema, thrombosis, embolism, and infarction, with their results, should be referred is a matter of opinion. Whether these processes should be regarded as belonging to the primary disease or as complications of it, would depend, to a great extent, upon the prominence of the morbid phenomena to which they give rise. On the other hand, pneumonia, erysipelas, phlegmonous abscesses, diphtheria, and other septic processes are obvious complications, concerning the relation of which to the original disease there can be no question.

Among the less common of this latter group is meningitis, the occurrence of which as a complication has, from time to time, been the subject of much discussion in view of the fact that, while symptoms pointing to its existence are by no means rare in the course of typhoid fever, for a long time its anatomical lesions had been sought for in vain, even in instances in which the symptoms had been during life pronounced. More recently, the occurrence of cases characterized by convulsions, paralysis, hyperæsthesia, opisthotonos, with the discovery upon examination, *post mortem*, of the associated lesions of cerebro-spinal meningitis, has placed this affection indisputably among the complications of typhoid.

FREYHAN (*Deutsche med. Wochenschr.*, August 2, 1888) has recently reported three cases of meningitis occurring as a complication of typhoid, observed in the wards of Dr. Fürbringer, in the Hospital Friedrichshain, in Berlin. These cases occurred in individuals aged nine, twenty, and twenty-six years respectively. They all terminated in recovery; nevertheless, the symptoms were so well marked as to leave no doubt of the propriety of the diagnosis. As the result of the study of these cases and of the literature of the subject, which is limited, Freyhan makes some general statements, which are of value as illustrating the clinical history of this complication and as shedding light upon the differential diagnosis between mere functional disturbances of the nervous system and meningitis.

The time of the occurrence of meningitis as a complication is in the second period of typhoid fever, occasionally not until the convalescence. Prodromes are, as a rule, absent; occasionally the outbreak is preceded by headache and restlessness. The earlier symptoms are severe headache and vomiting. Headache occurring after the end of the second week thus becomes significant. It is often diffuse, most intense in the occipital region, sometimes localized in the brow, continuous with occasional intensification. It is associated with pains in the neck and back and tenderness upon pressure along the spine; there are also muscular stiffness and opisthotonos. Intellectual disturbances range from mere confusion to furious delirium or deep coma. Most significant symptoms are paresis and paralysis. They vary in intensity from mere weakness of a leg or arm difficult to recognize, to complete hemiplegia. Partial palsies of the facial or oculo-motor nerves and paralysis of the tongue likewise occur. Especially characteristic is the rapid development of optic neuritis. Paralysis of spinal nerves is less common, but hyperæsthesia

and increased cutaneous and tendon reflexes are especially important. The fever is of an irregular remittent type.

The differential diagnosis between meningitis as a complication and mere intensification of the symptoms of meningeal irritation in uncomplicated typhoid will rest chiefly upon the association of a number of symptoms pointing to meningitis, and especially upon the simultaneous occurrence of hyperæsthesia, intensification of the reflexes, and positive motor disturbances. The distinction between meningitis of the ordinary form and tubercular meningitis is not always practicable. The differential diagnosis between meningitis and other forms of nervous disease occurring as complications of typhoid fever, such as hemiplegia, paraplegia and monoplegia due to central local lesions, and peripheral neuritis, rests upon well-recognized data. These affections almost invariably occur during the period of convalescence, and are not accompanied by fever or marked cerebral symptoms.

As regards the etiology of meningitis as a complication of typhoid fever, two views may be advanced: first, the doctrine of a localization of the typhoid infection upon the meninges, and, second, that of a mixed infection. Freyhan inclines to the former of these views. In the present state of knowledge this question cannot be decided; for our own part, we believe it more in accordance with the natural history of typhoid fever and cerebro-spinal fever to explain their association on the principle of mixed or independent infection.

THERE has been an unusual, and almost epidemic, prevalence of typhoid fever in the eastern or French-Canadian quarter of Montreal. Nearly one-fourth of the beds at the Hotel Dieu and other hospitals are now occupied by cases of fever. The Board of Health, having entered upon a thorough investigation of the epidemic, early discovered that the law requiring physicians to report the contagious cases, including typhoid fever, occurring in their practice, was not heeded by the fraternity of the French quarter. Prosecution of the alleged delinquents was ordered and several were brought into court under arrest. The judge declined to try the cases, however, holding that the health officer had full jurisdiction in the question of the non-reporting of contagious diseases. Under a discreet administration of his powers, by that officer, Dr. Louis Laberge, it is probable that the important duty of a timely notification of diseases tending to become epidemic will be accepted by the physicians of that frequently afflicted city. The interests of the public health call for it, not only, but it is also greatly to the advantage of the medical profession that the onset and course of those diseases shall be fully known. An amicable understanding between the health authorities and the profession in this matter is a consummation greatly to be desired.

CREMATORIES for destruction of garbage and dead animals are not uncommon in our western cities, but the only one we know of in the Atlantic line of States is the one recently built at Coney Island, New York, for the Board of Health of the town of Gravesend, which town has an enormous summer population, and an enormous amount of hotel-waste. The furnace was accepted, after trial in the presence of experts. It is built of brick, and is twenty feet long, eight feet high, and five feet wide. It will destroy four or five tons of wet hotel garbage and a number of dead animals in about an hour. It does its work without odor, except during the process of charging.

A CHICAGO Associated Press dispatch announces the resignation of Dr. N. S. Davis, as editor of the *Journal of the American Medical Association*, to take effect on January 1st next, and that the Trustees of the *Journal* have elected Surgeon-General John B. Hamilton, of the U. S. Marine-Hospital Service, to fill the position thus vacated.

DR. JOSEPH O'DWYER, the originator of intubation of the larynx, has been appointed Professor of Diseases of Children in the New York Post-Graduate Medical School and Hospital.

DR. R. J. HALL has been appointed to fill the Chair of Anatomy, at the College of Physicians and Surgeons, New York, made vacant by the death of Dr. Sabine. Dr. Charles McBurney has been made Adjunct Lecturer on Surgery.

THE book of Sir Morell Mackenzie, which is said to have reached the enormous sale of 100,000 copies in two weeks, it is stated, is approved by the Empress-Queen Frederick, who has sent him an autograph letter expressing her complete approval of the manner in which he has performed his difficult task, and confirming some of his statements by her own independent knowledge.

The Third Congress of Russian Physicians will be held at St. Petersburg in 1889; an exhibition, embracing the various departments of medicine, will be held in connection therewith.

A new institute for the practical study of sanitary science has been organized at Rome, being the tenth school of this kind to be undertaken in Europe. Original research in sanitary subjects will receive governmental aid through the Italian National Board of Public Health. The curriculum promises to be very thorough and the school will have authority to grant a diploma to those who successfully pursue a full course of study. The institute will be under the direction of the eminent Dr. Paglioni, now the Professor of Hygiene at the University of Turin, who will also occupy the chair of sanitary engineering.

A prize of five thousand roubles is offered in Russia for the best research on the development of toxic elements in uncooked salt fish, to be handed in to the Minister of Interior by January 1, 1893. The scheme to be filled is as follows:

1. To define, by exact experimentation, the physical and chemical nature of the poison.
2. To study, on animals, its effect on the circulatory, digestive, and nervous systems.
3. To determine its rapidity of absorption.
4. To explain the signs by which affected fish may be distinguished from non-affected.
5. To describe means which will prevent the development of poison in fish.
6. To indicate the antagonists to the toxic elements and the medical measures to be employed in cases of persons poisoned by them.

Miss Florence Nightingale is said, by an English publication, to be a confirmed invalid from a spinal disease incurred through over-devotion to the cause of nursing. She went home sick from the Crimea, and her health was never thereafter thoroughly reëstablished. She is now approaching her seventieth year, and is destined to pass the evening of her days as an inmate, and its most favored inmate, of St. Thomas's Hospital, London. It was at that institution, in 1858, was established the Nightingale Fund of £50,000, in perpetual commemoration of the heroic labors of that lady in the Crimean hospitals.

REVIEWS.

Hygiene of the Nursery. By Louis Starr, M.D., Clinical Professor of the Diseases of Children in the Hospital of the University of Pennsylvania, etc. 8vo. pp. 202. Philadelphia: P. Blakiston, Son & Co., 1888.

This book contains much that will be of value to young mothers, for whose guidance it has been written. The chapter on dietetics is full and explicit, as are also the directions as to the clothing and the ventilation and character of the nursery. The term "scarlatinal nephritis" is perhaps somewhat too technical for the lay reader, and the description of the lingual papillæ is unnecessarily accurate.

We do not think that the majority of the profession will agree with the author in his statement that hand-fed babies are stronger and enjoy better health than those nourished at the breast, not only because of the practical difficulties of good hand feeding, but also because the tendency toward such a course is already so unfortunately common among women that the profession should not only encourage maternal care, but, of all things, refrain from making such statements in books prepared for the popular direction of the laity.

In the chapter on disinfectants we are surprised to find copperas, sulphate of zinc, and carbolic acid are the disinfectants recommended. Not only are these not the best disinfectants, but it is also a fact that the poisonous properties of corrosive sublimate cannot be the explanation for its non-appearance on the list since carbolic acid is far more deadly. The table of the eruptive fevers as to their date of incubation, etc., is well condensed, but of doubtful utility.

The book, as a whole, is a safe and reliable guide, pleasantly written and presented in attractive form, but scarcely adapted to the perusal of "my little patients, some of whom, in the rapid passing of time, may soon assume parental duties," to whom "this volume is affectionately dedicated."

SOCIETY PROCEEDINGS.

PHILADELPHIA NEUROLOGICAL SOCIETY.

Stated Meeting, October 22, 1888.

The Vice-President, Charles K. Mills, M.D., in the Chair.

Dr. William Osler presented a

NOTE ON PACHYMENINGITIS HEMORRHAGICA.

There are several points of interest in this condition:

First. Is it in any sense of the term an inflammatory process? Practically, we see one of three conditions in these cases:

a. Subdural vascular membranes, often of extreme delicacy.

b. Simple subdural hemorrhage.

c. Combination of the two—vascular membrane and blood-clot.

In two specimens which I showed last year at the Pathological Society, I remarked on the absence of any of the features to which we could apply the term inflammatory.

Dr. Joseph Wiglesworth, in the January number of the *Journal of Mental Science* for this year, takes the same ground. Apart from injuries, dura-arachnitis is rare. I have seen two instances in the specific fevers. In both there was delicate fibrinous exudate between the dura and the arachnoid.

Second: Which is antecedent, vascular membrane or hemorrhage?

It is usually stated that the hemorrhage occurs first, and from the blood-clot, when organized, the vascular sheet arises. This may be the case, and the fact that subdural hemorrhage is often found alone—in fifteen out of forty-two cases in Wiglesworth's series—lends weight to this view. On the other hand, the vascular membrane may exist without a trace of past hemorrhage; neither staining nor melanin grains, simply a fibrous sheet, varying in thickness and permeated with large vessels. The specimen here shown illustrates this condition: It was removed from a man, aged fifty-six, who died of aneurism. The skull cap was unusually thick and dense and extremely vascular. The meningeal arteries ran in deep grooves through the bone. There were many points of vascular union between the inner table of the skull and the dura. In spite of this, the calvaria was removed without much difficulty. The inner surface of the dura was everywhere covered with a fibrous, highly vascular membrane. Toward the vault it was from half a line to a line and one-half in thickness. Toward the base it was extremely thin. It was chiefly made up of large veins forming in places beautiful arborescent tufts. On section, where the membrane was thickest, the veins bled freely, but there was no trace of clot. Microscopically, the membrane was composed of bundles of connective tissue forming a supporting framework for the numerous vessels. At one small area alone, in the middle fossa on the left side, there was a brownish-red staining on the surface of the vascular membrane.

In the two specimens which I studied last winter the identical condition existed, though in neither was the blood-supply abundant, nor the vascular membrane thickened.

Third. Whence the hemorrhage, dural or pial?

I have always thought the former, but I see that Wiglesworth, in referring to the atrophy of the convolutions as a possible cause for hemorrhage, speaks thus: "The pia mater over a variable area may be so intensely congested as actually to resemble an ecchymosis. . . . It is manifest that the conditions may be highly favorable to actual rupture, and I doubt not that this frequently occurs."

Certainly in the instances I have seen the subdural membranes were intimately associated with the dural vessels, and it seems more probable (and is, I believe, generally acknowledged) that from these the hemorrhage always proceeds.

Fourth. The explanation of the occurrence of this singular structure is by no means clear. The cases are commonly met with in asylums. In general hospitals years may pass without seeing an instance. During eight years in the post-mortem room of the General Hospital of Montreal, no instance occurred. The first specimen which I saw, after having been for fourteen years interested in morbid anatomy, was demonstrated by Virchow, in 1884, at the Pathological Institute. At the Philadelphia Hospital cases are by no means uncommon. Within the past two or three months there have been four specimens found, usually in the bodies of persons from the insane department, but in the three instances to which I have referred, the patients came from the medical wards, and had not shown any mental symptoms.

One reason urged why the subdural hemorrhage is much more common in the insane, is the atrophy of the convolutions so constantly associated with this condition. But there must be something more than this, for if atrophy alone is the chief factor, we certainly would meet with it in phthisis and in other cachectic conditions in which the cerebral wasting is quite as common as in general paresis.

The frequency of this condition in asylum work may be gathered from the fact that Wiglesworth's paper is based upon forty-two specimens which occurred in a series of four hundred unselected post-mortem examinations in which the persons died of various forms of insanity. Wiglesworth's contribution is one of the most interesting and valuable that has been made upon the subject.

DR. F. X. DERCUM asked if Dr. Osler accepted the view of Wiglesworth that this condition of the dura is really due to hemorrhage from the pia. He could not understand how a hemorrhage from the pia could become so intimately connected with the dura. He had always regarded the formation as dural.

He asked Dr. Osler if he had any explanation to offer for the formation of these curious cysts in old cases of pachymeningitis.

DR. JAMES HENDRIE LLOYD said that Dr. Osler had stated that in the case reported there was aneurism of the aorta. He would ask if there was any connection between the two conditions. Were there any brain symptoms? The idea has prevailed heretofore that we mostly find this condition in connection with brain troubles such as general paresis, trauma, and chronic alcoholism.

DR. CHARLES K. MILLS said that the paper was interesting in connection with a case of a child nearly three of age, with spasms of a peculiar type, for which he advised trephining and the operation was done by Dr. John B. Roberts at the Philadelphia Polyclinic. After the removal of the skull and dura mater, a membrane was found which was easily separated from the pia-arachnoid. It was a vascular membrane, between the dura mater and the pia-arachnoid. Œdema and great vascularity of the pia mater were also present. After the escape of some serous fluid, the brain apparently receded. The history was that a clock had fallen upon the child's head, and the question was whether or not a slight hemorrhage beneath the dura had not taken place, or whether there might not have been the formation of a membrane without the presence of a clot. It may be that this is the explanation of some of the cases of infantile spasm of peculiar type. This child often had from eight to ten attacks a day. The day after the operation it had two slight attacks, but since then none. He had seen a considerable number of cases of pachymeningitis hemorrhagica at the Philadelphia Hospital, some of which he had reported.

DR. OSLER did not see how the hemorrhage could be connected with the pia as Dr. Wiglesworth thought. The cases he had seen had been in medical wards,

and had presented no indications of cerebral trouble. Atrophy of the convolutions does not always coexist. If atrophy were one of the prime factors in the causation of this condition, we would expect to see it more frequently in phthisis and the chronic cachexias, in which the cerebral wasting is often quite as marked as in general paresis. There is often as much thickening of the pia-arachnoid and gelatinous œdema between the convolutions in phthisis as in general paresis, yet, so far as he knows, subdural hemorrhage has not been described in connection with phthisis except in the inmates of lunatic asylums. The condition is rarely met with in general practice. He had himself twelve years' experience in general autopsical work before he saw a case of pachymeningitis hemorrhagica. The first case that he saw was demonstrated by Virchow in 1884, in the Pathological Institute in Berlin. At the Philadelphia Hospital the condition is met with two or three times a month, usually in patients from the Department for the Insane.

Dr. Osler then presented a communication entitled

injury to the cauda equina and syphiloma of the cord and cauda equina.

which will appear in full in an early issue of The Medical News.

Dr. F. X. Dercum reported

three cases of spinal accessory spasm unsuccessfully treated by excision of the nerve.

The following cases were placed on record, not only to confirm the inutility of the treatment by excision of the nerve, but also to provoke discussion.

Case I.—J. F., aged forty years, married, and a gas-fitter by trade, presented himself at the Nervous Dispensary of the University Hospital, with the following history: He had had rheumatism at various times, one attack of which had kept him in bed nine weeks. Eight months after this last attack he had rheumatism of the muscles of the shoulders, and then began to have turning of the head to one side, which, up to the time of his first examination, had lasted a year. The movements were at first slight and painless, as they still are, but about one month after their first appearance the movements became excessively violent, coming on in paroxysms, and interfering with sleep. His wife described these attacks as irritable convulsions. However, they were limited to the neck, and were unattended by loss of consciousness. These excessively severe paroxysms were, later on, merely occasional. Short, sharp, jerky movements were, however, never absent. The sterno-cleido-mastoid of the right side felt hard and contracted, and was evidently the principal muscle at fault. Indeed, in the movement observed by us it appeared to be the only one involved, though in the severe paroxysms described by the patient the other neck muscles, doubtless, played a part.

Some years ago, Dr. H. C. Wood successfully treated one of these cases by severely cauterizing the back of the neck with the hot iron, and acting upon this hint, the Paquelin cautery and antimonial ointment were freely used in the present case, but without relief of the spasm.

Finally, the patient was admitted to the hospital under the care of Dr. Agnew, who excised a portion of the right spinal accessory nerve. The immediate effect of the operation was a disappearance of the spasm, but as this man had left the hospital, in which he remained twenty-five days, the small, jerking, rotatory movement of the head had again appeared, and he could discover little, if any, difference in the character of the movement. Whether any of the more severe paroxysms recurred he was unable to say, as the patient has not since been under observation.

Case II.—E. L., aged fifty-eight years, married, a watchcase-maker, likewise presented himself at the University clinic two years ago. When apparently in good health, he commenced to have slight twitching in the neck. This twitching had gradually become marked, and, at the time of making the note, was present in the form of a severe clonic spasm. There was no history of rheumatism or syphilis.

Examination showed that the left sterno-cleido-mastoid and trapezius muscles were affected. The spasm was slow and irregularly recurring, and was accompanied by pain in the mastoid and occipital regions. It interfered greatly with sleep, the patient being kept awake two or three hours after lying down. Phonation also seemed to be occasionally interfered with.

The patient refusing to be cauterized, various internal remedies were prescribed, all without avail. Finally, he was admitted to the surgical wards, and likewise operated on by Dr. Agnew, who again removed a portion of the nerve. However, within a few hours after recovering from the effects of the ether, we might say almost immediately, the spasm recurred, and it persisted during the entire stay of the patient in the hospital, some three weeks. I should remark, however, that the spasm appeared to be less severe. Certainly, the movements were of less extent.

It is exceedingly probable that in this and the preceding case, other muscles than those supplied by the spinal accessory nerve were involved, and to this, in part at least, the failure is to be ascribed. However, I determined to give the method another trial in the following case, which seemed more favorable.

Case III.—M. K., female, aged fifty-five, a housekeeper, presented herself at the clinic with constantly recurring slow spasm of the right sterno-cleido-mastoid. This, she said, had existed for two years. At its commencement she had been in her usual good health. Examination showed the right sterno-mastoid to be markedly hypertrophied; further, that the right trapezius also participated, but to a slight extent. It could not be determined that any other muscle was, or had at any time been involved. The patient complained also of occipital pain, and pain along the dorsal spine.

After a rather prolonged trial of the cautery, galvanism, and various drugs, the knife was again appealed to, Dr. Ashhurst this time being the operator. Owing to the apparently limited character of the spasm, he was hopeful of a good result. Dr. Ashhurst performed an extremely thorough excision, removing over four inches of the nerve-trunk, including not only the supply to the sterno-mastoid, but also that to the trapezius. Previous to making the excision, the nerve was thoroughly stretched, very marked force being used. After the operation, and during the entire stay of the patient in the hospital, some twenty-one days, no spasm whatever was observed. However, that an inference as regards cure would have been altogether premature, was proved subsequently. The operation was performed on the 2d of June, and in

the early part of the following August he received a letter from the patient, bitterly complaining that the spasm had returned, saying that it was "very bad again." Of the extent of the recurrence he could not speak with certainty.

Whether in these three cases the recurrence of the spasm was due to the spreading of the affection to other muscles, or to the vicarious nerve-supply of the sterno-mastoid and trapezius, is, he thinks, a matter of minor importance. The belief that these spasms are centric in origin, certainly gathers additional force, and the problem that presents itself is, whether the centres affected are spinal or cerebral, and how this differentiation shall be made. Secondly, whether a more radical surgical treatment should be invoked. These were the points to which he invited discussion.

He purposely refrained from speaking of the morphia treatment of these cases, inasmuch as its application to dispensary patients, who can be so loosely controlled, would be of more than doubtful propriety.

DR. CHARLES K. MILLS added another to the list of unsuccessful cases treated by this operation. On the 6th of this month Dr. Roberts operated on a case which had been sent to Dr. Mills by Dr. Tomlinson, of Wilmington. Dr. Roberts cut down on the spinal accessory nerve of the affected side, and, after identifying the nerve by the faradic current, excised one and a half to two inches. Two weeks after the operation the patient left the hospital, the spasm somewhat improved, but certainly not cured. Dr. Mills had had a number of these cases, and some years ago wrote a paper on the subject. Two of the cases reported recovered largely under the use of the actual cautery.

One of the questions which arise in a consideration of these cases is whether some of them are cortical in origin, due to lesion of the centres for conjugate deviation of the head. He believed that such a view could be entertained, but probably not for such a case as he had referred to, or for such as Dr. Dercum had reported. The persistence of the spasm and its tonic character in most cases are against the supposition of cortical lesion.

DR. DERCUM said that the point is, How are we to differentiate between the spinal and cerebral cases? If conjugate deviation of the eyes occurred with the movements, there would be reason for supposing that there was a cortical lesion. It is, however, rare to have this association. It was not present in his case.

As an indication of the utter hopelessness of operations on the muscles and nerves, it would be well to bear in mind that the movement is one in which a large number of muscles are involved. There are nine muscles, in addition to the sterno-mastoid and trapezius, which are called into play in the act of turning the head and neck, besides two others which act as rotators at times.

DR. J. H. LLOYD reported the following

CASE OF ALCOHOLIC MULTIPLE NEURITIS,

which presented such a characteristic clinical picture of a disease which is not common, that he was led to report it in spite of the fact that the pathological study was incomplete.

Margaret M., aged about thirty-five years, was admitted into the nervous ward of the Philadelphia Hospital in May, 1888. She had a family history of phthisis on the father's side. The patient had never been very strong, but had had no sickness except the ordinary diseases of childhood. She was married at seventeen and had had four children, the last labor occurring five years before admission. She denied syphilis, and presented no lesions of it. She also denied excessive drinking, but an inquiry of her friends revealed the habitual use of alcoholics, sometimes in excess, from her childhood. Four weeks before her admission she awoke one morning to find both her feet paretic. For one week preceding this she had had severe pains in both legs.

On examination the following facts were noticed: The patient was anæmic, very despondent in expression, and rather emaciated. She presented double wrist-drop, more marked on the left side, with wasting of the arm muscles, also more marked on the left side. There was paralysis, quite complete, of the anterior leg muscles on both sides, with consequent foot drop, and wasting. The extensor muscles of the left forearm contracted sluggishly to the faradic and galvanic currents, and showed the serial reactions of degeneration: A. C. C. > C. C. C. The extensors of the feet (muscles especially supplied by the anterior tibial nerves) also reacted sluggishly and showed reactions of degeneration to galvanism. The patellar reflexes were abolished. There were small areas of anæsthesia over the legs and feet. She would believe that a pin was touching the foot when it was touching the leg, and confused the legs. The sensory symptoms were very significant. She suffered from severe burning pain on the soles of the feet, and later in the palms of the hands, causing her to complain. The nerve trunks were acutely sensitive. Pressure over the popliteal and peroneal nerves of the main trunks of the arm was productive of most severe pain. The peroneal nerves especially were sore. The muscles of the leg were extremely sensitive to touch, and those of the calves especially were very tender.

The lungs were normal. The heart presented a faint systolic murmur at the apex; not always heard, and possibly anæmic (?). The pulse was small in volume, very rapid, constantly ranging from 122 to 140, and easily compressible. Her temperature was constantly afebrile, except on two days, when it rose to 101⅘°. For more than half of the time she was under observation (about four weeks) the temperature was rather subnormal, falling as low once as 96⅗°. It was taken in the axilla. The loss of appetite was complete, and the tongue was furred. She slept poorly and her mind wandered. At times she was in a well-marked delusional condition, and was restless always and complaining.

The patient, as she lay in bed, with the wrist-drop and foot-drop, bore a striking resemblance to the picture which Gowers has, in his recent work, of a patient with this disease.

The indications for treatment were especially to relieve pain and sustain the power of a failing heart. It was soon evident that the patient would not respond to treatment. The heart, in particular, never improved in its action. Digitalis was given in the form of tincture, infusion, powder, and poultices of the leaves, but the pulse remained rapid and feeble. A full liquid diet was administered in oft-repeated quantities, but alcohol was not given until toward the last, and then in small doses. It is not necessary to detail all the treatment. Partial relief was obtained from the burning pains in the soles of the feet by lotions of carbolized water; and small cantharidal blisters were used with some benefit over some

of the most painful nerves, as the peroneal. The patient gradually sank from a weak heart and died rather suddenly about the end of the fourth week of her sojourn in the hospital.

He regretted to say that the specimens from this case became decomposed, in some unaccountable way, and were unfit for microscopic study. The brain, cord, and affected nerves, clear to their ramifications in the muscles, were removed, and did not exhibit any marked change on gross examination. It was thought that some parts of the posterior columns were sclerosed; an observation which, he believed, has been made before in some of these cases. The history and observation of the case do not point to an original posterior sclerosis, and it may be a question whether such a change in the cord in a case like the one described could not be secondary to the original nerve lesions. It is also a question whether the obstinately feeble action of the heart in these cases may not be due to changes in the pneumogastric similar to those which occur in the other nerves. The heart was small and the valves normal. The liver was fatty and the kidneys slightly congested and enlarged.

DR. W. T. SHARPLESS reported a case of

EMBOLISM OF THE MIDDLE CEREBRAL ARTERY. LEFT HEMIPLEGIA, ULCERATIVE ENDOCARDITIS, AND LATE GENERAL CONVULSIONS, AND SKIN INFARCTS.

M. D., aged thirty-one years, married (service of Dr. C. K. Mills, at the Philadelphia Hospital), had nothing special in family history. Had been very intemperate for several years, and there was a probable history of syphilis although he denied it. He had acute articular rheumatism last winter which was his only attack. In March last he was suddenly paralyzed on the left side and entered the hospital on April 18th. His condition Aug. 1st, when he came under Dr. Mills's care, was as follows: Left hemiplegia; paralysis marked in the arm, less so in the leg, and not at all in the face; œdema of feet and legs, extending to the knees. He had a very loud double aortic murmur that could be heard as far down the back as the sacrum. Area of cardiac dulness was very much enlarged, as was also that of the liver and spleen. The urine contained albumen in considerable quantity, and later hyaline, granular, and a few epithelial casts were found. In testing his sensations it was found that he could not perceive a light touch as well on the paralyzed side as on the other; but the sense of pain was preserved. Paralyzed muscles responded to the faradic current and showed no reactions of degeneration. His temperature rose to 101° or 102° every evening and regularly fell to normal in the morning.

On Sept. 6th he had two general epileptiform convulsions, and later he had another of a similar character.

On Sept. 15th petechial spots were noticed on his legs and ankles, which increased in size and depth until his death, which occurred Oct. 15th. These spots varied in size from that of a pin's head to a dime and showed no disposition to heal. They were probably skin infarcts.

Autopsy, October 15th: Right middle cerebral artery close to, but just beyond its orgin in the internal carotid, was closed by an evidently old embolus. All branches of the middle cerebral beyond this were thready and cord-like, and could be distinctly seen lying in a bed of yellowish softening, which extended over the island of Reil and the internal surface of all the convolutions which cover in the Sylvian fissure. The cortex of the motor zone, except as just stated, was not softened. A cut through about the middle of the lenticular body revealed softening of the entire breadth of the internal capsule and adjoining lenticular and caudate bodies. This softening was in the middle part of the capsule and did not extend into the anterior and posterior third. Evidently some collateral circulation had been established between cortical branches of the middle and the anterior and posterior cerebral arteries. This was plain in several places where the narrowed and atrophic vessels beyond the embolus again took up their calibre.

The heart was enormously hypertrophied. On the tricuspid and aortic valves were the vegetations of recent ulcerative endocarditis, with a perforation on the septum leading from the left to the right ventricle, just below the aortic ring.

Probably the sequence of events in this case was as follows: First, the abuse of alcohol, and the syphilitic infection; then disease of the aortic valves resulting in their thickening and contraction; next, in March last, the embolus lodging in the middle cerebral artery and producing the hemiplegia, and recently the ulcerative process engrafted on the sclerotic valves.

DR. WILLIAM OSLER said that we are apt to think that the cortical cerebral arteries have not special anastomoses, but an examination of many of these cases of total occlusion, particularly of the middle cerebral artery, shows that a collateral circulation can be established, usually, as in this case, by the enlargement of the anterior cerebral, so that the nutrition is maintained in the central gyri.

NEW YORK NEUROLOGICAL ASSOCIATION.

Stated Meeting, October 2, 1888.

THE PRESIDENT, GEORGE W. JACOBY, M.D., IN THE CHAIR.

DR. B. SACHS presented three cases of

MUSCULAR DYSTROPHIES,

referred to in his paper before the American Neurological Association in Washington. The author referred to the relation between pseudo-muscular hypertrophy and other forms of muscular dystrophies, particularly Erb's form. Erb had stated that the two were identical. Erb's juvenile form consisted in atrophy attacking the upper extremity, particularly the deltoids, the infraspinatus and sometimes the latissimus, the lower extremity being intact. The question was whether pseudo-hypertrophy and Erb's atrophy were distinct or merging types.

Case 1 was twelve and a half years old. The child had suffered from severe fright at ten months. She had never walked well. She had diphtheria when four years old and after this her gait had been worse. When six and a half years old increased size of the legs had been first noticed. The characteristic difficulty in getting up from the floor had been present. There was atrophy commencing in the palmar interossei and affecting the arm and forearm. The thenar and hypothenar eminences had not been involved. There was hypertrophy of the whole lower extremity, but the hypertrophy of the legs had not kept pace with that of the thighs. It was apparent that atrophy of the legs would soon supervene.

The atrophy of the hands had not been present two years ago. The case proved that in the atrophy associated with pseudo-hypertrophy it was not necessary that the shoulder should be first affected as in Erb's form. For the interossei to be attacked first was rare, but only proved that any muscle could be affected by the disease, while in Erb's typical form the hand was exempt to the last.

Case 2 was that of a boy of ten years. There was no history of heredity and no constitutional taint. The patient was a newsboy. He had walked late and had been treated for rickets. He had never been able to run and had been always easily fatigued. The hypertrophy in this case was most marked in the thighs. A peculiarity of the case was the fact that the boy could rise from the floor without climbing upon himself as was customary in the disease and considered by Gowers as a differential test. There was some atrophy of the serratus anticus of the right side. The upper extremities were not affected.

DR. BIRDSALL suggested that the face had a peculiar appearance.

DR. SACHS had not referred to this peculiar puffiness, because, while suggestive, it was not sufficiently characteristic of the Landouzy-Dejerine type. It was possible that it might develop into this appearance.

Case 3 was that of a girl of twelve years. She had walked at nine months. At the age of ten months she had fallen and later had had something the matter with the knee. This was treated with the plaster splint in St. Petersburg and recovered. The circumstance was mentioned because it had been denied that so young a child could be successfully treated with this instrument. At the age of three the child had measles, at four smallpox, at six scarlet fever, and at six and a half typhoid fever. The loss of power in the limbs was not preceded by fever or convulsions. Five months ago it was noticed that motion was impaired in the toes, there was a modified gait, fatigue and difficulty in mounting the stairs. There was no pain. There had been at times a creeping sensation of the skin, and once fibrillar contraction had been noted. The atrophy affected the right leg, thigh, and gluteal region. The electrical reactions were slightly altered, particularly in the tibialis anticus. For four months the knee-jerk had been absent upon both sides, but now it was exaggerated upon the left side, while upon the right side it was still absent. The gait was that of poliomyelitis affecting the anterior group, while the history was one of progressive muscular atrophy of the peroneal form. The gradual onset without convulsions or fever and the progressive character of the affection and the atrophy which was not so profound, distinguished it from atrophies of spinal origin. On the other hand, however, the exaggerated knee-jerk suggested a possible substratum of spinal implication. The case was an anomalous one of a type seldom seen. The author made the diagnosis of peroneal form of progressive muscular atrophy.

DR. BIRDSALL had been interested in the types shown and was not inclined to question the doctor's diagnosis. The last case was, he thought, allied to the progressive muscular atrophy type, rather than to that of an acute poliomyelitis; he thought, however, that there might be grades between the two, that there was no sharp line of demarcation between them. The former presented the characters of a degeneration, while the latter was an acute inflammatory condition which might involve not only the gray matter but extend to the neighboring tracts. The speaker had a case in mind diagnosticated as acute inflammatory poliomyelitis. There was involvement of the muscles of the anterior and posterior aspects of the thigh, slight affection of the anterior tibial group, and exaggerated reflex showing extension to the lateral column. In the speaker's opinion the different varieties of atrophy represented grades rather than distinct pathological entities. The fact that the atrophy in one case had affected an arm and a leg, in one was hemiplegic, and in another paraplegic, should not blind one to the possibility that the pathological processes might be the same. In the present stage of our histological knowledge, he thought that we were not even able to separate cases into those of myopathic and myelopathic origin. The number of cases was meagre and our methods of examination were not calculated to reveal minor degrees of atrophy. In the muscles, nerves, and cord it might be possible to have a gradual destruction and regeneration going on which would escape detection. The value of the electric reaction was equally open to doubt. If fibres degenerated one by one, it was probable that the reaction would remain normal until the number of atrophied fibres had attained a certain grade. The degeneration reaction would be, in any case, interfered with by the normal reaction of the healthy fibres. The question was whether there was great uniformity in these various types or great diversity; he predicted the latter, the types running into each other.

DR. PUTNAM JACOBI suggested that the gluteal muscles were unaffected in the second case presented. This accounted for the lack of the usual difficulty in getting up from the floor.

DR. SACHS accepted this explanation. He had referred to the point because Dr. Gowers had mentioned the symptom as pathognomic.

DR. DANA referred to a case of pseudo-hypertrophy in which the disease had advanced from the calves to the thighs, and thence to the shoulder girdle. There was slight hypertrophy of the forearm, the part said to be unaffected in Erb's form. The fundamental distinction between the symptoms of chronic anterior poliomyelitis and progressive muscular atrophy was the retrogressive or stationary character of the former, and the progressive character of the latter. It was difficult to criticise the diagnosis in Dr. Sachs's last case. He would prefer to postpone his decision, but would suggest that a careful examination of the urine be made for lead. A number of cases of anterior poliomyelitis in children had been recently ascribed to lead.

DR. GRAY would, upon *a priori* reasoning, decide the case as one of chronic anterior poliomyelitis, but that anterior horn myelitis was, as had been suggested, retrogressive. Muscular atrophy could be, he thought, divided into that of spinal and peripheral origin; of the latter, however, we must distinguish between that arising in the muscles and that due to peripheral neuritis. The results of treatment varied. There were cases which, with rest in bed, faradism, and gentle massage, improved, while other cases were unaffected by treatment. He thought that the former were of spinal while the lateral were peripheral, either neural or muscular in origin. Formerly the diagnosis of a central or peripheral origin was deter-

mined by the presence or absence of the reaction of degeneration. Now confusion surrounded this test also. He inquired in regard to opinion upon this point. Was the degeneration reaction present only where the muscles were degenerated?

Dr. Sachs closed the discussion. He was pleased that Dr. Birdsall, who had not heard his paper in Washington, had been in substantial agreement with it. While there was diversity of types there was no anatomical distinction between pseudo-hypertrophy and atrophy. The primary and secondary affections were distinguished by their symptoms. The primary affection occurred early, there was absence of fibrillary contractions and absence of the reaction of degeneration. This group included pseudo-hypertrophy, Erb's type and that of Landouzy and Dejerine.

Dr. Gray begged to refer to a case recorded by Schultze, which had been assumed to be primary, but in which there had been found changes in the cord.

Dr. Sachs explained that the change referred to was independent and unconnected with the muscular symptoms. It was in a part of the cord unconnected with the muscular tract. He suggested that in Dr. Dana's case the atrophy in the arm might have given rise to a fictitious appearance of hypertrophy in the forearm.

Dr. Dana added that the muscles had also the peculiar feel of pseudo-hypertrophy.

Dr. Sachs did not question the diagnosis. He believed that all present had agreed upon the desirability of getting rid of the present classification upon anatomical distribution of the hypertrophy or atrophy. He had retained the term peroneal form for convenience only.

Dr. M. D. Field followed with a paper entitled

OTHÆMATOMA OR INSANE EAR.

The title referred to a shrunken, shrivelled condition preceded by a period of active congestion during which the organ was swollen, hot, and very painful. Between the cartilage and the perichondrium there was effused a sero-sanguinolent fluid, which might become purulent. This was absorbed or rupture occurred with healing and the deformity described. The deformity was not uncommon among the insane. It had been attributed to trophic change. The most general opinion had been that othæmatoma was characteristic only of chronic cases, and usually indicated an incurable condition. The question of a traumatic origin had received some attention. It had been remarked that a Greek statue represented a boxer with this deformity. The author could not recall the reference. It had been said to result in boys from the violence of the game of foot-ball. It had also been observed among soldiers. The author had had under his care the case of a professional pugilist who had presented the deformity in question. Upon directing his attention to it, the man had remarked that it had resulted from a blow upon the head, and that it was common in his profession, that he knew as many as a hundred men similarly injured. Arrangements were made with this man to be present at the meeting. He had been unable to come, but had sent substitutes. Several under-sized, meek-looking professional men, pugilists, here appeared, all presenting the deformity. It could be added, that only one had ever been in an asylum. This one had been in for delirium tremens. It was evident that the insane ear could proceed from traumatism; also that it was more common than was commonly supposed.

Dr. Petersen felt indebted to Dr. Field for the opportunity of examining the cases. He had seen the condition frequently in the insane, and believed it was always due to traumatism. It was more frequent among the insane, probably, on account of the necessity for restraint, also because the insane were apt to injure themselves in many ways. He also believed that the changes in the walls of the vessels in insanity predisposed to the result. Retrograde metamorphosis of the cartilage and perichondrium, like that of senility, was common in general paresis and other varieties of chronic insanity.

Dr. Parsons exhibited a cast of othæmatoma in the recent state, taken some years ago. He had always considered the condition a result of nerve degeneration. The exhibition this evening had, however, demonstrated that it could result from traumatism alone.

Dr. Douglas had seen a considerable number of instances of the insane ear, and thought that it had been due to violence in every instance, either from the attendants, other patients, or the sufferer himself.

Dr. Ingram could corroborate this statement. The insane had the habit of rubbing the ears, which might account for some cases. He could add to Dr. Field's record that of a case of recovery after double othæmatoma during an active maniacal attack. With improvement of the mental condition there was improvement in the ear. Upon recovery there was diminution in the size of the ear but no deformity.

Dr Petersen added that the reference to the Greek statue had been by Fuerstner, *Arch. f. Psych.*, iii.

Dr. Field, in closing the discussion, referred to the case reported by Dr. Hunn, after the patient had been struck with a broom-stick, the hematoma appeared upon the opposite ear. Dr. Hunn cited the case as an instance in which traumatism could not have been the direct cause.

PHILADELPHIA ACADEMY OF SURGERY.

Stated Meeting, October 1, 1888.

R. J. Levis, M.D., in the Chair.

REMOVAL OF THE VERMIFORM APPENDIX.

Dr. Nancrede exhibited a vermiform appendix which he removed seventeen days ago. The patient is doing well. This was a hyper-acute case. The child thought that she had injured herself, suddenly experiencing acute pain in the right iliac region. There was vomiting followed by profuse purging. The attack was supposed by the parents to be one of cholera morbus. The vomiting and purging lessened, but from the very inception of the attack there was retraction of the thigh. He was called to see the patient forty-eight hours after the onset. The pulse was then 150. There was moderate pain and tenderness in the region where he supposed the appendix should be, but it afterward was shown not to be exactly in this position. There was no impairment of resonance. The right thigh could not be straightened out, although motion could be made in other directions without causing pain. The temperature was a little over 100°. The next morning at twelve o'clock, the temperature was over 101° and there was, in the right iliac fossa, impairment of resonance on light percussion and tympan-

itic resonance on deep percussion. At three P.M. the temperature was between 102° and 103° and the pulse about 160. He sent the patient to the Jefferson Hospital, where Dr. Barton, and Dr. Conner, of Cincinnati, saw her with him. When the peritoneum was opened purulent peritoneal fluid escaped. There was no limitation of the inflammation toward the median line. He did not find the appendix in its usual position, but after opening with the finger one or two foci of pure pus, the appendix was found pointing directly downward and backward from the outer surface of the cæcum, so that there was much difficulty in applying the ligature. A foreign body was felt which was pushed along the appendix until room was made to ligate between the concretion and colon. A little spot of sloughing was found near the middle of the appendix where the end of the foreign body pressed.

In the discussion on this subject at the recent meeting of the American Surgical Association, it was held by some that the median incision was the preferable one in these cases. In this instance it would have been impossible to reach the appendix through a median incision. It has been advised that the whole wound be left open for drainage. If he had done this, the small intestines would certainly have escaped. There was no limiting membrane. He had seen in consultation one case in which there was secondary hemorrhage after the spontaneous opening of a perityphlitic abscess, the blood probably coming from the deep circumflex iliac. Mr. Hutchinson had, he believed, reported a similar case of severe hemorrhage in which he thought that the blood came from this vessel.

DR. T. G. MORTON said that in the case just reported by Dr. Nancrede the symptoms which demanded operation had existed only a few hours, so that very properly the case should be regarded as belonging to the supra-acute variety of perforative appendicitis. It is somewhat difficult, perhaps, to classify the varieties of inflammation, perforation, and abscess of the appendix, but a division according to the history of the supra-acute, acute, and chronic cases, which he suggested some time since, appears for all practical and clinical purposes quite sufficient. The incision to reach the appendix should be lateral, not median, indeed by the latter it would often be impossible to reach the appendix, and the belly cavity would often needlessly be opened. From numerous dissections he has found that the appendix is normally placed immediately under a point two inches distant from the right anterior superior spinous process, on a line drawn horizontally from the process toward the median line of the body. If the general peritoneal cavity has become involved, it can be washed out as thoroughly by the lateral as by a median section, while by the former more perfect drainage can be secured.

By a lateral incision either vertical or oblique, the appendix can more readily be reached and dealt with, and in the subsequent treatment sloughs, and suppuration can be discharged through the lateral incision; experience has shown that the wound should be left well open except in the supra-acute cases, while such a course could not be adopted in the acute and chronic cases with a median incision.

The presence of the colon, which is more or less firmly held in position at the bottom of the wound, in the cases in which the wound is kept open, prevents any intestinal protrusion during the wound-healing process. The appendix vermiformis almost constantly contains some matter having the appearance of feces; in thirteen consecutive post-mortems recently made at the Pennsylvania Hospital, the appendix in every instance but one contained such matter.

The diagnosis of appendix inflammation, perforation, and abscess ought generally to be readily made, pain in the cæcal region being about the earliest symptom, often paroxysmal, and increased by pressure; nausea and sometimes vomiting; the occurrence of pus is announced by temperature, pulse, and sweatings; perforation of the appendix is often accompanied by the most excruciating pain; general peritonitis by extension of inflammation and symptoms.

Since abscess generally in the ileo-cæcal region is due to appendix disease, we may safely and promptly make an explorative incision, indeed, any uncertainty of diagnosis had best be cleared up by an early section. The danger in all such cases is greatly increased by delay.

DR. MEARS had had two cases in which he operated, one ten years ago, and the other two years ago. In both he made a lateral incision and evacuated the abscesses. In both cases death followed. The post-mortem examination in the first case showed general peritonitis, constriction of the small intestine by a band, and perforation of the appendix, which contained a number of cranberry seeds.

DR. WEIR, who has written ably upon this subject, concludes that the lateral incision is the best. After the occurrence of general peritonitis the median incision is to be preferred to the lateral. There is no doubt as to the value of the lateral incision, but it occurred to him that the median section may be best in certain cases in which it is necessary to deal with complications.

MONTREAL MEDICO-CHIRURGICAL SOCIETY.

Stated Meeting, October 19, 1888.

THE PRESIDENT, WILLIAM GARDNER, M.D., IN THE CHAIR.

DR. BLACKADER read a paper on

FOUR CASES OF PERITONITIS OCCURRING DURING GESTATION.

Case I.—Mrs. R., æt. thirty-two, in the sixth month of her third pregnancy, was suddenly seized with severe abdominal pain. She had always enjoyed good health with the exception of being the subject of constipation. She had taken some purgative medicine, and during the night was obliged to get up to attend to one of her children and got chilled; an hour later severe pains came on. When seen she was suffering severely, her abdomen was slightly distended and tender; temperature 104°; pulse 140, small and weak. Morphia was administered hypodermatically in quarter-grain doses and hot cataplasms applied. Her pulse rapidly failed and it was soon seen that she was suffering from acute general peritonitis. The os was examined and found to be soft, closed, and with prominent neck. There did not appear to be any special contraction of the uterus. By midnight her pulse was scarcely perceptible, but afterward improved. The pains now assumed a bearing-down character, and twenty minutes after a dead fœtus was born. Vomiting of grumous matter set

in and she expired in a very short time. No post-mortem was allowed.

Case II.—Mrs. S., æt. thirty-three, in her eighth pregnancy, had always enjoyed good health. Toward the end of the eighth month of pregnancy caught cold and suffered an attack of bronchitis causing her to be confined to her bed for a week; while recovering from this, acute parenchymatous glossitis set in, the pyrexia lasting three days. On the fourth day the swelling had almost subsided. The same afternoon Dr. B. was sent for in haste and found patient with pinched features, feeble, quick pulse, and a temperature of 103°. There was considerable tenderness over the lower part of the left abdomen, especially in left groin; there was no distention of the abdomen. Morphia was given hypodermatically. Next day she was somewhat improved and only suffered pain whilst turning to either side. In the evening a live child was born with scarcely any pain and very rapidly. Immediately after the birth her pulse was 120, and temperature 101°. Dr. George Ross was called in consultation and also Dr. Gardner. Two days after her child was born her pulse began to fail rapidly and her condition seemed most serious. Vomiting and hiccough set in, and there was great distention of the abdomen. Arrangements were made for abdominal section, but death took place during the administration of the ether and before the operation had been commenced.

Case III.—Mrs. C., æt. twenty-eight. Dr. B. first saw her June 23, 1885, in the sixth month of her fourth pregnancy, and naturally of a very strong constitution. She was complaining of severe abdominal pain with diarrhœa, which she attributed to getting her feet wet a day or two previously. Pulse was rapid, but her temperature was normal. An anodyne was prescribed, and she was not seen again for forty-eight hours, when she had a rapid pulse (108) and a temperature of 99.8° F.; she complained of pain and tenderness in the abdomen, and was confined to her bed. Next morning she was much worse. She had an anxious expression of countenance, considerable lividity of face and lips, with a temperature of 102.5°, and pulse of 120; tenderness was marked in the right iliac region and extended across the median line; there was slight abdominal distention. That evening she was comfortable. At 2 P. M. labor pains came on and the child was born before Dr. Blackader could reach the patient. There had not been much hemorrhage, but the mother was very pale, her lips were livid and her pulse feeble; the placenta was retained. After waiting a short time the placenta was delivered by passing the hand into the uterus; there was no hemorrhage. Vomiting set in shortly, and she died the same evening at six o'clock. No post-mortem examination was allowed.

Case IV.—Mrs. B., æt. twenty-four, consulted Dr. B. about the end of October, 1887, for frequent and painful micturition. She had been married in August. The symptoms did not yield to remedies, and a vaginal examination was made and the uterus was found anteverted and decidedly enlarged. Absolute rest in bed was insisted on. By the end of December she was up and about and apparently as well as ever. She was not seen again until the middle of February. She then complained of pain in the right iliac fossa and back; there was also a good deal of nausea, a thickly furred tongue and constipation. Pulse and temperature normal; no tenderness on pressure was detected. Salines were administered (March 2d) with partial success. A fortnight later the pain became suddenly much aggravated, apparently after eating heartily; there were much tenderness over the cæcum and slight distention of abdomen. Temperature 102°, pulse 100. Slight nausea but no vomiting. The patient was anxious, restless. On the evening of the 5th Dr. Brune was called in and agreed that there was a local peritonitis. A few days later the symptoms became so serious that the question of abdominal section was discussed. There were considerable distention and great tenderness of the abdomen, especially in the right iliac region, and vomiting was frequent. Pulse weak, and 120–130; temperature 101°. Morphia was given hypodermatically and the symptoms gradually subsided. On the 12th the right parotid gland became inflamed, and then the left gland was likewise affected, but both subsided without suppuration. On the 14th of May the patient was safely delivered of a healthy child, labor was in every respect normal and convalescence was uninterrupted. Since her confinement there have been two slight attacks of abdominal tenderness in the right side, with slight pyrexia—but now the patient is quite well.

Dr. Blackader said that there was no reason why peritonitis should not occur during gestation, while there are reasons why it might even be more frequent at that time. A very small number of cases are recorded in medical literature, and he thought it must be of rare occurrence. No reference is made of peritonitis during gestation in any of the works on obstetrics, and very few cases are reported in medical journals. Dr. Blackader could find only four. Dr. Gow reports a case in the *Edinburgh Medical Journal* for January, 1888, which was given by the reader of the paper in full. The patient died, and no cause for the peritonitis could be found. Dr. Gow refers to one of Sir James Simpson's cases in which also no local cause could be found at the post-mortem. Dr. Matthews Duncan reports two cases of a similar kind, in both of which death took place, and no local cause of the peritonitis could be discovered. One of the patients suffered from enteritis. In not one of the cases cited by Dr. Blackader could the exciting cause of the peritonitis be discovered.

The diagnosis of the cases will lie between peritonitis, concealed hemorrhage, rupture of the uterus, and perhaps rheumatism of the uterus. Dr. Blackader said that he much regretted being unable to procure a post-mortem in his fatal cases, but that he had not the slightest doubt that his diagnosis of peritonitis was correct.

Dr. J. C. Cameron said that he did not see why pregnant women should not have peritonitis; their condition would rather predispose to it than otherwise. The great defect in the paper was the fact that no autopsies were held, and whether the peritonitis was idiopathic or not could only be determined by a post-mortem examination. He himself was rather sceptical as to the occurrence of idiopathic peritonitis. Peritonitis may, in these cases, have been caused by a perforating appendicitis, ruptured cyst or tube, abscess, etc.

Dr. Harvey, of Calcutta, related a case in which postpartum hemorrhage was caused by adhesions of the uterus to the parietal peritoneum, this prevented contraction of the uterus. He saw no reason why pregnant women should be exempt from peritonitis, as the same causes which produce it in the non-pregnant would be found in the pregnant.

DR. T. JOHNSON ALLOWAY said that the pregnant uterus could stand a great deal of injury; he himself thought pregnant women were not so liable to peritonitis as other people. In the cases reported by Dr. Blackader he was of the opinion that if a post-mortem examination had been held a ruptured tube would have been found, or remains of old peritonitis may have lighted up pelvic inflammation.

NEWS ITEMS.

Prevention of the Spread of Smallpox among the Indians in New York and Pennsylvania.—Official information having recently been received by the Secretary of the State Board of Health of Pennsylvania, from the Secretary of the New York State Board, of the existence of smallpox among the Indians of the Catarangus and Allegheny reservations in that State, he at once telegraphed instructions to Dr. J. L. Stewart, of Erie, Medical Inspector to the Board for the lake district, to visit the Cornplanter tribe in Warren County, Pennsylvania, the members of which are in constant communication with those of the New York reservations, and take the necessary means for their protection. The instructions were carried out with commendable promptness. The entire tribe was vaccinated and the chief, Marsh Pierce, promised to forbid his people from crossing the border until the disease had disappeared. He rendered every assistance to the vaccine physician, and extended the thanks of himself and his people to the State Board for its timely action in their behalf.

Dressed Poultry.—The Legislature of Massachusetts, according to *The Prophylactic*, has enacted the following: 1. No poultry, except it be alive, shall be sold or exposed for sale until it has been properly dressed by the removal of the crop and entrails, when containing food. 2. Whoever knowingly sells or exposes for sale poultry contrary to provisions of section 1 of this act shall be punished by a fine of not less than five nor more than fifty dollars for each offence. The Boards of Health in the several cities and towns shall cause the provisions of this act to be enforced in their respective cities.—*Journal of Amer. Med. Assoc.*, Nov. 10, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM NOVEMBER 6 TO NOVEMBER 12, 1888.

By direction of the President, BASIL NORRIS, *Lieutenant-Colonel and Surgeon* (U. S. Army), and HENRY R. TILTON, *Major and Surgeon* (U. S. Army), are detailed as members of the Army Retiring Board appointed to meet at San Francisco, California, by War Department Order dated October 27, 1888, published in Special Orders No. 253, October 30, 1888, from Headquarters of the Army, vice Colonel and Surgeon Elisha J. Bailey and Captain and Assistant Surgeon John J. Cochran, hereby relieved.—Par. 13, *S. O. 261, A. G. O., Washington*, November 8, 1888

By direction of the Secretary of War, JOSEPH C. BAILY, *Lieutenant-Colonel and Assistant Medical Purveyor*, will transfer at once the public funds for which he is now responsible, to Captain and Medical Storekeeper Henry Johnson, who will assume temporary charge of the medical purveying depot in New York City, retaining charge thereof until relieved in person by Lieutenant-Colonel and Surgeon E. P. Vollum, under his assignment as Acting Assistant Medical Purveyor, to whom Captain Johnson will then transfer the public funds.—Par. 1, *S. O. 257, A. G. O., Washington, D. C.*, November 3, 1888.

MCCLELLAN, ELY, *Major and Surgeon.*—Is relieved from duty at Jefferson Barracks, Missouri, and will report for duty at Chicago, Illinois, as attending surgeon and examiner of recruits.—Par. 15, *S. O. 261, A. G. O., Washington*, November 8, 1888.

BARTHOFF, JOHN H., *Major and Surgeon.*—Is relieved from further duty in the Department of Texas, and will report to the commanding officer at Plattsburgh Barracks, New York.—Par. 15, *S. O. 261, A. G. O., Washington*, November 8, 1888.

EWEN, CLARENCE, *Captain and Assistant Surgeon.*—Is relieved from duty at Fort Sidney, Nebraska, to take effect on his present leave of absence, and will report in person to the commanding officer Madison Barracks, New York, for duty at that post.—Par. 2, *S. O. 258, A. G. O., Washington*, November 5, 1888.

APPEL, DANIEL M., *Captain and Assistant Surgeon.*—Is relieved from duty at Fort Davis, Texas, and will report in person to the commanding officer Fort Sill, Indian Territory, for duty at that post, reporting by letter to the commanding general Department of the Missouri.—Par. 2, *S. O. 258, A. G. O., Washington*, November 5, 1888.

PRICE, CURTIS E, *Captain and Assistant Surgeon.*—Is granted leave of absence for two months, with permission to apply for an extension of ten days.—Par. 2, *S. O. 257, A. G. O., Washington*, November 3, 1888.

WOOD, MARSHALL W., *Captain and Assistant Surgeon.*—Is granted leave of absence for one month, with permission to apply for an extension of ten days.—Par. 2, *S. O. 257, A. G. O, Washington*, November 3, 1888.

ARTHUR, W. H., *Assistant Surgeon.*—Upon being relieved by Acting Assistant Surgeon J. L. Ord, will proceed to comply with Par. 21, S. O. 250 c. s., Headquarters of the Army.—Par. 5, *S. O. 123, Headquarters Department of Arizona, Los Angeles, California*, November 5, 1888.

By direction of the Secretary of War, ALFRED E. BRADLEY, *First Lieutenant and Assistant Surgeon* (recently appointed), will report in person to the commanding officer David's Island, New York, for duty at that depot, reporting by letter to the superintendent of the recruiting service New York City.—Par. 14, *S. O. 260, A. G. O.*, November 7, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING NOVEMBER 10, 1888.

DICKINSON, D, *Surgeon.*—Ordered to Naval Hospital, Mare Island, California.

BRADLEY, G. P, *Surgeon.*—Detached from Naval Hospital, New York, and ordered to the "Iroquois."

PERSONS, R. C., *Surgeon.*—Detached from Army and Navy Hospital, Hot Springs, Arkansas, and ordered to Naval Hospital, New York.

NORFLECK, ERNEST, *Passed Assistant Surgeon.*—Detached from Naval Hospital, Mare Island, California, and ordered to the "Trenton."

HARRIS, H. N. T., *Assistant Surgeon.*—Detached from Naval Hospital, Mare Island, California, and ordered to the "Kearsarge."

SAYRE, J. S., *Assistant Surgeon.*—Ordered to examination for promotion.

BEYER, H. G., *Passed Assistant Surgeon*—Detached from the "Trenton," and granted six months' leave, with permission to leave the United States.

BRYANT, PATRICK H.—Commissioned Assistant Surgeon, United States Navy.

VON WEDEKIND, LUTHER L.—Commissioned Assistant Surgeon, United States Navy.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LIII. SATURDAY, NOVEMBER 24, 1888. NO. 21.

ORIGINAL ARTICLES.

THE OPERATIVE AND MECHANICAL TREATMENT OF SOME JOINT DISEASES AND INJURIES;

With especial reference to the hip-, knee-, and elbow-joints, with illustrative cases; with twelve illustrations.[1]

BY W. R. WHITEHEAD, M.D. (PARIS),
OF DENVER, COLORADO;
EX-PRESIDENT OF THE COLORADO STATE MEDICAL SOCIETY.

I. CONCERNING HIP-JOINT DISEASE, ETC.

I know of no deformity in which the proper use of tenotomy is so much ignored, and in which a more unreasonable use of braces is resorted to, than in hip-joint disease; and this, I believe, results from an inattentive consideration of the pathology of this disease. I have repeatedly met with inflammation of the coxo-femoral articulation in which the first thing thought of was the use of a brace or extension splint, without any regard whatever, apparently, to the contracted condition of the muscles about the hip, or of the flexion of the thigh on the pelvis due to effusion into the joint; or even of the atrocious pain caused by the grating together of eroded joint surfaces. In such cases there has evidently been an attempt to fit a crooked and painful limb to a straight splint without any benefit, and with much suffering to the patient.[2]

The following are some cases that I shall relate as examples of this attempt to fit a crooked limb to a straight instrument.

Fibrous ankylosis of the hip-joint; tenotomy; brisement forcé.—Harry S., aged eleven years, was seen by me with Dr. P. V. Carlin, of Denver, during July, 1887, who saw him for the first time some weeks previously. The boy had limped more or less for two or three years, complained of his left hip, and especially of his knee; had scarlet fever, and some months afterward measles, and complained of pain on the inside of his knee during the scarlet fever. About a week after the subsequent attack of measles, which was in January, 1887, his left leg drew up. Later he was seen repeatedly by a practitioner of Denver, some time during the spring of 1887, who proposed a hip splint, and measured him for it. This doctor applied a weight and pulley to his left leg for three or four weeks. On questioning the parents of the boy, it was discovered that the doctor alluded to, made extension without placing a pillow under the thigh, and making traction "in the line of the deformity;" in other words, extension was made without any heed to the pathological condition; in violation of the anatomical arrangement and physiological action of the muscles about the hip; and necessarily with the pelvis more or less tilted to compensate somewhat for the faulty use of the extension weight. The parents said the leg would hurt him in the night, and often the extension weight would be found on the floor in the morning.

Oct. 6, 1887. The patient having been etherized by Dr. W. W. MacGregor, then of Denver, now of Glenwood Springs, Colorado, I did tenotomy of the rectus femoris and adductor longus muscles; and after sealing hermetically the little wounds of the skin and bandaging the groin, I did *brisement forcé* at the hip, and restored mobility to the joint. Ice-bags and extension weight applied, with the thigh slightly flexed on the pelvis. Saw him each day; there was no notable rise of temperature.

23d He was etherized and forcible movements of the limb were made; ice-bags to the hip and groin, and after a few days the parents were properly instructed how to make motion at the joint, which they did well and with excellent results.

Nov. 13. Applied hip splint; my modification of the Sayre-Shaffer hip brace, made for patient by Tiemann & Co. (see Fig. 1). Subsequently good movement about the joint; brace discarded and patient cured.

Another example of an attempt to fit a crooked limb to a straight splint, has already been published by me in the *Transactions of the Colorado State Medical Society* of last year (1887), and is the case of Katie M., in which *brisement forcé* was done and subsequently successful restoration of the functions of the limb was established and maintained; the same can be said of my case of *brisement forcé* published in the *Medical Record* of December 18, 1886.

In these cases I have referred especially to the utility and desirability of *brisement forcé* at the hip-joint when properly practised and afterward suitably managed by the use of extension weight and ice-

[1] Read before the American Orthopædic Association, at its associate meeting with the Congress of American Physicians and Surgeons, at Washington, 1888.

[2] I wish here to record my protest against immobilization alone in the treatment of hip-joint disease. I have been successful, as have Sayre and others, in curing this disease with motion, indeed with perfect restoration of the function of the limb, and I regard attempts generally to obtain a so-called cure of hip-joint disease by ankylosis, as a retrograde movement in surgery, and as such unworthy of imitation; as entirely opposed to a sound and well-established principle of the treatment of inflamed joints by extension and counter-extension rightly applied. To impart motion judiciously to an inflamed joint, as its inflammation subsides, is a most rational act on the part of the surgeon, and the action of a suitably constructed traction brace is to perform this office.

bags to the hip and groin; the neglect of which would make of *brisement forcé* a most formidable undertaking. A most remarkable case of this kind I have yet to relate.

Fibrous ankylosis of the hip-joint from hip-joint disease; tenotomy and brisement forcé during pregnancy. —Miss ——, aged nineteen years, had fibrous ankylosis of the right hip-joint from hip-joint disease, which first developed itself seven years previously. I first saw her December 13, 1887. She was a fine-looking, well-developed girl, except about the right hip and right lower limb, which were atrophied and the limb was shortened. No abscess had ever opened about the hip or groin; the disease was caused by a blow received on the hip; the general health had most of the time been good. There was some soreness occasionally about the hip, which was considerably elevated, with adduction of the thigh, eversion of the foot, and an apparent shortening of three and a half to four inches.

Dec. 19, 1887. Extension weight of nine pounds and elevation of the foot of the bed; thighs flexed on the pelvis with a pillow under them; extension weight did no good, except to relieve the slight soreness about the hip.

26th. I did tenotomy of the rectus femoris and adductor longus muscles, and also *brisement forcé* after thorough etherization by Dr. W. W. MacGregor. The snapping and cracking of the adhesions were distinctly audible at a distance; in fact, the adhesions were most thoroughly broken up, and perfect mobility of the previously ankylosed hip-joint accomplished.

No appreciable prominence of the abdomen was observed after straightening the limb, and neither Dr. MacGregor, myself, nor the woman attendant, her relation or connection, who assisted us, suspected her condition of pregnancy at the time, and everything passed off satisfactorily, even to the subsequent fitting of the brace by the instrument-maker about a month later.

Extension weight with thighs flexed and pillow under them; ice-bags to hip and groin.

28th. Morning temperature 99 5° F., evening temperature 101.3° F. Very sore about the hip. More explicit directions given about the use of the ice-bags; restless, antipyrin as a sedative.

29th Evening temperature 101.2° F.; antipyrin. After this the temperature was at no time above 101°, and gradually, in a week, it became normal.

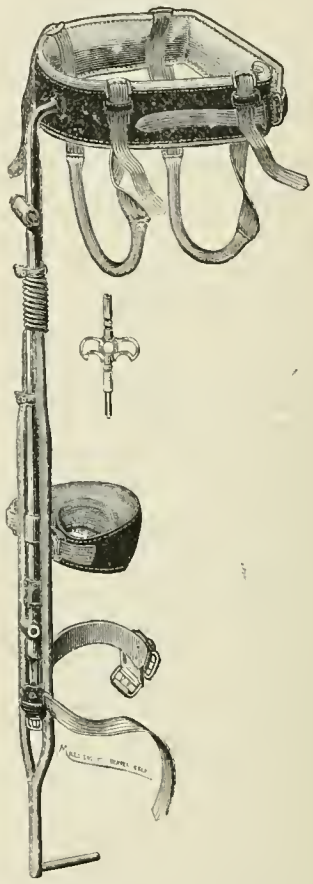
Afterward I practised daily, or caused to be practised, motion of the hip under proper care; and soon she was ready for the hip brace, which was applied by the instrument-maker in my presence about one month after the *brisement forcé*. She was remarkably straight, and the result of the treatment as good as could be wished for. She required a raised cork sole to her shoe of one and a half inches, which was the extent of the shortening.

I saw her repeatedly afterward, and on March 5, 1888, applied fresh plaster and bandages to her limb, and enjoined the use daily of motion of the joint. I lost sight of her for awhile, and my instructions were to notify me when the adhesive plaster and bandages required changing.

About May 15, 1888, I heard that she had just been delivered of a child at full term, much to my surprise, as well as to that of her aunt or relative, who up to the time of the labor pains was ignorant of her condition; besides, this woman, her relative, had during a part of her life been a nurse.

The lordosis of hip disease would, in the first place, and during the early period of pregnancy, have diverted me from the suspicion of pregnancy in a young but deformed girl whom I had no reason

Fig. 1.



to suspect of such a thing. This case, however, is a strong argument in favor of *brisement forcé* under suitable after-treatment; and is brought forward entirely with a view to support this operation as a valuable resource in the treatment of fibrous ankylosis of the hip-joint. Of course, it takes considerable time in such cases to give to the limb that strength and development which rubbing and the use of the limb will gradually produce. This is not understood, or there is an indifference to this fact on the part of those concerned; there has been neglect of motion, and further treatment has been declined, with no appreciation of what was done.

As examples of mechanical treatment of hip-joint disease, without tenotomy, or other operative meas-

ures, I beg to refer to a few cases treated by the extension weight and pulley, followed by the continuance of this at night, and during the day by the use of the brace which I use and which I have already mentioned—that is, my modification of the Sayre-Shaffer hip-joint splint; and which I thus described in my article on hip-joint disease in the *Medical Record* of December 18, 1886 (see Fig. 1 of this traction hip-splint recently made for me by Tiemann & Co., and exhibited to the Orthopædic Association):

"I wish to claim nothing for this splint except that it is a useful combination of other instruments, and I believe will be found to answer a better purpose than some of those in use. This instrument differs from the Shaffer hip-joint extension splint in not having the weight of the body deflected from its straight course along a bent or bayonet-shaped bar of steel to the sole of the foot, and which causes the bar to bend under the weight; and the foot to tend to turn inward. On the contrary, the force exercised by the weight of the body is decomposed, and transmitted solidly downward by two vertical rods of steel to the small horizontal rod under the sole of the shoe; and around this small rod the shoe turns to permit flexion and extension of the foot. The rest of the instrument is arranged for extension and other motions, like Sayre's short splint for the treatment of hip-joint disease. The Shaffer spiral spring is made strong enough to keep the weight of the body from stretching the adhesive straps, which are designed solely for extension at the hip-joint. This spring can be loosened or fastened, and moved up or down for an inch or two or more, by means of the same key that is used to extend or rotate the limb."

But the ball-and-socket joint at the hip makes this rotary movement of the instrument in its shaft unnecessary and adds to its expense. It is made by Tiemann & Co., N. Y.; and by Mr. Brittain, of Denver.

The first example of purely mechanical treatment that I shall cite is that of a consumptive with hip-joint disease, in which there was only improvement of the local hip trouble without any permanent benefit; but which, however satisfactorily establishes the utility of proper treatment in the worse cases:

M. M., æt. thirty years, laborer, was sent to me by Dr. J. C. Blickensderfer, of Denver, with disease of the right hip-joint. Patient came to my office December 6, 1887, on crutches, was very weak, and much emaciated, and in addition to his hip-disease is phthisical. The pain about the hip was excruciating, and he was in great terror of being touched. Allowing him to undress himself at his leisure, and to take a position on a blanket spread on the floor, I astonished him and soon gained his confidence by gently and suddenly seizing his right thigh with my left hand while the same arm supported his left thigh, and lifted him from the floor, making extension while so doing "in the line of the deformity." The poor fellow, who a minute before was terrified out of his wits at an attempt to touch him, at once became quiet and exclaimed "O! that feels so good!" If we owed nothing else to Sayre, it would be a lasting tribute to his memory, the fact alone of his having shown us how, without pain, to handle a patient with hip-joint disease; and this poor suffering patient's exclamation was an eloquent prayer for extension in hip-joint disease.

December 7, 1887. Applied adhesive plaster; and extension weight of nine pounds; raising foot of bed—motion made at regular intervals.

January 25, 1888. Ready for splint; had bed-sore; set him up in bed to take pressure off of sore; ordered splint for him of Tiemann & Co.

February 17. I fitted splint to him, and afterward repeatedly saw him walking about in his splint comfortably.

On June 3, 1887, a little boy, F., with hip-joint disease of left hip, aged three and a half years, of Boston, visiting Denver, was brought to me by its parents. The child was put to bed with extension weight and pulley, and the mother instructed in the use of extension in the proper direction, and being very intelligent she aided me well, so that in less than a week the child was ready for the brace, the contracted tendons not requiring tenotomy. The brace was applied June 7th; but there was some trouble with it, as it frequently needed repairing; and soon the child left for its home; and is now, I believe, under the care of an orthopædic practitioner of Boston.

As another example of the care required to prepare a patient with hip-joint disease for the traction splint or brace, I shall cite the following case sent to me by Dr. Carlin, of Denver:

"A. M., æt. five years, had hip-joint disease of the left hip, distinct, but in an early stage of development. Believing that hip-joint disease in its earliest periods may, sometimes, be cured by simply rest in bed, with an extension weight to the limb, I confined this child to bed. The improvement was so great that after a few weeks I omitted the extension during the day, and relied on extension at night alone. Soon she became lame again and I ordered a splint for her of Tiemann & Co. For some reason, while waiting for the splint to be made, neither during the day nor at night was extension applied, and when the splint came the limb was so contracted that it was necessary again to confine her to bed for two weeks with extension weight, before the soreness had sufficiently left the joint, and the limb had became straight enough to use the brace, which was September 5, 1888.[1]

This preparation for the use of an extension brace is, indeed, generally a very simple matter, but often requires tenotomy, and sometimes *brisement forcé;* and it is the neglect of such preparation that causes failure in the use of the traction brace. There are cases, however, which do well, and relapse because the brace is discarded too soon. There are others also, in which a scrofulous vice causes a return of the disease in the same joint, or its appearance in both joints. I have had two such cases under my

[1] November 9, 1888: It was necessary to do tenotomy of the rectus femoris and adductor layers to prepare the limb properly for the splint, which was done to-day.

care within the last two years, in which, after getting very fair results, and indeed nearly curing the disease in one of them, it has hopelessly returned and in both joints.

As examples of operative treatment without mechanical appliances, I beg to refer to the following cases. The first is one in which it appeared to me quite impossible to use to advantage any apparatus for producing extension.[1]

The case was that of a child of F. R., of Denver, aged fifteen months. May 10, 1888, this male infant was brought to my office; his thigh was very much swollen, flexed on the pelvis, and adducted; the hip elevated and the limb shortened. At first, however, it was extremely difficult to determine that the hip-joint was diseased; but it was easily perceived that a large abscess existed in the upper part of the thigh; the general condition of the child was good, with no discoverable history of its having received a blow or injury to the hip, yet the disease was of recent origin. Dr. J. E. Lowery, of Denver, having given him chloroform, I opened the abscess, made a suitable counter-opening, washed out the abscess cavity with Thiersch's boro-salicylic acid solution, and dressed it with antiseptic materials. The dressings were repeated a few times, always using iodoform liberally: at first packing the wound with iodoform gauze. After a few weeks, the wound seemed to have healed altogether; the treatment being merely palliative.

About eighteen months or two years ago, Mr. T., a prosperous German, a farmer, living near Denver, consulted me about his son, who had a stiff hip, the result of hip-joint disease. I proposed *brisement forcé*, which was declined, and the boy was taken to Europe for treatment.

June 1, 1888. This boy, aged eight years, returned to me, the parents stating that he had been under the care of von Esmarch at Kiel, after seeing me, and that Esmarch had done an operation on the hip, and removed a small piece of bone. An extensive scar over the trochanteric prominence was the site of the distinguished German surgeon's operation, which was an excision or an osteotomy. An abscess had formed on the outer side of the thigh, near the hip some months after the operation, and it was for this abscess that the parents of the boy again consulted me. Dr. Lowery having given chloroform to him, I opened the abscess and, making a counter-opening, washed it out and dressed it as in the preceding case. June 8th and 11th it was redressed; on June 19th it was well, and remained so to the time I left to attend the meeting of this Association.

This treatment suggests to me a plan that I have adopted in the management of abscesses about the hip-joint, and which I believe may obviate the necessity of excision in some cases in which the bone is not extensively diseased. When an abscess forms about the hip, open it, wash it out thoroughly with boro-salicylic acid solution, finally with a very weak mercuric bichloride solution, in a child; then put into the wound a piece of damp gauze well filled with iodoform, and firmly twisted into a cord; this acts as a drain; then seal the wound with antiseptic precautions. I have found one dressing of this kind nearly to heal an abscess, and two quite heal it.

The diagnosis of hip-joint disease may sometimes be quite difficult, in cases of hysteria or neuroses of this joint; but generally the main diagnostic symptom may be stated to be pain in the hip-joint, and confined to it, and manifested on proper manipulation; rheumatism being always a multiarticular affection. In children, however, it is sometimes difficult to decide.

April 30, 1888. Dr. Carlin called me to see a case which simulated hip-joint disease in a peculiarly striking manner; and in which he recognized an abscess about the hip in a boy aged ten years; the thigh was flexed, adducted, and the hip raised. After a careful examination of the hip-joint, and the head of the femur, which I moved freely in all directions, and without pain on firm pressure, I decided that the joint was not diseased, and that the abscess did not communicate with it. Dr. Carlin having given him chloroform, I opened the abscess, which was situated underneath the gluteus medius muscle, and near to the joint, but having no communication with it.

The above case was one easily mistaken for hip-joint disease. There was an abscess near the joint, and only the most careful examination could detect the absence of disease of the joint. But in marked contrast to it is the following case, which exhibits either extreme carelessness or ignorance of the pathology and symptoms of coxo-femoral inflammation.

J. C. D., aged thirty-two years, consulted me October 12, 1887, for what he was told was hip-joint disease. About two months previously, he fell and hurt his hip, and was confined to bed four weeks at a hospital, and was treated by a competent young physician for a contusion about the hip. On questioning this patient, who still complained of some stiffness of the muscles of the hip, he said that at no time since the receipt of his injury was he obliged to hold his thigh flexed on his pelvis to rest easily, and that he could always lie comfortably flat on his back, with both legs extended, without arching the lower part of his spine. In no stage of hip-joint disease can this be done, as we all know. My examination of him, while he was lying on a smooth, hard surface confirmed his statement, as his back and both popliteal spaces touched this surface at the same time, and he was quite comfortable. The femur was freely movable in its hip socket without any pain on pressure, it mattered not in what direction this pressure was made. His case, it seems, had been properly diagnosticated and treated at first,

[1] Bradford's method, with the child fastened on a light horizontal frame, might answer the purpose.

but doubting the correctness of the opinion of his first medical attendant, he sought the opinion of one whom he believed to possess considerable skill and reputation as a surgeon, and who gave him a certificate, of which the following is a copy; the original certificate is in my possession:

"Denver, Sept. 13, 1887.

This is to certify that the bearer, ——, has some of the symptoms of the incipient stage of hip-joint disease, and needs careful and long-continued treatment for it, otherwise he will be a cripple for life."

Signed "——, M.D."

On the opposite side of the paper on which the above was written, is the following supplementary expression by another medical man:

"I am certainly of the above 'opinion.'"

Signed "——, M.D."

The patient told me that this doctor made no examination of him whatever.

Of all injuries to the hip-joint, an old dislocation of this part is possibly the most interesting, especially since the introduction of Bigelow's method of reduction of dislocations at this joint.

July 9, 1888. Dr. Carlin asked me to see J. M., aged thirty years, laborer, or rather miner, and came with him to my office for this purpose. The doctor thought, as I did, that possibly the dislocation might be reduced notwithstanding its long duration. There was an upward and backward dislocation of the right femur of fourteen months' standing; the shortening was two and a half to three inches. Measured by Bryant's ilio-femoral triangle, the upper border of the trochanter major, the patient lying flat on his back, corresponded to a vertical line drawn from the anterior superior spinous process. The head of the femur rested on the dorsum of the ilium above this line.

Some days later at the St. Joseph's Home (Sisters' Hospital), I attempted a reduction under ether; five successive efforts were made in strict conformity with the Boston surgeon's method, and each time as the bone reached the rim of the acetabulum it unavoidably slipped back to its misplaced position. The attempt at reduction was consequently abandoned, and a cutting operation, under strictly aseptic precautions, was proposed, but declined by the patient. It was proposed, and Dr. Carlin readily assenting, to make an extensive straight vertical incision over the trochanter, *liberate the muscles attached to the upper part of the femur by division close to the bone, as I have done in sub-periosteal resection of this joint, scoop out the acetabulum with Volkmann's sharp spoon*, and put up the limb in an immovable plaster-of-Paris bandage, and afterward at the proper time begin passive motion, *with extension*, at the joint. All of which would involve the most careful antiseptic precautions, and subsequent judicious care of the case.[1]

[1] I confess that I had, at the time, no knowledge whatever of any attempt ever having been made to reduce an old dislocation at the hip-joint by cutting down on it, though acquainted with other dislocations reduced in this manner. I simply proposed to carry out what my judgment dictated to me, under aseptic precautions, to be a practical and rational operation, of which I was willing to assume the responsibility. In the discussion which followed the reading of Dr. Ashhurst's paper on "Excision of the Larger Joints," before the American Surgical Association at the Congress of American Physicians and Surgeons, Sir Wm. MacCormac, of London, related his successful experiences in the excision of the hip-joint for old dislocations. After the detachment of the muscles about the femur in my proposed operation, and the reposition of the head of the femur in its acetabular cavity, made ready for it, I cannot, at present, see any advantages of excision over this new operation.

II. Cases of Partial Excision of Knee-joint, to Correct Angular Ankylosis, etc.

In the first of the two cases of partial excision of the knee-joint which I shall report, it was wrongly believed that the patella was joined to the condyles by fibrous adhesions only, and it was proposed to break loose the patella, and after thorough division of the hamstring tendons and adjacent fascia, by open incisions, to straighten the limb by *brisement forcé;* then by the use of a back-splint, extension weight, and graduated movements of the joint subsequently, to restore mobility gradually to the joint.

About two years ago, with the same object in view, I attempted to straighten both contracted knee-joints of a lad about eighteen years of age. Previous attempts to effect this had been unavailingly made, by mechanical means, at an orthopædic establishment, as well as by different physicians, and I thought that by the aid of the subcutaneous section of the hamstring tendons, I should be successful; but I quite failed to straighten either limb, which I thought, erroneously at the time, was due entirely to an imperfect division of the fascia by a subcutaneous operation. Consequently I determined that in future I would not rely on subcutaneous division in such cases, but resort to open section, under aseptic precautions, by which means I could cut the fascia to better advantage, and surely be able to straighten the limb.

In the following case, the patient being etherized, it was found impossible by any properly directed manual force to budge the patella, and an operation was deferred. In the meantime the following paragraph from the last edition of Stephen Smith's work on *Operative Surgery*, p. 840, 1887, met my eye: "If the joint has long been bent at a right angle, not only do the structures above the joint contract, but the condyles lengthen, so as to render it impossible to bring the tibia down to its proper position, even by dividing the resisting tissues, as the hamstring tendons; in such cases the extremities of the condyles have been cut away successfully with antiseptic precautions." This is quoted from Lister. Hence, at my second appointment, I went prepared to exsect a part of the condyles, if required, which

was done, and the limb straightened; and then it was perceived that without such exsection all attempts to straighten such limbs must prove failures; and the reason is this: The growth of the extremities of the femur and tibia necessarily occurs in the direction of their length; and if the joint has been a long time bent, the epiphyses of the bones, in such cases, forming an angle with each other more or less acute, the articular surfaces adapt themselves to each other somewhat like the abutting ends of the rafters of a house. Hence, Lister, as quoted by Stephen Smith, found lengthening of the condyles, in the long-bent position of the knee-joint, to interfere with straightening of the limb, and resorted to partial excision, which I did also successfully in the two cases which I now propose briefly to report.

CASE I. *Ankylosis of knee-joint; partial excision.—November 3, 1887.* Charles B., aged thirteen years; ankylosis of right knee-joint of several years' duration; unsuccessful attempt to dislodge the patella, which was firmly united by bone to the femur. Further attempts were deferred to a cutting operation. Present: Drs. H. A. Lemen and P. V. Carlin, of Denver. Fig. 2 shows appearance of patient before the operation.

FIG. 2.

FIG. 3.

9th. Partial excision of the knee-joint. Open section of the hamstring tendons as a preparatory measure to straightening the leg. It was then discovered that the joint surfaces abutted together in such a manner, that to straighten the leg was quite impossible without a partial excision of the joint; and this was made still more apparent after the joint surfaces were exposed to view. An incision was made on the external side of the joint, as shown at Fig. 3, along and below the external border of the patella, and an incision at right angles connected with this below. The patella was detached from its bony union to the femur, by means of saw, chisel, and mallet; *but the patella was not removed;* Drs. H. A. Lemen and Carlin assisting me. Sufficient bone was removed—which I here exhibit to you—through the external cut to permit the limb to be brought to a straight position, when the knee was dressed with antiseptic precautions and put in a wire splint, with extension weights applied, and ice bags put to the knee. *Care was taken not to divide the external lateral ligaments or any of the ligaments about the joint.* The average temperature for the first week was 99.5° F.

FIG. 4.

24th. Changed dressing and removed drain tubes.

29th. Changed dressing; wound nearly healed.

Dec. 10. Dressed wound, and substituted plaster-of-Paris splint for wire splint.

18th. Removed dressing; cured; continued, however, to wear a splint to support the knee and secure firm ankylosis, which afterward took place.

March 14, 1888. Patient was photographed.

Fig. 4 shows a wood-cut from a photograph of the boy; exhibiting also on the outer side of the leg, opposite the knee-joint, the scars of the incisions; and more posteriorly the scar of the lower drain tube hole.

CASE II. *Ankylosis of knee-joint; partial excision.*—Edward L., æt. eleven; fibrous ankylosis of right knee-joint; joint free from inflammation; patella firmly united to condyles by bony union.

Operation, January 31, 1888. Partial excision of knee-joint.

Fig. 5, a wood-cut, from a photograph taken before the operation, shows the appearance of the knee and right leg at that time; the boy's general condition being excellent.

FIG. 5.

FIG. 6.

Preparatory section of the ham-strings, and popliteal fascia by open incision; assisted by Drs. W. W. MacGregor and J. E. Lowery; the latter gave ether. Operation done as in preceding case, *by an external incision, and the ligaments were respected—that is, were not cut—and the patella was left in place*, and the same kind of after-treatment as in the preceding case was adopted, with the exception, that hydronaphthol as an antiseptic was used exclusively in the dressing. *Extension and ice bags to joint*, as in preceding case. The extension during the first week or two allays pain, by controlling muscular spasm, and, in conjunction with the ice bags, keeps down inflammation, even in those cases in which there is no hope of obtaining motion in the joint subsequently; and, in this way, extension is a valuable aid in the treatment.

February 2. Temperature 100° F.; it subsequently fell to 99°, and was this on an average during the first week.

14th. Changed dressing; inserted a rubber drain tube; some suppuration; knee swollen; the hydronaphthol gauze caused considerable irritation; he said it burnt him immediately it was applied. Discontinued hydronaphthol dressings altogether, and two days afterward returned to my usual dressings of mercuric bichloride and iodoform.

16th. Changed dressings; rubber tube acting well; used dressings of mercuric bichloride and iodoform.

22d. Changed dressing; large ulcerated surface around the drain-tube holes; inflammation exterior to the joint, which is doing well; removed drain tube.

March 5. Changed dressing; ulcerated surface healing rapidly. After this I saw him quite often, and twice curetted the drain-tube holes, which greatly accelerated their healing.

June 11. Drain-tube holes all healed; and after obtaining his photograph, he was discharged cured, and he left a few days afterward for his mountain home in Middle Park, Colorado, wearing a splint to favor firm ankylosis of the knee-joint. Fig. 6 shows a wood-cut of him after the operation.

July 25. Relapse: After leaving Denver he was exposed to a snowstorm in crossing a high range of mountains, and while camping, it snowed on him during the night. He was attacked with a severe cold and inflammation of the knee-joint, and finally, after more than a month of suffering, was taken to Denver, where I saw him again July 25th, in a most pitiable condition—worn, haggard, with knee-joint much swollen and intensely painful, and with a temperature of 103.5° F. Dressed his wound.

27th. Having been removed to the Sisters' Hospital at Denver, Dr. Lowery gave him chloroform, and I opened the joint in several places, and made counter-openings above the knee, from which escaped about half a pint of the most offensive smelling dark-colored pus. The wound was thoroughly irrigated with a mercuric bichloride solution, and injected with an ethereal solution of iodoform, and then a number of iodoform gauze drains, such as I have already described, were introduced, and the wound was sealed with antiseptic precautions.

August 5. Knee dressed as on the 27th of July; *doing splendidly and not a drop of pus;* temperature normal.

21st. Changed dressing; slight suppuration; patient walking about with a crutch.

30th. Dr. Lowery gave him chloroform, and I curetted the sinuses with Volkmann's sharp spoon; new felt splint applied.

Sept. 7. Dressed wounds aided by Dr. Lowery, who was left in charge of the case during my absence in attendance at this Association.[1]

I believe that even after a knee-joint has begun to assume a permanently angular ankylosis, which will eventually lead to a lengthening of the epiphyses in such a manner as to make them meet together like the joined ends of two rafters, as in the two cases just reported, that much may be done to restore the limb to a normal position as the following case will illustrate.

Case of scrofulous disease of the left knee-joint of several years' standing; tenotomy; extension.—February 1, 1888. Dr. John P. Kelly, of Golden, Colo-

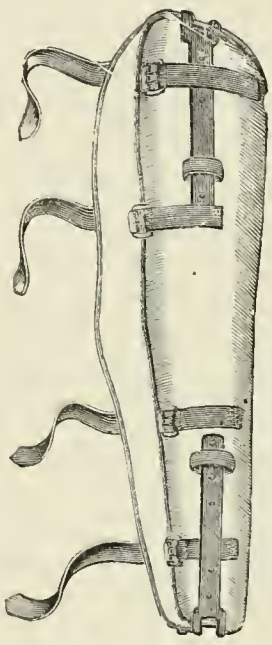
[1] November 9th: His condition is excellent; two small sinuses need curetting; he walks to my office to be treated; limb ankylosed in straight position.

rado, called me to Golden to amputate a cancerous breast, and while there requested me to see a little girl, Jennie B., aged nine years, very much emaciated, and suffering with a painful scrofulous disease of the left knee-joint. At the suggestion of Dr. Kelly she was placed under my care.

Fig. 7 is a wood-cut engraving copied from a photograph of her, and exhibits her appearance

Fig. 7.

Fig. 8.



before treatment. The patella was freely movable, and the joint was not ankylosed. There was a subluxation backward of the tibia, and the characteristic overhanging knee-cap and condyles, as shown in the engraving.

April 4. She was etherized, and Drs. Clough and Lowery, of Denver, assisting me, I divided the ham-string by open incision. After freely dividing the ham-strings and all contracting fascia, I could not entirely straighten the limb owing, as I believe, to the pathological condition mentioned above, already taking place in the joint. After the wounds in the popliteal space were sutured with catgut and sealed with antiseptic precautions, I placed her in bed with an extension weight and pulley, after Sayre's method, but modified in this manner after a few days, because of excoriation of the calf of the leg. One pulley was put in the ceiling of the room immediately over the leg, which rested on a soft pillow, and there was just enough weight, about two pounds, attached to the pulley to support the leg gently, and to the webbing of the adhesive plaster attached to the sides of the leg were a weight and pulley to make extension in a line with the partially corrected deformity, after section of the ham-strings, but enough weight only to cause gradual extension and without pain, and the weight after a few days was slightly increased; and the line of deformity gradually brought to a straighter normal line as the case progressed toward cure, so that on May 13, 1888, I applied my new knee-joint extension brace with complete success.

It is so simple and comparatively so inexpensive; affords such complete relief; and is so easily applied by the mother of the child or attendant that I believe when it has been once tried, that it will invariably give entire satisfaction for the purpose for which it is used—that is, to procure relief from pain in making an easy, comfortable, and continuous extension and counter-extension of an inflamed and painful knee-joint.

I must give the caution, however, which would hardly seem necessary, that before the use of this brace the limb must be made ready for it; that is, made straight by the appropriate preparatory treatment as in hip-joint disease.

Fig. 8 shows an engraving of the instrument from a drawing which I made; and Fig. 9 shows a drawing exhibiting the manner of applying the adhesive plaster above and below the knee-joint, with pieces of webbing for making the extension and counter-extension. The dotted lines represent the adhesive plaster underneath the bandage.

Fig. 9.

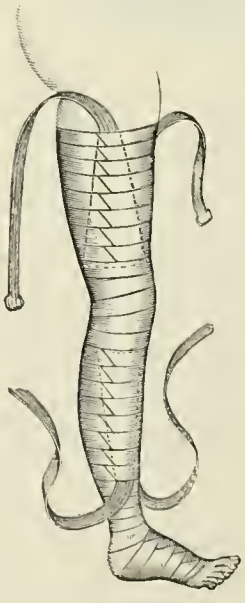


Fig. 10.

The instrument is made in the following manner: Leather might be preferable, but a piece of Russian felt is moulded accurately to the leg and thigh; upright pieces of brass or light iron are riveted to each side of the brace above and below, as seen in Fig. 8, and at each distal end of these pieces of brass is a little roller, over which rolls the webbing attached to the adhesive plaster above and below the knee; thus extension and counter-extension are secured, and an elastic knee-cap and buckles fasten the apparatus about the limb, as seen in an engraving from a photograph of the girl taken about the 15th of May (see Fig. 10). To strengthen the instrument a flat steel bar may be riveted along the back of it. Buckskin or chamois should be sewed along the edges, and the projecting points on each side of the little rollers should be covered with chamois to prevent irritation of the skin.

In infants the manner of managing acute or chronic inflammatory diseases of the knee-joint is confessedly difficult, and I believe the following successfully treated case worthy of brief mention:

April 17, 1888. Dr. L. H. Wood, of Denver, recommended the parents of a little boy, aged eighteen months, to consult me concerning a subacute inflammation of the knee-joint of several months' standing. I adjusted adhesive plaster with pieces of webbing attached to each side of the leg from just below the knee, and I bandaged the leg and thigh from the toes up. The child was chloroformed and a silicate of soda bandage applied over the first bandage; but while applying the silicate of soda bandage, firm extension and counter-extension were made at the knee-joint, and the limb straightened as much as possible without undue force. The pieces of webbing, sewed to the adhesive plaster, for making extension were on each side of the leg above the ankle left free. At night and during the day while the child was asleep an extension weight and pulley were attached to the webbing, the bed being raised at the foot.

May 1. Substituted an adjustable felt splint, moulded accurately to the limb, for the silicate of soda bandage.

13th. New dressing.

20th. Dressing and new splint.

25th. Ice-bags to knee, and their continued use for ten days or longer.

June 25. Dressing and new splint; saw him July 5th and 7th.

July 14. Cured; all inflammation had left the joint, and he could move it freely without pain, and walk on the leg comfortably. As a precautionary measure, I advised the continued use of extension at night.

III. Resection of the Elbow-joint for Gunshot Wound. New Apparatus for Extension and Counter-extension at this Joint.

The management of the elbow-joint, after resection, is a subject that has always more or less interested surgeons; and I think that the apparatus that I used in a recent case will commend itself to the use of military and civil surgeons. This instrumen is equally applicable to the treatment of acute inflammatory diseases of the elbow-joint in their earlier stages, as after resection.

Dec. 7, 1887. Mr. C., a deputy sheriff, while attempting to arrest a desperado near Deer Trail, Colorado, was shot through the right elbow-joint; and I here show you the bones that I removed by resection at night by lamp-light, assisted by two cowboys, with other cowboys and deputy sheriffs looking on. The resection was done through a posterior longitudinal cut, which joined the two bullet-holes of entrance and exit. The wound was dressed with scrupulously antiseptic precautions; my cowboy assistants cleaning their finger-nails with a nail-brush, and scrubbing their hands and arms in repeated changes of hot water and soap in the most approved manner. The elbow and arm were adjusted in a felt splint, and some hours afterward he was removed to Denver and placed at the County Hospital, where I saw him every day or two. Average temperature 99° F.

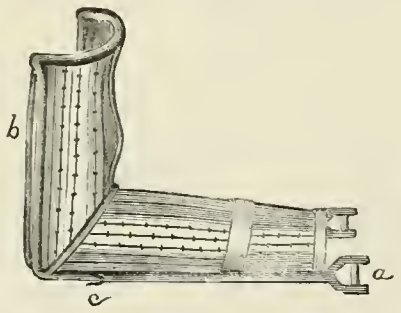
Jan. 6, 1888. Applied my apparatus for extension and counter-extension at the elbow-joint. (See wood-cut engraving of him with splint applied, copied from a photograph, as shown at Fig. 11.) The outside

Fig. 11.

bandage on the forearm, that keeps the splint in its place, has been temporarily removed so as to show its action. The webbing for making extension passes over the little rollers at the lower end of the splint or brace, as seen in Fig. 12 at *a*. In the engraving, copied from the photograph of Mr. C., there is shown a loop of rubber tubing attached to the webbing on the outer side of the arm, the same arrange-

ment exists also for the inner side of the arm. To each piece of rubber tubing is a chain, which can be caught at any link desired into a hook at each

Fig. 12.



side of the brace near its bend at the elbow, as seen at *c* in Fig. 12.

Application and action of the brace.—The forearm having been shaved, and a gauntlet bandage properly applied from the tips of the fingers to the wrist; pieces of adhesive plaster with webbing sewed to these are applied to the inner and outer sides of the forearm, and covered by a bandage from the wrist, joining with the gauntlet bandage. In the meantime the arm is held between pronation and supination, with the thumb directed upward. Traction on each side of the arm by means of the webbing, which is reflected over the little rollers at the lower end of the brace, pushes the whole brace backward, so that the upper vertical portion of the brace, padded and fitted to the front part of the arm, in pushing the arm backward, makes counter-extension at the elbow-joint; while the pieces of adhesive plaster, to which the webbing is sewed and reflected over the little rollers, pull the forearm forward and make extension at the elbow-joint. The brace is steadied and kept to its place by an outside bandage on the forearm. The brace is also secured by a bandage to the arm. In the use of this brace by Mr. C., extension and counter-extension at the elbow-joint were accomplished in a most effective manner, and afforded him immediate relief from pain, and, indeed, made him perfectly comfortable, and facilitated the rapid healing of his wound. The instrument is a stout wire brace smoothly padded. In applying it a short felt splint or piece of pasteboard, lined with cotton batting, should be placed behind the arm just above the elbow to prevent the bandage, which passes between the rod at *b*, in Fig. 12, and the brace, and then around the back of the arm, and also around the brace, from compressing uncomfortably the soft parts on the back of the arm.

Jan. 19, 1888. Mr. C. came to my office, and afterward was photographed.

28th. Wound healed; removed splint; he came afterward to my office to have passive motion practised.

Feb. 6. I broke up the adhesions, under ether, at the hospital; arm extended during one week in a straight position by means of adhesive plaster, weight and pulley; ice-bags to elbow-joint.

13th. Removed dressing, and stopped extension in straight position; pronated and supinated and flexed arm thoroughly under ether; used extension apparatus, as shown in engraving from photograph, which afforded him the greatest relief and comfort.

June 20. I received a letter, probably written by his wife, expressing his gratitude, and saying that he was thrown from a wagon, hurting his arm, and that from this accident he had suffered more than from the gunshot wound. I have not heard from him since; but when he quitted me there was good motion in the joint.

In treating inflammation of the wrist-joint, I think the new Russian felt, as made by Tiemann & Co., is preferable to the sole leather used by Sayre; and no delay in application is occasioned, as with the sole leather, waiting for it to dry; besides, the use of ice-bags is a valuable addition to the treatment. The following case is an illustration:

April 27, 1888. Mr. S., of Denver, aged thirty, had acute inflammation of the right wrist-joint, with the most atrocious pain; applied Sayre's adhesive plaster method, and repeated the same, but with the quickly moulded Russian felt instead of leather; immediate relief; ice-bags to the dorsum of the wrist.

INDICATIONS AND CONTRA-INDICATIONS FOR ALTITUDE IN THE TREATMENT OF PULMONARY TUBERCULOSIS.[1]

By FREDERICK I. KNIGHT, M.D.,
of Boston, clinical professor in harvard university.

It is generally admitted at the present day that the study of the climatic relations of pulmonary tuberculosis is an exceedingly complicated one, not only with reference to the origin of the disease, but also with reference to its progress and termination. It is also now generally admitted that an outdoor life in the purest attainable air is one of the most desirable conditions to secure for those patients affected with the disease, in whom its arrest is hoped for.

The purest, most nearly aseptic air is found on the ocean and at high elevations; but as, in order to be of lasting benefit, stay in the new conditions should be considerably prolonged, ocean air is out of the question for most patients, and one looks to the mountains for a place of prolonged residence. Here we have also, in the beginning at least, an increased respiratory activity, which acts beneficially on the nutrition of the pulmonary parenchyma.

It is, however, well known that high altitude disagrees with and is thoroughly unsuited to some

[1] Read at the meeting of the American Climatological Association, Washington, September, 1888.

tubercular patients, and it is for the purpose of guarding a part, at least, of these patients against an experiment in climate, the result of which might be an irremediable injury, that I ask for a discussion upon a few propositions laid down in a rather tentative way.

In considering the question of high altitude in this paper, I will restrict the application of this term to such elevations as will usually allow of prolonged residence without danger of anoxyhæmia (4000 to 6500 feet above the sea-level).

The contra-indication to altitude in the treatment of patients with pulmonary tuberculosis may be found to pertain to some general factor, such as the age or temperament of the patient, to the type or stage of the disease itself, or to some complication of other disease.

Is there any limit of age which would forbid or render less promising the residence of a tuberculous patient in high altitudes?

I am inclined at present to put such a limit at about fifty years. After that period the chest-walls are less elastic, the patient is more susceptible to cold and sudden changes of temperature, and at the same time less inclined to take active exercise.

Is there any temperament which should be prohibited a trial of the high altitude treatment?

It may be said that the energetic stimulation of the mountain air is suited rather to the phlegmatic than the nervous temperament, and that individuals of the latter type sometimes do very badly in it. These patients usually have an irritable heart, frequent pulse, and inability to resist cold. We must be sure, however, before denying a patient the benefit of this treatment on account of temperament, that we classify him properly, for there are patients, weak and irritable from disease, who at first might strike us as of a neurotic nature, but who are not constitutionally so, and who will improve quickly under mountain stimulation.

What is there in the nature or condition of the disease itself which may contra-indicate residence in a high altitude?

For the sake of convenience, I will make use of the types of the disease employed by me in a previous paper.[1]

1. Patients presenting the earliest physical signs of tuberculosis of the apex, who have as yet shown little, if any, general disturbance from the disease, and who complain only of morning cough and expectoration.

These are the patients who are known to recover under a great variety of conditions, both climatic and social; but it seems to me, after considerable experience, that a larger proportion have recovered under the high altitude conditions than under any other. With a few exceptions, such as for general reasons previously mentioned, I should recommend high altitude for these cases.

2. Patients with more advanced disease, showing some consolidation, but no excavation, nor any serious constitutional disturbance.

High altitude is suited to many of these cases also; but if a considerable area of one lung, or the apices of both are consolidated, if the pulse and temperature are both always above 100, it may be well to try some low altitude first. When quiescence in the morbid processes is established, a change to higher altitude can be made.

3. Hemorrhagic cases. Patients in whom pulmonary hemorrhage has been, perhaps, the earliest, and a frequently recurring symptom, but in whom there is, as yet, no marked febrile reaction, nor much physical evidence of disease.

In my experience this class has done particularly well in high altitudes. The tendency to hemoptysis seems to be diminished rather than increased. This seems to me to be explicable more through improvement in nutrition of the lung parenchyma than by change in the atmospheric pressure, for the lung cannot be considered an internal organ, as far as atmospheric pressure is concerned, but must be considered as subject to the same pressure as the skin, and, therefore, in high altitude more liable to superficial congestion and hemorrhage. Theoretically, therefore, there was good reason for the old custom of avoiding the sending of such patients to the mountains, but practically I have never experienced ill results from so doing.

4. Patients with advanced disease; those with cavities, or severe hectic symptoms.

Patients with advanced disease, or, better stated, with great area of lungs involved, should not be sent to high altitudes. The demand for increased respiratory activity, which cannot be answered, is apt to be quickly followed by fatal result. The existence of a small cavity, in a case in which the disease had became quiescent, would not contra-indicate high altitude. Hectic symptoms would do so.

5. Patients in an acute condition.

None of these should be sent into high altitudes.

6. Cases of so-called fibroid phthisis or interstitial pneumonia.

If the patient is over fifty years of age, if his heart is dilated, or if there is great bronchial irritability, producing harassing cough, he should not be sent into high altitude.

7. Patients convalescent from acute pleurisy or pneumonia, in whom the eruption of tubercle is dreaded.

Unless otherwise contra-indicated, elevation is particularly suited to this class of cases.

[1] On the selection of a climate for patients with pulmonary tuberculosis. Boston Medical and Surgical Journal, April 5, 1888.

8. Patients in whom the tubercular process has seriously invaded the larynx.

It is generally recommended by those familiar with them, that these patients be not sent to high altitudes. In view of modern methods of local treatment, they certainly should not be sent there to the deprivation of this; but should they be sent to high altitudes if they can also have the benefit of good local treatment? With others I have been prejudiced against sending these patients to the mountains, but it may be that this prejudice is groundless for high altitudes which are free from dust, and that they do no worse here than anywhere, the disease when it has once seriously attacked the larynx usually pursuing an unfavorable course. I know that some of the resident physicians of high altitudes do not share this prejudice.

9. Those with complications of other diseases.

Much care should be exercised in regard to cases of this class.

One of the first in importance to suggest itself will be cardiac disease. Cardiac dilatation should preclude the consideration of altitude; and it would be safer to say the same in regard to most cases of hypertrophy, though if this be moderate and of slow development, the patient might be allowed some elevation. There are many patients, however, who are unwarrantably denied the benefit of high altitude on the ground of heart disease, *e. g.*, patients with a cardiac murmur the result of endocarditis quite long ago, in whom there is no evidence of deranged circulation, and no sign of cardiac enlargement. Of course, the mere existence of a murmur is no evidence of cardiac condition liable to be unfavorably affected by rarefied air. On the other hand, there are some patients with nervous derangement of the heart who had better be advised against high altitudes. These, however, would usually be of the general neurotic type before spoken of.

Disease of the large bloodvessels is an evident contra-indication.

Patients with bronchial dilatation or pulmonary emphysema are not usually recommended to high altitudes, presumably on account of diminished respiratory area. I have not had much personal experience with such patients in high altitudes, but would like to hear from those who have had. There are some with excessive bronchial irritability who certainly do better in lower regions.

In regard to renal disease, while it is admitted by resident physicians that acute nephritis, like acute pneumonia, is severe in high altitudes, they claim that chronic nephritis is often benefited.

Intestinal ulceration would not contra-indicate a high altitude, but no great good could be expected from the change.

In cases of epilepsy, diseases of the brain and spinal cord, which are said by some to contra-indicate altitude, I have had no experience.

It looks to me as if the claim that heredity is a contra-indication of altitude must have originated in the mind of one who was afraid lest his percentage of cures should be lowered by bad cases, for, while admitting that patients with hereditary tendency to tuberculosis are on that account less favorable for any treatment, when taken in hand early they are especially benefited by mountain-air life.

Diabetes would seem properly to contra-indicate high altitude treatment, as its subjects are very liable to succumb to attacks of any acute disease, and these would be more liable to occur in a variable than in an equable climate.

Upon what grounds syphilis is put down by some as a contra-indication I know not.

The combination of tuberculosis and syphilis is a very unfavorable one, and liable to result badly in any climate.

TWO SUCCESSFUL CASES OF BRAIN SURGERY.[1]

BY CHARLES B. NANCREDE, M.D.,
SENIOR SURGEON TO THE EPISCOPAL HOSPITAL; SURGEON TO THE JEFFERSON MEDICAL COLLEGE HOSPITAL, PHILADELPHIA.

I AM fully warranted, I believe, in reporting the following cases at this time, without waiting for many months to ascertain the ultimate condition of the patients, because each case involves one or more of the essentially new principles of modern brain-surgery, as yet a comparatively unexplored field, accounts of each new inroad upon which should be at once published for the guidance, encouragement, or warning of those so eagerly pressing forward in the same direction.

In the annual oration which I had the honor of delivering before the Philadelphia Academy of Surgery, in January, 1888, I emphasized several procedures which, while not new,[2] certainly were *not* "known to every one," as stated in a review of my remarks; nay, more, so far as I am aware, they have never been practised in this city, although taught by Professors Agnew and S. W. Gross. I shall merely quote part of what I then said as a preliminary to the history of my first case, which admirably illustrates the practical value of some of the principles enunciated:

"The general principles governing the treatment of compound skull-fractures are strictly applicable to gun-shot wounds, so far as the bone lesions are concerned, Wharton's[3] tables so conclusively show the ultimate evils of the retention of a foreign body in the brain, that if the operation can be done without fatal injury to the

[1] Read before the Philadelphia Academy of Surgery, November 6, 1888.

[2] I need hardly point out that *no originality* is claimed, but merely the strong emphasis.

[3] Philadelphia Medical Times, 1879.

encephalon, balls should always be removed, since even primarily such injuries are certain to be followed by suppurative inflammation, which too commonly is of the diffused form, when death is inevitable. The most superficial glance at the histories of recoveries after apparently hopeless brain injuries, shows that the result was due to free drainage, as in the famous tamping-iron case, and one of extensive shotgun disorganization of the anterior fourth of the left hemisphere, which I reported to this Society some two years ago.

"*The principle of free drainage, then*, rather than the mere removal of the foreign body, is the guiding principle of the modern treatment, although to effect perfect drainage, both theoretically and practically, the course of the ball must be followed throughout and disinfected, when the missile being accessible, and capable years hence of producing serious trouble, should be removed."[1]

CASE I. *Ball wound of the anterior lobes of the brain; failure to find the ball, owing to its deflection by the base of the skull; drainage of the track; recovery.* —Henry C., æt. fifty-three years, was brought to the Jefferson Medical College Hospital, by the Police Patrol, at 7 A.M., September 15, 1888, having been found lying at the corner of Twelfth and Spruce Streets, suffering from a bullet wound of the right temporal region, about one and three-quarters inches behind the external angular process of the frontal bone, and the same distance above the zygoma, the ball-track passing downward, forward, and inward to the bone, which was bared and slightly depressed. The man presented no signs of mental or cerebral disturbance, beyond what could be readily accounted for by the ascertained fact that he had been on a week's spree. He slept quietly for some hours after admission, and at 1 P.M. he was etherized at the clinic, when, assisted by my colleague, Dr. Barton, I proceeded to operate as follows:

A large semilunar flap was freely reflected, exposing a slightly starred and depressed portion of bone directly over the course of the middle meningeal artery, but no *perforation* was apparent. Convinced that penetration had occurred, with partial replacement of the small, trapdoor-like fragment from intracranial pressure, I trephined, removing a number of depressed fragments of the inner table, which enabled me to see a perforation of the dura mater, and recognize that the middle meningeal artery was wounded.

After partially arresting the very free hemorrhage from this vessel, and enlarging the bone opening with the rongueur, the patient's head was placed so as to render the ball-track as nearly vertical as possible, when the aluminium gravity probe[2] was introduced, and allowed to *gravitate* along the ball-track, which it readily did, until it struck the base of the skull — somewhere about the lesser wing of the sphenoid bone, it was thought. Thus determined, the track was carefully examined by a Nélaton's probe, but without detecting the ball. Further search demonstrating the probable truth of one of two alternatives, viz.: (1) that the ball had perforated or was imbedded in some one of the bones forming the base of the skull, which view was favored by a bared surface of bone with a doubtful sensation of perforation; and (2) that the ball had struck this bared portion of the base, and had been deflected, burying itself in the opposite frontal lobe; this latter is the view I am inclined to hold.

The manipulations with the brain proper must have occupied fully half an hour, comprising the repeated introduction of probes and forceps, the length and frequency of which manipulations I wish to lay stress upon. Failing to find the ball, a drainage-tube was carried along the whole track of the wound in the brain, and a careful antiseptic dressing was applied, all hemorrhage from the middle meningeal artery having now ceased.

There was little, if any, shock from the operation, no symptoms of paralysis or paresis at any time; no visual, aural, or olfactory disturbances, and, in fact, no cerebral symptoms beyond some slight hebetude and a moderately severe headache during the first five days, which returned partially on a few occasions— usually after dressing the wound—but was promptly relieved by a laxative. Rest in bed, milk diet, and an occasional laxative, comprised the after-treatment.

September 30. Prof. Victor Horsley, of London, saw him with me to-day, and concurred in the diagnosis as to the position of the bullet, finding nothing abnormal in the pupils, reflexes, sensation, or motion.

His temperature before operation was 100° F., reached 101.1° the same evening, touched 101° on the seventh day, and during the second week was about 99.5° at night, 98.5° in the morning, after which it kept below 99°. The pulse was always about normal as to frequency, etc.

I would call attention to some important lessons taught by this case, viz., that the gravity probe will readily, surely, and safely follow the course of a bullet through the brain; that prolonged manipulation of the brain, if guarded by reliable antiseptic precautions, is harmless, and that thorough drainage and disinfection of ball-wounds of the brain will avert that generalized suppuration, the result of infection, which proves so fatal after such injuries. This is the second case recently in which I have introduced a drainage-tube in the bullet-track in the brain with recovery of the patient; the one here reported returned to Boston four and a half weeks after the accident, a minute granulating point remaining, suggestive of a fragment of dead bone.[1]

It is interesting to remark, that the wound I made healed per primam, without suppuration, while the ball-track in the soft parts, having been exposed for some hours before antiseptic measures were instituted, after sufficient time for development of the microörganisms had elapsed—*i.e.*, about one week—presented a slight amount of suppuration. Had the opposite extremity of the wound-track been at an accessible portion of the skull, I should have unhesitatingly trephined at that point, and would, probably, have then been able to find and extract the missile.

CASE II. *Excision of the thumb-centre for Jacksonian epilepsy; recovery, with non-recurrence of the*

[1] THE MEDICAL NEWS, January 28, 1888.

[2] Fluhrer's.

[1] I have recently learned that this man has remained well.

attacks.—Charles L. R., æt. twenty-seven years, with a good family history, containing no record of epilepsy or of any chronic neurosis, states that up to nine years of age he was in perfect health, at which time he was struck upon the left parietal region with a piece of wood with such violence as to be rendered unconscious for three hours. Immediately after regaining consciousness he was seized with a convulsion, which recurred three times in rapid succession; he is positive that it was right-sided chiefly, and, he is told, resembled those which he has recently had. For the next three months he had a diurnal paroxysm, followed by an intermission of two weeks. Next in order was a period of five months, when the fits were repeated three to four times daily, again to be followed by a two weeks' intermission. From ten to fifteen years of age he averaged five seizures a week, while from fifteen to twenty years he was attacked slightly less frequently, averaging only about four fits a week. From twenty years of age until May 7, 1888, the number of attacks increased, so that while he has always had at least a diurnal attack, they have varied in number from this up to forty per diem.

He has been under treatment at various institutions, such as Bellevue Hospital, New York, and the University Hospital, Philadelphia, without benefit, until on May 7, 1888, Dr. Steinbach removed by trephining, at Blockley Hospital, an inch and a half button of very dense bone from the middle of the left anterior parietal region, the posterior segment of the trephine cut slightly overlapping the line of the Rolandic fissure; at this time a scar in the scalp overlying the portion of bone removed, was excised, because pressure upon this cicatrix excited the paroxysms, which, as I am informed by Dr. C. K. Mills, *commenced on the left side—i. e.*, were evidently dural, or, at least, of fifth pair origin. The button was replaced, the wound did well, and the paroxysms did not recur except once, ten days after the operation, until September 29, 1888, a period of nearly five months, when he came under my care, and was admitted September 1st to the Jefferson Medical College Hospital.

August 3, 1888, Dr. W. W. Keen admitted this man to his wards at St. Agnes's Hospital, where he removed the partially necrosed button of bone from a bed of granulations, a suppurating sinus leading down to the fragment.

A careful study of about twenty-five attacks which he had in the hospital during the three days prior to the operation demonstrated that the following order of phenomena was always observed: A sharp pricking pain darts from the seat of the injury toward the median line of the head, a numb feeling is sometimes experienced in the right leg, the right side of the face flushes, and often his vision becomes hazy with flashes of light before his eyes. These prodromata proceed so slowly, that the man asked to be allowed to lie down, recognizing that an attack was coming on. Almost coincidently with these sensations the right thumb is strongly flexed upon the palm, the wrist and fingers are next extended, with only partial action of the interossei, for there an imperfect "claw-hand" formed; the forearm and hand then become strongly but slowly pronated, when flexion at the elbow with rigid fixation of the extremity in the position just mentioned, obtains. Closely following these movements, the head is rapidly and powerfully flexed laterally to the right, with marked rotation to the same side; the tongue is thrust out to the right between the rigidly opened jaws; coincident with all which is conjugate ocular deviation to the right. These movements are all tonic, occupying about nine-tenths of the paroxysm, to be followed by generalized clonic movements, most marked upon the right side, occupying the remainder of the period; the loss of consciousness is always complete.

I had the advantage of studying three of the paroxysms in conjunction with my friend Dr. Morris J. Lewis, who kindly noted the sequence of the phenomena, as above recorded.

The day previous to the operation, after careful shaving, cleansing, and disinfection of the scalp *a la* Horsely, with the aid of Dr. M. J. Lewis, I located the fissures of Rolando and Sylvius; the former of which I marked with a point of nitrate of silver, and the latter at its commencement only by the same agent; in addition, the presumed position of the thumb-centre, which it was proposed to remove, was marked out upon the scalp at the exact position where after the operation it was found to lie. Dr. M. J. Lewis's modification of Thane's and Horsley's method, Hare's method, and the ready method of Lucas-Championnière, the latter only for determining the bregma, were used to locate the Rolandic fissure, which the after-evidence afforded by the operation proved to have been absolutely correct, although the man's head was so exceptionally large as to require a lengthening by some inches of Dr. Lewis's instrument, which allowed for a head measuring thirteen inches. A thorough cleansing, renewed disinfection, and a bichloride dressing, were in turn made use of, and the patient remanded to the ward. Up to two o'clock on this day the patient had *ten* attacks.

October 4th, in the private operating room of the Jefferson Medical College Hospital, in the presence of Prof. S. W. Gross, W. W. Keen, my colleagues Drs. Hearn, Allis, Barton, and Wirgman, who kindly assisted me, Dr M. J. Lewis, who managed the battery, Drs. Dercum, J. M. Taylor, Usilton, Neilson, etc., my interne, Dr. McDonald, and many undergraduates, I proceeded to operate, Dr. Callender administering ether, the patient having received one-quarter of a grain of morphia hypodermatically about one and a half hours previously, and ʒij ext. ergot. fluid. in divided doses during the morning; just before profound anæsthesia was induced, the patient had a characteristic but slight paroxysm.

The extremities of the Rolandic line were marked by nicks in the bone, a large horseshoe-shaped flap, including the periosteum, was reflected, whose centre was attached to the thick and exceedingly dense fibrous tissue—fully three-sixteenths of an inch thick—which filled the old trephine opening. The attempt to control the bleeding from the scalp vessels by an Esmarch tube proved abortive. The crown of a medium-sized trephine was applied below and

somewhat anterior to the old trephine cut, to enable me to reach the non-attached area of dura and pia mater. The bone was exceedingly dense. The dura mater having been incised, it was found that, except below and behind, the membranes were firmly attached over nearly the whole of the lower two-thirds of the motor area. This cicatricial mass was carefully dissected off from the subjacent brain, the two trephine openings having been united by cutting away the intervening bony ridge, and the bony orifice enlarged in all directions by the rongeur, until portions of the membranes which were unattached to the brain were reached. All cicatricial tissue having been excised, including an ovoidal portion of the membranes, about two by two and three-quarters inches, and the fissure of Rolando found, Dr. Morris J. Lewis kindly proceeded to locate the thumb-centre by the battery.

When a spot in the ascending parietal convolution, corresponding to the focal point indicated by Horsley, was reached, *i. e.*, in the second fourth, from below upward, the thumb suddenly flexed, and at once, although profoundly anæsthetized, an epileptiform paroxysm ensued identical in its sequences and details with those observed before operation. Owing to the bone opening requiring to be slightly enlarged opposite this point, the centre had twice again to be located by the battery, each application at this spot, and this only, reproducing an attack. It is of very great interest to note this, for while the discharging centre has been several times located by electricity, I believe that this is the first instance upon record in which a generalized convulsion has been produced by the excitation by this agent of the discharging lesion, although Macewen mentions one in which the curette provoked a paroxysm. Again, although *nothing but boiled water* was allowed to touch the cortex, a strong electric current was required, and no response was obtained in the area assigned to the thumb in the ascending frontal convolution. The shoulder, elbow, forearm, and facial centres were readily picked out, and are situated as delineated by Horsley.

One-half inch of the whole breadth of the ascending parietal convolution was excised, the apex of the wedge reaching into the corona radiata; after this section had been made both the thumb motions were lost and no paroxysm could be excited by the application of the electrode to this spot.[1]

The hemorrhage from the vessels of the pia mater, which must have amounted to from eight to ten ounces, having been in great part arrested by the pressure of serre-fines applied as each vessel was divided, was now permanently arrested by fine gut ligatures very carefully tied by Dr. Allis, and the main trunk, or a branch of the middle meningeal artery, was secured by passing a needle armed with a gut ligature through the dura mater. A final irrigation with the mercuric solution was made, and the flap was rapidly sutured with silk-worm gut and fine silk, small rubber drainage tubes having been previously introduced at the two most dependent portions of the wound.

The patient now and subsequently vomited, apparently, all the ergot injected. The combined effect of opium, prolonged anæsthesia (the patient was fully two hours under ether), loss of blood, and electrical excitation of the brain produced such an alarming amount of shock that only by the most vigorous use of artificial respiration and the battery, atropia, digitalis and whiskey hypodermatically, hot water enemata, etc., was a fatal termination averted.

Upon recovering consciousness all power in the thumb was found to be lost, flexion and extension of the hand, fingers, and wrist were enfeebled, there was nearly complete right-sided facial paralysis, and loss of power of the same side of the tongue, with almost total aphasia. Unquestionably all these paretic symptoms, except those pertaining to the thumb and wrist, must have been due to the combined effect (1) of dissecting off with the adherent pia mater a portion of the external layer of large motor cells of the cortex, as was inevitable from the dense cicatricial nature of the adhesions; and (2) from the deprivation of the cortical centres of speech and the seventh and ninth nerves of their due vascular supply from the destruction of so much of the pia mater whose vessels are mainly terminal. The temperature was, at 10 P.M., 98.2°, pulse 108.

Oct. 5. The wound was dressed in the evening, the blood-stained dressings removed with the drainage tubes, and mercuric dressings reapplied. Temperature, morning, 100.1°, pulse 108; evening temperature 100°, pulse 108.

Upon the third, fourth, and fifth days the wound was redressed, and an attempt made to relieve tension which seemed great, the flap being much elevated, but the probe gave vent to only a few minims of bloody serum, proving that there was no real accumulation of wound-fluids, but that there was protrusion of the brain tissue through the bony opening. A tight stitch was cut on the third day. On and after the third day the temperature remained under 100°, usually nearly or actually normal; while the pulse fell to 70, between which point and 90 it fluctuated until the second week, when it became and remained normal.

By the fifth day after the operation the *paresis* of the hand and wrist had become almost complete *paralysis*, only the most prolonged efforts of the will *at times* producing slight movements of flexion *when the wrist was extended*. This condition persisted for thirty-six hours, when it rather suddenly improved, coincidently with the subsidence of the elevation and tension (?) of the flap; at the same time the aphasia and seventh and ninth pairs' paralysis began to disappear. About the eighth day, doubtful movement in the thumb was noted, which by the tenth day amounted to distinct but feeble flexion yet the grasping power of the other fingers was strong; while at the end of twenty days the patient had regained all the movements and power of the hand, except that the thumb was weak, and while he could unbutton his vest, he could not *button*

[1] No more of this centre was removed, which is said by Horsley to extend into the ascending frontal convolution, because of the impossibility of locating it by the battery and on account of the belief that much of his trouble was due to the extensive meningeal adhesions which had all been dissected away.

it, *i. e.*, the coarser movements remained while the more delicate were, as was to expected, lost.

The patient's general condition was throughout excellent, the stitches were removed, some on the eighth, the remainder on the eleventh day, except two which had been overlooked, while not one drop of pus formed. Becoming impatient of restraint the man eloped October 28th, twenty-four days after operation. So far no convulsions have occurred, but it is, of course, entirely too soon to decide whether the operation will permanently relieve the paroxysms.

In conclusion, I am inclined to criticise my procedures as follows: I believe that morphia was injurious and conjoined with the ether tended to produce the marked respiratory failure, while it can hardly be necessary in operations for epilepsy in which the excised portions of brain are not usually large and are never deep-seated. Electrical excitation of the encephalon is injurious, especially with the strength of current I was compelled to resort to, and in consequence the desired point once located should immediately be marked and removed, to avoid the necessity for a repetition of the application. Anæsthesia, especially when induced by ether and preceded by morphia, should never be prolonged a moment more than necessary, and should not be pushed to its extreme limits. As a corollary to this, the mapping out of the Rolandic fissure and other points on the scalp should be done the day before, as I did, with some indelible agent, so that neither hurry in determining these all essential points nor *prolongation* of the anæsthesia will be necessitated.

2109 Pine Street, Philadelphia.

THE POLYPNŒIC CENTRE.

Preliminary Note.

By Isaac Ott, M.D.,
of Easton, Pa.

On a hot day animals like the dog are seen to breathe very rapidly in order to keep themselves cool. To this state the name of polypnœa has been given by Richet. In rabbits etherized and the cortex removed, I have found that removal of the corpus striatum and the parts between it and the optic thalamus abolishes the polypnœa, although the external temperature was elevated. If the corpus striatum and the parts adjacent are electrically irritated at an ordinary temperature the respirations are doubled or trebled in number.

This discovery adds another proof that the basal heat centres are the regulators of body-temperature. For upon these heat-centres antipyrin acts to reduce temperature, and through the basal heat-centres septic poison produces fever.

Exact localization will be published hereafter.

MEDICAL PROGRESS.

On the Surgical Aspects of Typhlitis and Perityphlitis.—Dr. William T. Bull, of New York, at a meeting of the Medical Society of London, on November 5th, read a paper on the diagnosis and treatment of typhlitis and perityphlitis from a surgical point of view. For the purposes of a brief summary, he divided these cases into three groups: 1. Ten cases in which abscess was opened by incision through its walls without opening the peritoneal cavity. In these cases the operation was performed within from seven days to six weeks of the commencement of the attack, and was successful in all, thus showing the advantage of the extra-peritoneal operation. 2. Six cases, in which the peritoneal cavity was opened for supposed perforation. The earliest was performed thirty-six hours and the latest five days after the commencement of the attack. Two of these cases proved fatal. 3. This group comprised only a single case, in which the abdomen was opened on the third day in the presence of threatening symptoms. No pus was found and no evidence of peritonitis, but the pelvis was full of old adhesions.

Referring to the fact that the necessity for early operation in threatened peritonitis had mainly occupied their minds, he observed that it was a universal comment in such cases that the operation should have been performed earlier. He said that while they preached early intervention their practice was not always early enough to save the life of the patient. He urged that there were good clinical reasons for preserving the designation of perityphlitis, since the exact nature of the case was not often easy to make out on the living subject. Suppurative inflammation was induced by perforation, the pus being first in the appendix, and later finding its way into the peritoneum, or the pus might burrow through into the iliac fossa and so a secondary abscess be formed. He thought that the intraperitoneal origin and situation of the abscess might be considered as proved by the following evidence: Both the cæcum and appendix were completely invested by peritoneum, and in operations for well-developed abscess, when the thickened walls had been incised, the iliac sac had been opened up and found quite free from infiltration. Dr. Weir had called attention to this, and he had been enabled to confirm his observations.

The general rule of treatment as to opening up purulent collections as soon as detected was one which had met with general approval. The disease sometimes ended in resolution, and even suppuration might be limited by strong adhesions, and thus permit of a safe termination by a timely incision. The first advance was made by cutting down for pus before fluctuation had been detected, thus preventing the possibility of an accumulation of pus Then came the idea that constitutional signs alone might suffice to show whether there was any pus or not. That, however, did not help them in general peritonitis from perforation. Those cases were a source of great anxiety, and would continue to be so until they insisted upon an explanatory operation before general extension of the peritonitis took place.

He preferred to use the terms "spreading" and "circumscribed" peritonitis, as marking the characteristic feature of each variety. Suppurative peritonitis might

be spreading, circumscribed, and intra-peritoneal, or there might be cellulitis with secondary abscess; he would add hepatitis with or without abscess of the liver. The author then recapitulated the symptoms of the disease, insisting on the surgical importance of fever and shivering. In such cases the abdomen and rectum should be frequently examined, tenderness and the presence of an area of dulness indicating pus. The outline of the cæcum might be made out, filled with feces, and that might exist alone or in connection with a less distinct area of induration, and the latter might persist when the former had disappeared. The end of this should be reached in about ten days. The abdomen might then become tympanitic, with debility, loss of appetite, sweating, and marked anæmia. In order to determine the presence of pus under these circumstances the exploring needle was the best instrument. He mentioned that since this plan of diagnosis was introduced he had heard of peritonitis being caused by it; but he urged that, although the use of the needle was not altogether devoid of risk, yet, if proper precautions were taken, the risk was very small.

He then narrated three cases characterized by the disappearance of the pain and the fever after a few days; but the tumor had persisted, and the needle had revealed the presence of pus in large quantities. In all these cases the abscesses were opened with a satisfactory result. At any moment the symptoms of perforation might supervene, even though the general symptoms had subsided. Severe constitutional disturbance, however, was usual, and might be held to justify interference. By the third or fourth day the tumor would be well marked in the right or left iliac fossa, and it was about this time that the needle was likely to prove useful. The more rapid the development of the symptoms the earlier should the surgeon interfere. Exploration in case of doubt was preferable to waiting for unequivocal information. The operation for perityphlitis might be laparotomy or mere incision. In washing out the cavity no solution should be used stronger than 1 in 10,000 of corrosive sublimate or 1 in 100 of carbolic acid. He then discussed in detail the steps of the operation, and read the notes of his principal cases, concluding with the aphorism that the risk of operation was less than the risk of waiting.

Mr. Frederick Treves said that, clinically, one heard a good deal of inflammation of the peritoneal investment and cellular tissue of the cæcum, but observed that no cellular tissue existed round the cæcum. He asked why the cæcum and the appendix should be singled out as liable to take on a form of catarrh which involved such serious consequences. He thought that it could be shown that the appendix played a very prominent part in the production of typhlitis. In seventy per cent. of the cases the appendix was found to be the source of the mischief. Referring to extra-peritoneal abscess, he said it was very difficult to understand how pus originating within the cæcum could find its way outside. As Dr. Bull had pointed out, it was very rare to find pus round the cæcum, except in connection with pus inside the peritoneal cavity. He endorsed the need for rest, etc., but added that many people would hesitate as to the early employment of the needle. Personally, he considered the procedure somewhat risky. He thought it was exceedingly bad practice to ligature and cut off the appendix, which, after all, was an integral part of the intestine. When removed, the edges ought to be united by a continuous suture, or joined to the parietal peritoneum. Alluding to the fact that typhlitis was very apt to recur, he advocated operating after the second attack, and removing the appendix, which was the cause of the trouble. He mentioned such a case in which after the third attack he had operated, and found the appendix twisted in consequence of the non-development of its mesentery, and acutely distended with mucus. Since the operation there had been no recurrence of the malady, and the patient might be looked upon as cured.

Dr. Weir, of New York, said that, according to some statistics which he had collected of a hundred patients operated on after the eighth day, seventeen per cent. had died, whereas of those operated on before that date, only eight per cent. had succumbed. He looked askance at the catarrhal theory, and, indeed, at the stercoral inflammation. He thought the practice of giving purgatives and enemata was all wrong, seeing that the trouble was due, in the majority of cases, to perforation of the appendix. Perforation of the cæcum was rare, occurring only three times in 300 cases. Last year he had collected notes of a hundred necropsies of typhlitis, and in only six cases was the cæcum filled with feces. He quoted some statistics, according to which the mortality was forty per cent. under the old method of treatment, and only sixteen per cent. since purgation had been abandoned. Reverting to the necropsies, he said that in twenty-two cases the abscess was localized, and in thirty-two cases there was abscess *plus* peritonitis, while in fifteen cases there was general suppurative peritonitis. In only four cases was there any extra-peritoneal disease. About fifteen abscesses out of sixty-seven burst into the peritoneal cavity. The needle was a good means of arriving at a diagnosis provided one fell upon the pus, but the not finding pus was no proof that pus was not present. In some cases in which general suppurative peritonitis was suspected, no tumor could be felt, and in such cases he thought it was advisable to operate.

Mr. Knowsley Thornton said that no surgeon of the present day would hesitate to operate when pus had been recognized to be present. With reference to washing out in these cases, he said that he never found it necessary to do this, and he thought that good drainage was all that was required. He alluded to the troublesome sinuses which were apt to form, the cure of which was often impossible. He mentioned the case of a lad aged seventeen, who had suddenly developed symptoms of typhlitis, for which a purgative and enema were given; a day or two afterward he suddenly became collapsed, and when they operated they found the appendix standing upright, distended, black, and gangrenous, together with the adjacent portions of mesentery. The patient lived for about a week after the operation and then died, probably from an extension of the gangrene along the mesentery. Another case was that of an aged gentleman with symptoms which pointed to typhlitis and a large dull mass on the right side. The question was as to whether this mass was malignant or not. He determined to puncture, which he did with a long, narrow knife. He found at once that he had to do with a solid mass, and desisted from anything further, under the impression that it was a sarcoma. Only a little bloody serum

exuded. Curiously enough, that patient recovered after the puncture and got quite well. He said he had often seen Sir Spencer Wells ligature and cut away the appendix, and he had never seen any ill results follow. Latterly, however, he had taken to bringing the edges together by means of a continuous suture, which, on the whole, was perhaps preferable.

Dr. Bull, in reply, observed that he had purposely only dealt with the surgical aspect of the disease. He doubted whether patients could often be persuaded to undergo any operation after an attack had subsided, as suggested by Mr. Treves. He had never met with any accidents in the use of the exploring needle himself. He said that no one would hesitate to wash out fecal matter, and he asked why they should hesitate to wash out pus that smelled as bad as feces, and was as injurious in its effects. He made his incision from the middle of Poupart's ligament vertically upward, and even a little up outward, and he much preferred this to the median incision.—*British Med. Journal*, Nov. 10, 1888.

Creolin, Iodoform Ointment, and Antipyrin in Ophthalmic Practice.—Mergl, in the September number of the *Centralbl. für Augenheilk.*, reports the following as observed at the eye department of the hospital at Pressburg: creolin was used in one per cent solution in acute and chronic catarrhs of the conjunctiva, in trachoma, and in ulcerative conditions of the cornea. In acute catarrhal conjunctivitis a one per cent. solution was applied twice daily to the conjunctiva of the lower lid; in most cases the redness and swelling disappeared in one or two days, and the secretion diminished but did not entirely disappear; it is thus better after two or three days to use one per cent. solutions of sulphate of copper or zinc. Creolin afforded no good results in chronic conjunctivitis. In four cases of trachoma, however, the remedy appeared to act as a specific: the redness and swelling disappeared in two to four days, the purulent secretion in one week, and the granulations in two to three weeks. In other cases, the redness and swelling disappeared, but the granulations would not submit. Finally, exacerbations occurred in some cases. The author, therefore, now begins the treatment of acute trachoma with creolin; if improvement does not proceed, nitrate of silver and sulphate of copper are used. In trachoma with pains or corneal ulcers, creolin is an excellent remedy: the ulcers clear up and the pannus recedes; in combination with atropine, it causes the ulcers to heal. Although creolin frequently cures corneal ulcers, it sometimes fails. On the other hand, the ten per cent. iodoform-vaseline ointment used by Kauka is of incalculable value, particularly when abscesses have formed in the cornea and chambers. A gauze pad, covered with the ointment, is laid over the closed eyes and fastend with a pressure bandage. Pain is diminished, the ulcers clear up, and the abscesses disappear in two to three days. Upon the recommendation of Aldor, antipyrin has been used to clear up corneal opacities. As the introduction of the powder is painful, cocaine is first instilled and then the cornea is dusted with antipyrin. After the flow of tears has ceased, which occurs in a few minutes, the cornea is rubbed through the upper lid. The results have been good. In the case of a child, having extensive opacities of both corneæ following smallpox, this procedure was adopted. After three months the child, formerly able to see nothing, could walk alone and recognize small objects, such as a watch and coins. Similar results were obtained in two other cases.—*Wiener medizin. Presse*, No. 41, 1888.

Splenectomy.—The operation of removing the spleen was performed recently by Surgeon W. K. Hatch, at the Sir J. J. Hospital, Bombay. The patient was put under chloroform, and Dr. Hatch, with the assistance of Drs. Banks, Manser, Dimmock, and Galleghar, removed the spleen successfully. Collapse followed, and it was deemed necessary to perform transfusion of blood. A Parsi student, Mr. Hirji J. Dady Sett, of Grant College, volunteered to give his blood in order to save the life of the patient, and several deep incisions were made on Mr. Dady Sett's right hand. But Mr. Dady Sett fainted, transfusion was not carried out, and Bhaiaji died within twenty minutes after the operation. This operation is the second of its kind in Bombay. The first was performed by Dr. Blanc, some ten years ago, and it, too, proved unsuccessful.—*Indian Medical Gazette*, September, 1888.

Cannabin in Basedow's Disease.—Valeiri, of Naples, has used cannabin in three cases of exophthalmic goitre with good results, after other measures had failed.

℞.—Cannabin . . . . . gr. ivss.
Sacch. lactis . . . q.s. ut ft. pil. No. v.
S.—To be taken during twenty-four hours.

Or,

℞.—Cannabin . . . . gr. ivss.
Aquæ destil. . . . . ℥iij.
Syrup aurantii floris . . ℥j.—M.
S.—To be taken in teaspoonful doses during twenty-four hours.

A decoction of two to four parts to the one hundred, or doses of fifteen to thirty minims of the tincture may be given.—*Wiener medizin. Presse*, No. 41, 1888.

Acetic Acid as an Antiseptic.—In 3-5 per cent. solutions, acetic acid has given favorable results as an antiseptic in gynecological practice. It has several advantages, in that it is not poisonous, like carbolic acid, it is hæmostatic, and becomes absorbed readily. It does not injure instruments like the bichloride of mercury.—*Journal de Médecine de Paris*, October, 1888.

Internal Administration of Creolin.—Heller (*Deutsche medicin. Wochenschr.*, No. 47) holds that for the thorough disinfection of the cavity of an empyema creolin (1 to 5 : 1000) in lukewarm water is to be preferred to other remedies, on account of its non-toxic and unirritant action in connection with a powerful antiseptic influence; also in putrid bronchitis, in a strength of 1 to 500. In these cases it acts admirably, while in simple, non-putrid catarrh of the bladder, ordinary measures will suffice. In disorders of the stomach and intestines the author thinks that creolin will not be superseded by another remedy. Its antizymotic action in the various fermentative and putrefactive processes in the stomach and intestines is most conspicuous. Its non-toxic quality prevents any anxiety as to an overdose. It is given for meteorism, in typhlitis, for catarrh of the small intestine, for habitual atony of the intestine with constipation

and especially in typhoid fever—it being hoped in the last that the removal of the meteorism will prevent threatened perforation. The remedy has, further, been useful in the flatulency accompanying acute and chronic intestinal catarrh, in dilatation of the stomach, combined with lavage, to overcome the development of gas, in acute and chronic diarrhœa with liquid evacuations. Four to fifteen grains are given three times daily one hour after meals. On account of its disagreeable tarry taste, the remedy is given in gelatin capsules. No unpleasant complications have been noticed even from large doses. In a case of tænia solium, and in one of oxyuris vermicularis its antiparasitic action was manifested.—*Correspond. Bl. f. Schweiz. Aerzte*, November 1, 1888.

Cancer by Skin Grafts.—The *Centrlblt. f. Chirurgie*, 1888, p. 726, mentions the following case, in which carcinomatous nodules were transplanted from one breast to the other by means of skin, and which possesses considerable interest both pathologically and therapeutically. Having determined that a case in which the breast had been previously removed for cancer was too far advanced to permit of a second operation, Hahn obtained the patient's leave to ascertain if it was possible to inoculate the skin over the second breast by pieces derived from the affected skin over the first. Numerous small cancerous nodules were, on April 9th, cut off as evenly as possible with grafting scissors, and transplanted by Reverdin's method on the sound breast, after skin on the selected spot had been removed so as to leave an ulcer for their reception. On May 1st the transplanted pieces had taken firm root, and the ulcer was completely covered with epidermis. On May 19th at the edge of the pieces of skin some small projecting nodules appeared about the size of a millet seed; they gradually increased in dimensions, and by June 26th had reached the size of a cherry-stone. Four days later the patient died. On microscopic examination of sections of the transplanted skin, all of which gave a characteristic appearance, it was evident that the main mass of the tumors consisted of a well-developed connective-tissue stroma, containing irregular masses of epithelial cells inclosed in it. These masses had clearly insinuated themselves into the healthy tissues, which were on all sides beginning to be invaded by the epithelial nests. The above related facts seem to prove clearly that carcinoma can under suitable conditions be inoculated upon healthy tissues; and the practical deduction to be drawn from this circumstance is that great care should be exercised during an operation to avoid taking up pieces of cancerous tissue in the forceps and leaving them adherent to the edges of the wound, where they may afterward find a permanent resting-place.—*The Practitioner*, November, 1888.

Prevention of Diseases of the Joints.—In the following *résumé*, Dr. Leroy Hubbard gives his opinion as to the best method of preventing joint diseases in children:

A careful inquiry by the surgeon into the hereditary history of each family which he may have charge of; and if a well-marked history of hereditary disease, especially tuberculosis, is found, a warning should be given to the parents of the dangers to which the children are exposed.

Instruction in regard to hygiene, diet, etc., with the endeavor to keep the nutrition of the children up to the highest point until they have passed the period at which they are most liable to contract a joint lesion, viz., the period of puberty.

When tuberculosis is present in a family, either as phthisis pulmonalis, or a joint lesion with an abscess, all sputa or discharges should be destroyed or disinfected; and healthy children should be brought as little as possible in contact with the sick. In this way the risk of direct contagion may be reduced to a minimum.

Instruction should be given in regard to the importance of any traumatism of a joint or the parts near it, however slight it may be. After such an injury, absolute rest of the joint should be insisted upon until all evidence of inflammation has subsided and the function of the part is perfectly restored.

The prohibition of all sports or exercise which bring repeated traumatism upon one joint. Young children should not be allowed to go up and down stairs frequently.

After one of the acute exanthematous fevers, a considerable period should elapse before active exercise, such as running, jumping, or long walks is allowed.—*Med. Record*, Nov. 10, 1888.

Salicylate of Mercury in Syphilis.—This new drug, an amorphous, white powder, without taste or odor, is obtained by precipitation, when an alcoholic solution of salicylate of potassium is added to an aqueous solution of nitrate of mercury. Szadek has used it extensively in gonorrhœa, and, while he finds it has marked antiseptic properties, he thinks it does not materially shorten the course of the malady. His formula is:

R.—Salicylate of mercury . . .	gr. ij.
Sodii bicarb.	gr. xv.
Aquæ	℥viij.—M.

For injections.

In primary and secondary syphilis he combines it with subnitrate of bismuth in the form of ointment and applies to the chancre. Internally he gives it in minute doses. In twelve cases he administered it subcutaneously, mixed with gum arabic and distilled water. He concludes that it is as good as any of the preparations now in use, and does not cause local irritation or septicæmic poisoning.—*Journal de Médecine de Paris*, October, 1888.

Ingluvin for Hyperemesis Gravidarum.—As a result of personal experience, Dr. Julius Papp recommends ingluvin for the hyperemesis of pregnancy. In No. 40 of the *Pest. med. Chir. Presse*, he reports the following case: A thirty-two year old primipara, early in her pregnancy, vomited fifteen to twenty times daily, so that she could retain nothing on her stomach. All the usual remedies were tried, but they failed. Subnitrate of bismuth with powdered opium afforded temporary relief. The temperature rose and diarrhœa set in, so that the patient was unable to sit up in bed. The induction of abortion was thought of as a last resort. In the meantime ingluvin was proposed. Seven and a half grains were given morning, noon, and evening, a half hour before meals, with two tablespoonfuls of a one per cent. solution of hydrochloric acid after meals. The vomiting improved after the first dose. The remedy was continued for three

weeks. Ingluvin was also used in dyspeptic conditions and proved superior to pepsin.—*Wiener medizin Presse*, No. 42, 1888.

Baked Water.—M. Tellier finds that boiling water is not destructive to certain microbes. Boiling also deprives it of many of its salts, and gives it an insipid taste. Hence, he recommends that it be baked at a temperature of 302° F. The salts are not dissipated by this method, the water is palatable and entirely free from microbes. He places the solution in a closed metallic jar, which in turn is placed in a bath of water saturated with salt, and heat applied. At the bottom of the metallic jar is an opening with a plug, by removal of which the pure water can be drawn off, and any organic matter retained in a fine filter guarding the outlet.—*Lyon Médicale.*

Injection in Hemorrhoids.—Dr. J. Earl Dennis, of Falun, Kansas (Lauphear's Kansas City *Medical Index*), gives the following prescription for injection in hemorrhoids:

R.—Olei olivæ	℥ij.
Olei ergotæ	℥ij.
Sulph. cocaine (five per cent.) .	℥ij.
Acidi carbolici (pure) . . .	℥iss.—M.

The ingredients should be added in the order named, observing to dissolve the acid (by setting the container in a bucket of very warm water) before adding it to the others. From three to ten drops should be injected into the centre of the pile tumor.

Rosenberg on the Treatment of Laryngeal Phthisis.—In the *Therapeutische Monatshefte*, Hefte 7 und 8, 1888, Dr. Albert Rosenberg returns to the important subject of laryngeal treatment by menthol. He first relates briefly a case of spontaneous recovery from this disease which was under the care of Prof. Fränkel. The ulceration which was situated on the false vocal cords healed with the formation of a membranous band, extending across from the lower surfaces of the ventricular bands and leaving only a round opening of the size of a penholder (*sic*) through which respiration took place. There were no signs of syphilis, and bacilli were found in the sputum.

After reverting to the various local applications recommended in laryngeal phthisis, the author gives a table showing all the cases treated with menthol at the Berlin University Polyclinic, from June 1, 1885, to February 1, 1888. Of the fifty-seven cases enumerated only about twenty were available, chiefly from the patients attending irregularly and staying away after having been seen only a few times. All of these twenty, however, improved under treatment. In nine, actual recovery took place—*i. e.*, the infiltrations disappeared, the ulcerations cicatrized, and existing subjective troubles vanished. In all the cases included in the table the diagnosis was confirmed by the presence of bacilli. The most rapid in healing are the ulcerations, but of these the most obstinate are those on the posterior laryngeal wall. Infiltrations are more resistant, but they often diminish gradually. Commencing perichondritis on the arytenoid cartilages often disappears entirely. The duration of the treatment is from four weeks to four months.

A comparative test of the action of menthol and of lactic acid was made in a case of tubercular ulceration of the velum palati, one-half of the palate being painted with either drug. The menthol side healed more rapidly, and was much less painful than where lactic acid was applied.

In regard to the important question of recurrence, Dr. Rosenberg reports on the present condition of some of the patients mentioned in his previous communication. In one case, in which the patient ran to excess *in baccho et venere*, there has been recurrence; in eight others the ulcers have remained healed, five since March, May, or June, 1886, and three for the period of one year. One patient, who came with extensive laryngeal ulceration and advanced disease of the lungs, died after about six weeks' treatment. The preparation shows, on the posterior wall, an ulcer the size of a bean completely cicatrized, in addition to another unhealed, to which from its direction, the menthol could not be so well applied. With these exceptions, all the patients he has had an opportunity of watching, have remained healthy.

In phthisis pulmonalis he recommends tracheal injections of a ten per cent. solution of menthol in olive oil, combined with frequent inhalation of the drug, by means of a special inhaler, which vaporizes the menthol and allows it to be inhaled at a temperature between 113° and 122° F. He cautions against the use of any but Asiatic menthol, and considers that this drug is as efficacious as lactic acid, while at the same time it is more easily applied.—*London Medical Recorder*, October 20, 1888.

Treatment of Eclampsic and Uræmic Convulsions in Children.—Jules Simon, in *Gaz. méd. de Paris*, 1888, No. 9, p. 99, claims that in the eclampsia of children special attention should be paid to the secretion of urine. As long as the illness lasts the amount of urine will be found to be small; should it, however, increase, we may look for an early recovery. Should the urine increase, but the convulsions not subside, it must not be taken for an unfavorable symptom, as they will, nevertheless, soon disappear. From a prophylactic point of view the dyspepsia of children is of the utmost importance. To prevent all excitement they should be isolated. Should digestive disturbances be due to an eclampsic attack, a rectal injection of glycerine and water should be administered, or the stomach emptied by vomiting, which may be induced by tickling the throat, or, if the child be unconscious, by administering small doses of ipecac. Should the attacks still persist, chloroform or ether inhalations, chloral or mustard baths are indicated. As soon as the attacks subside, and the young patient is able to swallow, bromide of potassium should be administered. Should the paroxysms show signs of exhausting the little patient, a large blister to the nape of the neck may be applied, and allowed to remain until pus has formed. If the attacks are due to uræmia, venesection is indicated (for very small children, leeches may be applied to the mastoid process; should they have reached the age of five or six, cupping must be resorted to in the region of the kidneys); prolonged diaphoresis is also of service.—*Centralbl. für klinische Medicin*, Oct. 1, 1888.

Application for Burns.—As an application for burns, the *Centralbl. für Thérap.* suggests the following:

R.—Ol. olivæ	6 parts.
Salol	1 part.
Aquæ calcis	6 parts.—M.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,
PER ANNUM, IN ADVANCE . . . . . $5.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

PHILADELPHIA.

SATURDAY, NOVEMBER 24, 1888.

CALOMEL AS A DIURETIC.

ABOUT two years ago JENDRÁSSIK called attention to the value of calomel as a diuretic in the dropsy of heart disease, and the observations which have gradually accumulated show that his conclusions as to the efficacy of this drug were well founded.

Two interesting papers upon the subject appear in the *Deutsches Archiv für klinische Medicin*, Bd. xliii. Heft. 2 and 3. Stintzing, from Ziemssen's Clinic, reports a number of cases showing the effects of calomel in cardiac and in other forms of dropsy. In normal individuals the diuretic action appears to be very slight. In eighteen cases of dropsy associated with various forms of heart disease effective results were obtained in almost every instance, the urine increasing, within a few days, threefold or four-fold in quantity. Thus, in case 13, dilatation of the heart with high grade of anasarca, the urine, which on the fifth day was 650 c.cm., rose on the eighth day, after three days' action of calomel, to 5000 c.cm. In other cases the effects were quite as striking; in many instances the calomel acted on the bowels, producing copious watery discharges. It seemed also to benefit the general condition, as under its use the appetite improved and the patient slept better. In serous exudations, pleurisy and pericarditis, the drug did not appear to have any special influence. Increase of urine is usually noticed from the second to the fourth day. The polyuria continues for, at least, three days, usually for four or five; seldom for so many as ten days. The largest daily quantity in this series was somewhat over 8000 c. cm.

In the same number of this journal, BIEGANSKI reports equally good results in cardiac dropsy. The diuresis occurred, as a rule, two or three days after the administration. His statements are practically in accord with the observations of Stintzing and Jendrássik.

It is usually administered in small doses (0.2 gm.) three times a day. If the diarrhœa is profuse, it may be combined with opium in the form of Dover's powder.

Bieganski found the diuretic action most marked after subcutaneous administration. The action after inunction seemed very slight. The small doses do not appear to be effective; the action is much more marked in medium sized and larger doses. Salivation, stomatitis, diarrhœa and colic are occasional untoward effects.

Bieganski believes that the diuretic action of mercury depends on the direct stimulation of the renal tissue. Jendrássik and Stintzing hold that the drug favors the absorption of the transudate from the tissues.

Calomel cannot be substituted for digitalis in cases of cardiac failure; but when given with it, we certainly see the most beneficial results. The good effect of Niemeyer's pill, so much used in this country in cases of cardiac and hepatic dropsy, may be attributed to this combination.

BOARD OF HEALTH RELATIONS TO TYPHOID FEVER.

FOR a few years typhoid fever has, in Brooklyn, been managed sanitarily as one of the contagious diseases. The Board of Health has construed the rules to require a quarantine of the patient, an exclusion of children from school, and private and prompt funerals in the cases of death by fever. The Kings County Medical Society, after a full discussion, passed a nearly unanimous vote declaring these restrictions to be onerous and unnecessary, and recommending the Board to modify the rules. This has recently been done, and the medical profession of Brooklyn have been notified by circular, under date of November 1st, that the rule requiring the quarantine of typhoid cases will not be enforced. The rules that require the reporting of cases by physicians remain in force in order that the fever-records of the city may be continuously kept, and

that the drainage inspection of infected localities may be facilitated. According to the present views of sanitarians, these two points of oversight, last mentioned, appear to embrace all the official duties of our boards of health in respect of fever; if we except one other point of an advisory nature, which may with profit be added, namely, the promotion of a true and thorough disinfection of the excreta of the fever-sick, and, further, in the case of families of the less-favored class, all of whose means are needed for the purchase of proper diet and medicine, the supplying of potent disinfectants at the public cost. In not a few cities, having a competent health organization, this distribution of disinfectants is in constant practice in connection with the management of the infectious diseases.

THE profession has been shocked by the intelligence of the sudden death, last Sunday afternoon, of Dr. Henry B. Sands. He had left his home only a few hours before in his usual health and cheerful spirits. Although he had not yet entered upon his sixtieth year, Dr. Sands had achieved a position in the front rank as a surgeon and teacher. Conservative and cautious in his methods, though he was, there were few operations in the field of surgery which were not familiar to him. It will be remembered that he was one of the consultants in the case of General Grant, and in that of ex-Senator Conkling it was he who performed the operation which was to give the eminent patient his last chance for life.

The death of Dr. Sands will be seriously felt in the surgical circles of New York, where, as the trusted consultant and wise teacher, he occupied a position that is not readily filled. A sketch of his career will be found n another column.

DR. J. WILLISTON WRIGHT has resigned the Chair of Surgery in the University of the City of New York, and we learn that Dr. Lewis A. Stimson will succeed him.

THE Southern Surgical and Gynecological Association will hold its annual meeting at Birmingham, Alabama, on December 4th, 5th, and 6th, under the Presidency of Dr. W. D. Haggard, of Nashville, Tennessee.

THE Pasteur Institute was opened at Paris on November 14th, by President Carnot in the presence of numerous high officials and eminent visitors. Pasteur received a popular ovation when he advanced to deliver his address. He spoke chiefly of his indebtedness to those who had aided him in the organization of the Institute.

DR. T. GAILLARD THOMAS has resigned his position as surgeon to the Woman's Hospital in the State of New York, and it is stated that the Medical Board has requested the Board of Governors not to fill the vacancy for the present.

THE first of a series of lectures on bacteriology by Dr. G. M. Sternberg was delivered at the Hoagland Laboratory, Brooklyn, last Saturday.

DR. GAMALÉIA has gone from Odessa to Paris, to demonstrate to the Académie des Sciences his method of preventive cholera inoculation. It is his purpose to visit India in March to prove the efficacy of his method on man.

AN International Congress for Criminal Anthropology will be held in Paris from August 4 to 8, 1889. Prof. Brouardel will be honorary president.

THE French War Department proposes to furnish its officers and soldiers with a belt containing a linen bandage ten feet long, two antiseptic compresses, and a safety-pin.

WE are happy to learn that the statement which appeared in our issue of last week in reference to the prevalence of typhoid fever in Montreal is incorrect, and that there does not exist there this autumn any unusual amount of typhoid, and much less than at the corresponding period of last year.

DARTMOUTH MEDICAL COLLEGE, last Tuesday, conferred the degree of M.D. on twenty-six graduates.

SOCIETY PROCEEDINGS.

PHILADELPHIA ACADEMY OF SURGERY.

Stated Meeting, November 5, 1888.

THE PRESIDENT, D. HAYES AGNEW, M.D., IN THE CHAIR.

DR. C. B. NANCREDE reported

TWO SUCCESSFUL CASES OF BRAIN SURGERY.

(See page 584.)

DR. W. W. KEEN said that there are several points to which he should like to refer. In the first place, in regard to the history of this case. He was present at the operation of Dr. Steinbach. The button of bone accidentally escaped attention and lay on the chest of the patient for

perhaps twenty minutes before it was placed in the antiseptic solution. The bone was also an unfavorable specimen, in that it was so thick. There was very little diploë, and the circulation was, therefore, probably defective. He understood that the man had hemorrhage from the scalp the night after the operation, requiring reopening of the wound. It is remarkable that the man had no trouble with this piece of bone until ten weeks afterward. The operation was done by Dr. Steinbach May 7, 1888, and the patient was admitted in the latter part of July to St. Agnes's Hospital, complaining of headache, and with a small fistulous opening at the seat of operation with a considerable discharge of pus. This, he stated, had appeared only a week before from the rupture of a small abscess. The probe disclosed dead bone. All that he did was to reopen the wound and remove the bone, which he found white and bare lying in a bed of granulations. At Dr. Steinbach's operation the dura was not opened. He removed the piece of bone which was loose, provided for drainage, and the man recovered in a few days.

Another point to be noted is, that after each of these operations the patient has had no attacks for a long while. And this emphasizes the statement of Dr. Nancrede, that at the present time we can form no conclusion with reference to the ultimate result. We know that excision of a scar, or any other surgical procedure in cases of epilepsy, will frequently arrest the attacks for quite a long period. It is, therefore, desirable that we should, if possible, have reports of these cases one, two, three, or four years after the operation.

The necessity for the careful study of the convulsive attacks which was made by Dr. Nancrede, was emphasized by a case at present under his care. A young girl was brought to him not long since by Dr. Mills. The statement of her mother was, that she had had a large number of attacks, all, with the exception of four, beginning in the ring and little fingers of the right hand. This was followed by flexion of the wrist, the elbow, and finally of the shoulder, and by that time the attack became general. He placed the girl under careful observation in St. Mary's Hospital. She has had three attacks in addition to one which was distinctly hysterical. Only one of the attacks corresponded, and that only partially, to the description given by the mother. On Saturday she had one in which the hand was exactly in the position of the hand used to indicate in printing, with the forefinger extended, and the other fingers flexed. He could not think but that at the present time in our anxiety to relieve these cases we are in danger of hastily reaching conclusions based on the reports of relatives, rather than upon the observation of those not related to the patient, and whose sympathies are not involved, and who are trained observers. He should, therefore, not think it proper to operate in a case of epilepsy until the patient had been observed in a number of attacks by a trained observer. He had three other cases now under observation for the same purpose. This is a point that cannot be too strongly insisted upon. If we do ill-judged operations upon the brain, we are going to bring cerebral surgery into disrepute, and shall have a series of failures, in which more or less marked paralysis or paresis is present, and where injury, instead of benefit, will be the result.

He understood Dr. Nancrede to state that electrization of the white matter underlying the thumb centre produced only very slight movement of the thumb. In the third case that he reported at Washington, in which he excised the centre for the wrist, it was absolutely different. In that case irritation of the cortex produced extension of the wrist, and when this cortical centre was removed, the application of the poles to the underlying corona radiata was followed by the same movements.

He was not at all certain that Dr. Nancrede is right in supposing that strong currents may do injury to the brain. This is a matter to be borne in mind, and investigated with care. He was surprised at the strength of current required in his case. A current that would move the muscles of his hand had no effect when applied to the cortex. This gives rise to the query whether or not, in case the centre cannot be at once removed, it could not be marked in some way, so that having been once found, it will not be necessary again to apply the current. The point might be fixed with the aniline pencil, or by a nick in that part of the brain. This would do no harm, as it would be in a region which we intend to excise.

Dr. Morris J. Lewis said he was astonished at the strength of the faradic current required in Dr. Nancrede's case. No effect was produced by the application to the cortex until the current was so strong as to produce powerful and painful tetany of his first dorsal interosseus muscles, the skin being wet and the metal electrodes placed upon it. The battery was one of Flemming's largest faradic batteries, in perfect order, one-half of the secondary coil being used, with the graduating tube half withdrawn. There was an almost complete failure to obtain a reaction from application of the current to the white matter, this being possibly due to the fact that it was difficult to find the exact spot on the cortex, as a displacement of the electrodes of one-sixteenth of an inch caused the movement to cease. He was uncertain whether the convulsion which came on during the operation was due to the application of the current or simply happened to come on at that time. He thought, in future, that it would not be well to apply such strong currents any more than is absolutely necessary to localize the spot to be excised.

Dr. John B. Roberts desired at this time to report a similar case operated on about six weeks ago. The patient was a child two and a half years of age, referred to him by Dr. Mills, with the history of having been struck on the head early in infancy with a heavy clock. No scar was found. There was no evidence of injury of the scalp and no indentation of the skull. The child had the appearance of one with limited intelligence, but its youth made it impossible to determine how much brain capacity there was. The spasm, which occurred frequently during the day, was located in the left shoulder, the left upper arm, and head. After a good deal of discussion, it was decided to be a proper case for exploratory trephining, with excision of the centre or not, as would appear advisable. Drs. Keen, Mills, Nancrede, and some others were present. There was no difficulty in restraining hemorrhage from the scalp by the use of Esmarch's flat band. He applied the trephine about one and a half inches in front of the Rolandic line and a little to the right of the median line. He first used a two inch trephine and subsequently a one and a half inch trephine, the one cut slightly overlapping the other, and then removed on one side the little spur by means of the gnaw-

ing forceps. Immediately under the bone there was some adhesion of the dura. Opening the dura, the pia was found so œdematous that it could be pitted by pressure, like the leg of a man with dropsy from Bright's disease. Between the pia and the dura there was a thin membrane supposed to be a false membrane, possibly the result of inflammatory action, or from an old hemorrhage.

The poles of the battery were applied, but no response was obtained, although the current was made quite strong. The opinion which he expressed at the time was that this was probably due to the large amount of fluid in the pia. When the fluid was drained off by a snip made by the scissors the convolutions became distinct; but there was nothing to indicate the necessity for further operation and the wound was closed. Healing took place perfectly by first intention except at two points. One of these was at the exit of the catgut. A discharge of cerebro-spinal fluid from these openings kept up for two weeks or so. There had been only three convulsive attacks since the operation, when he last saw the patient. They were within the first forty-eight hours after the operation and were slight. What the lesion was and what he accomplished he was unable to say.

There are some points which have occurred to him as the result of this and other operations. The first is with reference to the trephine. We are all in the habit of using the trephine with the conical crown. This is objectionable since we have learned that it is desirable to preserve the disks of bone. With the conical trephine, especially in a thick skull, the groove formed between the edge of the disk and the rest of the skull is very wide. He saw no reason why we could not use a thinner trephine. The objection made to this suggestion by an instrument-maker was that this would cause slits between the teeth and weaken the instrument. He thought, however, that if the trephine is kept sharp, it does not require much force to cut through the skull, and such weakening would not be objectionable.

The centre-pin of the trephine is difficult to clean. This has led him to suggest that in place of the centre-pin we insert into the trephine a close-fitting solid block, with a short centre-pin projecting from its lower face. After the groove was sufficiently deep the plug could be dropped out. He thought that Dr. W. B. Hopkins once suggested something of this kind, his object being not cleanliness, but the prevention of the perforation of the dura with the projecting pin. In his next operation he proposes to leave the periosteum on the disk so as to give him something by which he can stitch the disk in position. He found considerable advantage in allowing one of the spurs separating the two openings to remain, as it gave more stability to the reinserted disks of bone.

DR. WILLIAM HUNT asked whether the replacement of the button of the bone is not an unnecessary refinement not adding to the success of the operation if it succeeds, but accompanied with risk of the failure of the whole object of the operation by necrosing and thus requiring reopening of the wound? Does anyone know of any accident or untoward event following leaving out of the piece of bone in ordinary trephining? He could conceive of cases, especially in the class we are considering, in which leaving out the disk of bone would be of advantage by relieving pressure. Ambrose Paré tells us, in referring to the silver plate quacks, that the brain will not tolerate so much as a hair, in the shape of a foreign body, and what else is even a small particle of necrosed bone?

DR. W. W. KEEN had the pleasure of seeing Dr. Roberts's operation. The false membrane of which he spoke was very distinct. He had seen quite a number of operations upon the brain besides those which he had performed himself, and had freequently seen the œdematous condition of the pia to which reference had been made. He was at first disposed to regard it as a normal condition, but he now considers that this is really an abnormal condition of the cerebral membranes. The relief which is obtained by getting rid of this œdematous condition, is possibly one of the means of effecting good. This is rather curious, if it be a fact, for von Bergmann has made a point that in operations upon the brain, especially where large portions of the skull are removed, the consequent œdema is one of the barriers to such operation, especially in the removal of large tumors.

He agreed with Dr. Roberts that the little spurs of bone should be saved where it is possible to do so. He did not recall in his own experience any case that would enable him to answer the question of Dr. Hunt, but he thought that the skull would serve its purpose better if it could be reproduced in its entirety rather than by allowing it to remain with a large aperture. He saw that day a case in which, from the explosion of an emery wheel two years ago, a large portion of the frontal bone was removed. The patient is now suffering with epilepsy If due care be exercised, he thought that there will be no trouble from replacing the bone. He thought that the case of a central block instead of the pin, may be an admirable device. There is great difficulty keeping the centre-pin and the inside of the trephine clean. There is also a great deal of difficulty with the set screw. The use of a little shoulder above the point of the pin he adopted in a new centre-pin which he recently had made. Some time ago he consulted an instrument-maker with reference to this large waste of bone caused by the conical trephine. While the adoption of the suggestion of Dr. Roberts might not weaken the instrument too much, yet in the larger sized instruments there would be danger of breaking. The method which Mr. Horsley has recently adopted seems to have some advantages. He now removes a button an inch in diameter, which gives him the thickness of the skull. Then with a Bonwill engine he makes his incision not going quite through the bone. He next with bone pliers readily divides the remainder of the bone. This method saves time and the groove cut in the bone is very narrow. In one case on which he (Dr. Keen) operated last spring, he removed the membranes, but he replaced the button of bone and attached it to the scalp; he completed the centre-pin indentation into a perforation and made a second opening near the edge of the button of bone. By means of a ligature passed through the button and the scalp and tied on the outside of the scalp, he obtained complete union.

DR. JOHN B. ROBERTS said that some time ago he made a number of experiments with the flat burr of Bonwill's engine. He made openings of various sizes and shapes. This will cut as long as it is in contact with bone, but it will not injure the dura mater.

DR. NANCREDE said that it is in the highest degree probable that the membrane found in Dr. Roberts's case was due to the extravasation of blood. The blood pig-

ment, etc., become absorbed, vessels form, and in the course of time the appearance described by Dr. Roberts will be presented. He saw no advantage in leaving the periosteum except for suturing purposes. The periosteum depends for its osteogenetic power on cells identical with those lining the Haversian canals, which are continuous with the medulla. He did see an advantage in leaving the periosteum upon the flap, as its inner layer probably contains some osteoblasts which may be sufficient to carry on the nutrition of the bone beneath. He thought that in many cases there is a manifest advantage in putting back the pieces of bone, perhaps not so much in epilepsy as in trephining for other conditions. If we can secure equable pressure, such as will be obtained from a large piece of bone, the risks of hernia-cerebri are lessened.

The objection to Hopkins's plug for the trephine, so far as antisepsis is concerned, is that it contains a spring difficult to clean; it also makes the instrument unnecessarily heavy.

THE GYNECOLOGICAL SOCIETY OF CHICAGO.

Stated Meeting, September 28, 1888.

The President, Henry T. Byford, M.D., in the Chair.

Dr. Henry P. Newman read a paper entitled

ALEXANDER'S OPERATION, WITH REPORT OF CASES.

His object in presenting a necessarily brief report of seven recent cases of Alexander's operation was: first, to invite the consideration of the Society to the operation of shortening the round ligaments for uterine displacements; and secondly, to refer briefly to the manner of operating, suggesting some modifications in the *technique* which have been applied in five consecutive cases.

The operation was given to the profession more than six years ago by Wm. Alexander, of Liverpool. Since then it has been performed upward of three hundred times, as reported by different operators, with very satisfactory results. Notwithstanding these promising reports, and all that has been said and written by those who are familiar with the operation, and convinced of its utility, there has been much adverse criticism from high authorities in gynecological literature. To this criticism must be attributed largely the tardiness with which the operation has been received and recognized as a therapeutic measure.

It was early objected that the operation was unscientific, upon the grounds that it was not the round ligaments, but chiefly the sacro-uterine ligaments, which were at fault. To this, Dr. Henry T. Byford, in a lecture on the operative treatment of retroversions, very aptly replied: "This objection is rendered untenable by the fact that when we draw the fundus forward, we restore the normal direction of the uterine axis with reference to abdominal pressure, although the whole uterus may be a trifle forward of its natural location; and by the fact that, after the os is rotated backward, the sacro-uterine ligaments tend to retract, and regain their supporting function."

The later objections have been:[1] "(*a*) to the difficulty of finding the round ligaments; (*b*) the possibility of breaking them; (*c*) their absence; (*d*) the insufficiency of their retentive action; (*e*) the complication of the wound, and the danger of peritonitis as a result of opening Nuck's canal; (*f*) the violent pains to which the patient is subjected after the operation; (*g*) the insufficiency of the operation as regards the prolapsus and the surrounding parts, etc." Of which objections, Dr. Doléris avers, from large experience in operating, that they have no important value, and further adds: "I was almost an opponent of the procedure of shortening, in my first studies as to its value. Practice and experience have modified my ideas. Nearly all surgeons have followed the same path. Hesitating at the beginning, they have ended by recognizing the exaggeration of their first objections. Therefore, for my part, I say there is neither serious difficulty of execution, nor are there grave results following the operation. Antiseptic precautions insure operative success. A good diagnosis and a good operative plan will insure therapeutic success."

The clinical evidence thus far obtained is even more decidedly in support of the utility of the operation. Dr. Alexander himself, in his brilliant report of eighty cases in hospital and private practice, has demonstrated the fact that the anatomical cure of retroflexions and retroversions by shortening the round ligaments is a most certain result of the operation; and in cases of prolapsus, when he operated upon the perineum at the same time, he was equally successful with what he termed the "double operation."

The unpublished cases of Dr. Byford, and those reported by Dr. J. H. Kellogg, of Michigan,[1] are confirmatory of the success of the procedure in the hands of American operators. Dr. Kellogg favors the operation in cases of anteflexion combined with retroversion, especially when accompanied by prolapse of the ovaries; also in carefully selected cases of anteversion. He further speaks of the benefit derived in ovarian prolapse, where the ovaries are not held down by adhesions. Of twenty-two cases in which he has operated, twenty presented prolapsed and tender ovaries, with one or both enlarged, and in every instance he reports the prolapsed organs restored to their normal position, and, with two exceptions, they have remained there.

Dr. Wm. L. Reid, of Glasgow,[2] in a paper read before the Gynecological Section of the International Congress, takes what he intends to be an impartial view of the remote results of the operation, and gives some opinions, *pro* and *con*, which he has obtained by correspondence with a few prominent colleagues in England and Scotland. While the weight of these opinions is mainly hostile, it should be borne in mind that it comes from those who have had little or no personal experience with the operation, and consequently must be based largely upon theoretical grounds.

Notwithstanding these adverse views, Dr. Reid's summary of his own cases, though few in number—eight reported—afford valuable testimony to the efficacy of the operation; and even where accidents or partial failures have occurred, the causes are obvious, and modes of prevention present themselves to one who studies them in detail. He classes them as follows: "From a thera-

[1] Doléris, Trans. Am. Gyn. Society, vol. xii. p. 499.

[1] Transactions of International Cong., vol. ii. p. 764.

[2] Trans. International Med. Cong., vol. ii. p. 757.

peutic standpoint, two completely cured, one nearly so, three considerably improved, one in about the same state as before, and one worse, inasmuch as an inguinal hernia resulted. From an anatomical standpoint, six of the eight completely cured, one very greatly improved, and one bad as before the operation." The latter, however, cannot be justly used as an argument against Alexander's operation. It was an aggravated case of prolapse of third degree, of several years' standing.

Quoting the report: "*The uterus measured five and one-half inches in depth, was very heavy, and cervix was torn up to vaginal roof; perineum was quite gone. No pessary could be worn for more than an hour, except when the patient maintained the horizontal position.*" "The ligaments were shortened and patient *kept in bed a fortnight, getting out of bed for a few hours each day of third week, at the end of which she insisted upon leaving the hospital.*" She was not again seen by the operator for three years, when this note was taken: "Patient wore an ordinary Hodge pessary for three months from date of operation and felt quite well. *At the end of that time, during a severe exertion*, the pessary was expelled, and a week or ten days afterward patient felt the uterus coming down, and also a swelling in the left groin. She was, however, able for work, and a year and a half after the operation was married, becoming pregnant immediately afterward. Was very well and comfortable during her pregnancy and labor, the latter lasting less than half an hour, although the child was large. On getting up nine days after the confinement, the uterus came down as badly as before the operation, but she states that she can go about pretty freely, as she has none of the pains from which she suffered before that time. Micturition and defecation normal. On examination, the uterus was found low down in the pelvic cavity, not retroverted, three and a quarter inches deep, and not tender. In the upright position the cervix comes to the vulva. The scar in the right groin is sound, but in the left the inguinal canal is left open, and when patient stands up, a piece of the bowel comes down at the slightest cough."

This case was quoted thus fully, not only to show the impropriety of using cases of accidental failure against the efficacy of the operation, but also to show that the mistake may be made of expecting more from the round ligaments than even their most ardent advocate has claimed to be their normal function. Like other operations for restoring a displaced uterus, it has a definite field of usefulness, and should no longer be used in a haphazard manner, nor should it be expected to do away with other accessory measures.

Due credit should be given to Dr. Doléris, of Paris, France,[1] for his excellent paper on "Combined Operations for the Relief of Uterine Deviations or Displacements," wherein he classifies the factors which unite in maintaining the pelvic equilibrium, and endeavors to point out the indications for the performance of the Alexander and other accessory operations.

In the author's own cases, he had early been convinced of the advisability of using all auxiliary therapeutic measures, preparatory to shortening the round ligaments, as will be seen in the appended cases. In three of the seven, the cervix and perineum were repaired; in one the cervix alone, in one anterior and posterior colporrhaphy were done, and in one scraping or curetting the uterus for vegetations, and in each instance shortening of the round ligaments was not resorted to, until other feasible methods had been given a fair trial. This manner of procedure seemed to him especially demanded in cases of procidentia, particularly when there is a capacious vagina, a relaxed anterior or posterior vaginal wall, or torn perineum; in other words, where anterior and posterior colporrhaphy and perineorrhaphy are indicated. While he would not say that, in these complicated cases, no benefit could result from Alexander's operation alone, he believed it to be good surgery to fortify it by such auxiliary measures as are known to remedy the tissues at fault, and not to over-estimate the proper function of the round ligaments.

For similar reasons he should favor the treatment of long-standing or aggravated cases of flexions accompanying backward or forward misplacements, by such methods as that devised by Professor A. Reeves Jackson and others, for restoring the integrity of the uterine walls.

His seven cases are of such recent date that he related them, in this connection, merely to illustrate a modified method of operating, which has been, in the main, suggested by Dr. J. Frank, attending surgeon to the St. Elizabeth's Hospital, and its adaptability verified by dissections upon the cadaver.

He begins the operation by cutting directly down upon the internal inguinal ring, using the superficial epigastric vein, and beneath this the ilio-inguinal nerve, as guides, lying as they do directly over the canal of Nuck. The superficial landmarks are the same as are usually followed in this operation, *i. e.*, Poupart's ligament, spine of the pubis, and the anterior, superior spinous process of the ilium. The superficial epigastric vein, as well as the internal ring, is situated midway between the two last-named bony prominences. The primary incision, beginning just above the spine of the pubis, and extending one and a half inches or more, upward and outward, parallel with Poupart's ligament, comes at once upon the vein, which will be found in the subcutaneous fat, near the upper third of the cut. This vein, though often the size of a goose-quill, having no material importance except as a guide, is ligated and cut across, leaving the ligature long, for facility in locating.

On reaching the underlying external oblique aponeurosis, which is easily recognized by its glistening-white appearance, it is cut through in the course of its longitudinal fibres, and corresponding with the superficial incision. The ilio-inguinal nerve is now seen lying along the course of the canal, just beneath or mingling with the lower marginal fibres of the transversalis muscles. It is just beneath the point where the epigastric vein crosses the course of the ilio-inguinal nerve that the round ligament can be readily defined. If the muscular and fibrous tissues surrounding the cord are picked up *en masse* by forceps and slightly pulled upward, and then spread over the thumb or finger, inserted beneath, the whitish, slightly flattened, cord-like ligament is seen. It is now isolated, largely by the fingers, and made to run, care being used not to injure the ilio-inguinal nerve, which should be drawn to one side.

The ligaments should now be pulled upon to their full extent, or until the uterus is drawn upward into an erect

[1] Trans. Amer. Gynecological Society, vol. xii. p. 448.

or somewhat anteverted position, as is determined by an assistant's finger in the vagina, who either holds the uterus in this position by a sound *in utero* or immediately inserts a previously fitted pessary. The ligament is stitched to each side of the canal by a suture of silkworm, or chromic acid catgut, passing the stitch through one pillar of the canal, then into the taut ligament and along its longitudinal fibres, and returning it through the pillar of the same side. The *canal* is then closed by two or three sutures of the same material, made to include a small portion of the cord, but drawn only sufficiently tight to approximate the edges. The loop of the ligament, instead of being excised, is secured by a firm stitch uniting the proximate ends, and then folded into the wound after the method of Dr. Burt, of Boston.

The wound is now closed, the customary drainage tube inserted—supplemented by prepared iodoform-wicking drawn into the depth of the tube for capillary drainage. The ligament of the opposite side—which, after being pulled out and held by a sponge or pledget of gauze inserted beneath, was covered with antiseptic gauze and left—is now treated in the same manner.

Strict antiseptic precautions having been used in all details of the operation, permanent iodoform dressings are applied and the wound exposed only in case of rise in temperature or excessive soiling of the dressings, until the fourth or fifth day, when the drainage tube is removed, and the wicking substituted. Patient is kept in bed about four weeks, great caution insisted upon in getting up, and for four or five months following, no severe exertion is allowed. The pessary is retained during this period, and an elastic abdominal support worn.

In each instance the healing has been by first intention, the amount of surgical disturbance nil, and the results, to date, all that could be desired.

The advantages claimed are: the readiness with which the round ligaments are found and separated from their environment, necessitating no tearing of the surrounding parts and disturbance of the tissues about the external inguinal ring, and the terminal filaments of the broad ligament at its pubic end, with the least possible danger of hernia as an after-result.

Should it be possible, as has been suggested by Dr. Frank, and, as is learned from late readings, is practised by Dr. Doléris, to do without the drainage tube, the operation and after-care would be even more simplified and devoid of some of its now possible accidents.

Dr. Henry T. Byford said that he had so far operated in twenty-one cases, and believes in the operation as at first, but he does not operate as much. He has had two failures. They were failures because he ought not to have performed the operation. In one case there was salpingitis with adhesions; in the other case there was an enlarged ovary and hydro-salpinx. The case of salpingitis resulted in slight peritonitis, with a temperature of 102° F. for several days. He took out the pessary at the end of six weeks, and at the end of two months, when she was at her housework, retroversion and peritonitis recurred. The uterus can now be easily held up by a pessary, while it could not before the operation, and will remain up after the pessary is removed until some strain forces it down. At present it is in position without a pessary. He thinks the uterus would stay in good position if the patient would allow him to remove the enlarged tube, but as it is, she is better off than before the operation. In all of his operations, he now leaves the pessary in place from six months to a year. He had another case which might be called a failure, as an inguinal hernia resulted. The patient had been to some of the most eminent gynecologists in Chicago, one of whom wanted to remove the ovaries. She could not tolerate a pessary of any description. Now she wears a pessary without trouble; the uterus is up, and she is one of the most grateful patients he has, in spite of her rupture. On account of this hernia, he threw aside his catgut and he now uses none but silkworm-gut sutures, and leaves those that close the canal and hold the ligament.

One great drawback to the operation is that the patients are not always immediately cured of symptoms. If there have been pelvic contractions or adhesions, there may be a dragging on these for some months. The first case he had was of this kind. The pessary was left in two months. She complained long afterward of a dragging on the groins, but at the end of a year she could, for the first time in several years, do her own housework and take care of her home. She had previously had gynecological treatment for five years, the last two by myself.

It is objected that the round ligament is not a normal support of the uterus. We do not shorten the round ligaments to support the uterus in cases of retroversion, as is so generally misunderstood; we merely turn the fundus forward and depend upon the normal abdominal pressure to hold it forward. Of course, the operation is only for the few cases in which the displacement causes symptoms, and in which it can be replaced, but cannot be permanently retained in position by less available or less dangerous means.

OBITUARY.

HENRY BERTON SANDS, M.D.

Henry Berton Sands was born in New York City, September 27, 1830, spent his entire life there, and there died on the 18th of this month, full of honors, if not of years.

He was graduated in medicine at the College of Physicians and Surgeons in New York in 1854, served as House Physician and then as House Surgeon in Bellevue Hospital, studied for a year in Europe, and on his return, in the autumn of 1856, began practice in New York and was at once appointed Demonstrator of Anatomy in the college from which he had been graduated, a connection which he retained until his death, having been advanced in 1867 to the professorship of anatomy, and in 1879 to that of surgery, dividing the work of the latter position with Professor Markoe.

His practice at first was general, but he early became known and trusted as a surgeon, and for several years before his death he had confined himself entirely to surgery. He served for two years, 1861 to 1863, as Attending Surgeon to the New York Eye Infirmary and St. Luke's Hospital, for ten years, 1866 to 1876, as Attending Surgeon of Bellevue Hospital, for twenty years, 1863 to 1883, as Attending Surgeon of the New York Hospital, and for about twelve years, 1876 to 1888, as Attending Surgeon of Roosevelt Hospital. For many years he was an earnest advocate of the plan of continuous hospital

service, and it was mainly through his instrumentality that the Governors of Roosevelt Hospital were led to adopt this plan in the management of their surgical service; for the last five years of his life he was the sole surgeon of that hospital, and by his fidelity and skill raised the service to a height of efficiency and reputation which has made it second to none.

In the winter of 1885–86 he suffered a slight cerebral lesion, which he accepted as a warning to reduce his labor, and in the spring of 1888 he resigned his position at Roosevelt Hospital, after having a year previously reduced his work in the college so that his lectures should occupy only a single month. In October he returned from a three-months' vacation spent in Europe, apparently in his usual health, and resumed his practice, and on Sunday afternoon, November 18th, while returning in his carriage in company with Dr. A. A. Smith, from a visit to a patient, he suddenly became unconscious, and died almost instantly. The autopsy disclosed no fresh cerebral lesion, and death was attributed to heart failure, as the cardiac walls were extremely thin and one of the coronary arteries contained a recent clot.

Dr. Sands's professional work was marked by extreme care, thoughtfulness, and accuracy, by a full sense of responsibility, and by great sobriety of judgment. Though a skilful and experienced operator, and feeling himself equal to any emergency, he was never blinded to the interests of his patients or the credit of his profession by the temptation to do a brilliant but hazardous operation, and was always cautious and deliberate in his acceptance of surgical innovations and novelties. His contributions to medical literature were not numerous, but they were remarkable for thoroughness, profound thought, accurate judgment, and literary finish.

Direct, straightforward, and upright, both intellectually and morally, he pursued his course openly, vigorously, and with determination, but also with charity and consideration for those who differed with him. Outside of his profession he was a widely read and cultivated man, an animated and attractive companion, a steadfast and trustworthy friend. His death has made a gap in the foremost rank of the profession.

NEWS ITEMS.

Diphtheria from Cats.—A report has been made to the Central Board of Health of Melbourne, describing an outbreak of diphtheria, the cases occurring almost simultaneously in the neighborhood of Dalesford. One child died, but the others are progressing favorably. The local health officer has furnished a report, pointing out the strong *prima facie* evidence that the children contracted the disease from cats, numbers of which are dying in the neighborhood.—*British Medical Journal*, Nov. 3, 1888.

Finger-nails and Nail-brushes.—A painstaking German physician, Dr. Mittmann, of Würzburg, has published in Virchow's *Archiv* a notable paper bearing the remarkable scientifico-naturalistic title, "Untersuchungen von Fingernägelschmutz auf Mikroörganismen." Although this contribution cannot be said to be based on painful experiments on live animals, a certain section of society will hold that there can be little poetry in those who make researches for microörganisms in finger-nail dirt. Yet nails can scratch, and scratches may undergo troublesome pathological changes; moreover, as some authorities have insisted, the nails may seriously affect operation-mortality, for they can convey bacteria in particles of dirt unremoved by the nail-brush. Dr. Mittmann has found that germs abound under the nails of persons pursuing dirty occupations and of careless schoolboys. He cultivated the adventitious matter from the nails of twenty-five subjects, in agar-agar, gelatine, and blood-serum. Micrococci were almost invariably present, next in frequency came diplococci; in only eighteen cultivations were bacilli found; and sarcinæ appeared in three. Moulds abounded and grew freely on cultivation. The subjects were grouped as follows: six ragsorters, four female cooks, three waitresses, seven schoolboys, two barbers, and three undertakers' assistants. The degree of septic virus must vary greatly in groups which represent such different conditions. The use of the nail-brush in private life needs no advocate in this country; on the other hand, it is questionable whether that toilet article may not be a source of danger in hospitals and medical schools. A dissecting-room or ward nail-brush is as likely to convey as to remove septic matter. Possibly it is better to rub the nails on the surface of a piece of antiseptic soap during ablution, subsequently employing a penknife, if necessary, than to use a nail-brush under these circumstances.—*British Medical Journal*, Nov. 3, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM NOVEMBER 13 TO NOVEMBER 19, 1888.

By direction of the Secretary of War, the retirement from active service, this date, by operation of law, of Elisha J. Bailey, *Colonel and Surgeon*, under the provisions of the Act of Congress approved June 30, 1882, is announced. Colonel Bailey will repair to his home.—Par. 1, *S. O. 266, A. G. O., Washington*, November 14, 1888.

Lieutenant-Colonel Smith, after being relieved by Lieutenant-Colonel Alden, will report in person to the commanding officer Department of Arizona, for duty as Medical Director of that Department, relieving Lieutenant-Colonel Richard H. Alexander.—Par. 10, *S. O. 268, A. G. O., Washington*, November 16, 1888.

By direction of the Secretary of War, leave of absence for four months is granted to Richard H. Alexander, *Lieutenant-Colonel and Surgeon*, to take effect from the date of his relief from duty as Medical Director Department of Arizona, by Lieutenant-Colonel and Surgeon Joseph R. Smith.—Par. 11, *S. O. 268, A. G. O., Washington*, November 16, 1888.

Alden, Charles H., *Lieutenant-Colonel and Surgeon*.—Is relieved from further duty at the Military Academy, West Point, New York, and will report in person to the commanding general Department of Dakota, for duty as Medical Director of that Department, relieving Lieutenant-Colonel and Surgeon Joseph R. Smith.—Par. 10, *S. O. 268, Washington*, November 16, 1888.

Waters, William E., *Surgeon* (Vancouver Barracks).—Is granted leave of absence for one month, to take effect on or about the 1st proximo, with permission to apply for an extension of one month.—Par. 1, *S. O. 129, Headquarters Department of the Columbia* November 9, 1888.

By direction of the Secretary of War, Charles Smart, *Major and Surgeon*, will proceed to Milwaukee, Wisconsin, to represent the Medical Department of the Army at the meeting of the American Public Health Association in that city, November 20 to 23, 1888, and, upon the adjournment of the Association, will return to his proper station.—Par. 2, *S. O. 268, A. G. O., Washington*, November 16, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING NOVEMBER 17, 1888.

Swan, Robert, *Passed Assistant Surgeon*.—Ordered before Retiring Board 19th inst.

ORIGINAL LECTURES.

PERCUSSION AS A MEANS OF DIAGNOSIS OF PNEUMOTHORAX.

A Clinical Lecture, delivered October 17, 1888.

BY EDWARD T. BRUEN, M.D.,

ASSISTANT PROFESSOR OF PHYSICAL DIAGNOSIS IN THE UNIVERSITY OF PENNSYLVANIA; PHYSICIAN TO THE PHILADELPHIA AND GERMAN HOSPITALS.

I desire to present this case in order to give prominence to some diagnostic features of percussion as a means of diagnosis of pneumothorax.

This colored woman entered the hospital, October 5, 1888; she is twenty-eight years old, of healthy parentage. Her father is living at seventy-five years of age, her mother died in childbed. She has had a pretty severe cough for the last three months with muco-purulent expectoration occasionally streaked with blood. She has also had night-sweats. This history without doubt tends to indicate that she has had pulmonary disorder for some time.

On admission she complained of cough and great dyspnœa. This symptom was marked—the respirations the day after admission having ranged from 52 to 70. Temperature October 5th was 100.3°, but on the 6th it suddenly rose to 104°, at midnight had fallen to 98°, and since then the temperature has presented a daily range from 98° in the morning to 102° in the evening. The cough has been constant and attended by the expectoration of abundant muco-purulent matter.

The diagnosis of this case from the outset demanded the consideration of some acute thoracic mischief in lungs or heart. On auscultation the breathing was audible as a harsh but distant murmur over the anterior and dorsal walls of the right thorax attended with a slight metallic tinkle on coughing, which contrasted markedly with the exaggerated quality of the vesicular murmur over the left side of the chest. The mobility of the right side of the chest was reduced, but its contour was not modified nor were the inter-spaces effaced. Palpation was negative. Percussion, however, was markedly suggestive and I would even claim for it a diagnostic importance in a large proportion of cases of pneumothorax. The physical sign on percussion to which I allude is essentially that described originally by Trousseau, who says, "on applying the ear to the posterior wall of the chest on the affected side, and having percussion made in front by an assistant striking a metallic pleximeter with a hammer or a piece of money, a sound may be elicited similar to that produced by striking an empty barrel, or, still more, that produced by striking a bronze vase." This phenomenon was casually pointed out by Laennec, but from the frequency with which I have made the demonstration to physicians to whom it has seemed a novelty or even a trick, I am persuaded that the diagnostic value of this variety of percussion-resonance has been largely overlooked.

When percussion is practised in a case of pneumothorax, the sound elicited must be tympanitic or hollow. The pitch is lower than the tympanitic sound of most cavities; it is lower than the pitch of stomach tympany for the obvious reason that the pleural air sac is large, its walls are tense, consequently the vibrations of the pulses of air occur in long curves, rendering the sound a good example of a low-pitched tympanitic note. Yet in certain cases the vibrations of the pulses of air may be so short that the pitch of the tympanitic sound becomes high enough to render the sound dull to an unpractised ear. It is because it is difficult to interpret correctly the significance of the tympanitic note in these cases that so much stress must be laid on the metallic percussion.

The special characteristic of the sound is elicited when a metallic plexor and pleximeter are used. Two ordinary coins will suffice for this purpose. When these are struck in the open air, only a dull metallic sound can be developed, but when used over a pneumothorax and in case there is a patulous opening through the visceral pleura, and if auscultation is practised while an assistant performs percussion by means of the coins, a beautifully clear, ringing, metallic sound will be heard. This sound does not occur in cases of pneumothorax when the fistulous orifice in the visceral pleura is closed, or in empyema with fistulous external opening. This percussion note is then chiefly characteristic of pneumothorax while the opening in the visceral pleura is still patulous It sometimes happens that the fistulous orifice may be temporarily closed by a flake of lymph forming over the opening, when the specific metallic character of the percussion sound will vanish. It is possible to bound accurately the area of pneumothorax as the specific note disappears when the margin of the lung is percussed.

This metallic tinkle on percussion after the manner described has never been present in any case of intra-pulmonary cavity which I have studied. In cases of old pleural adhesions on the left side, the stomach may be distended with gas, the fundus of this organ will enter the left inferior axillary region and it is, under these circumstances, possible to recognize the metallic timbre of the percussion note. This possibility of error may be quickly refuted by asking the patient to drink a glass of water. The tinkle produced as the water falls into the stomach can be readily detected if auscultation is carried on during the act of drinking. If the pneumothorax is local and sacculated by adhesions between the visceral and costal pleura, this sign, on percussion, becomes of especial importance, since the ordinary percussion note may be so high-pitched that its quality may be imperfectly defined and the resonance dull.

Metallic percussion of the variety just described was present in this patient's case from the first day of the occurrence of the pneumothorax, and it formed the

pivotal consideration in establishing the nature of the case. The absence of dulness and the absence of bronchial breathing on the side evidently the location of the thoracic mischief excluded pneumonia; while the patient's physical appearance and history, imperfect though it was, indicated that the present condition had been antedated by a pulmonary process.

The development of the symptoms of this case is also instructive, since they show that when a pneumothorax has once occurred, several days may elapse before the full characteristic series of symptoms are manifested. It is obvious that the ingress of air has widened the affected side and produced the aspect of rotundity; the interspaces have also been effaced. The chest is motionless, respiration diaphragmatic, the liver displaced downward, and the heart pushed markedly to the left of its usual place in the præcordia. To-day if percussion be practised over the lower zone of the right chest in a line one inch below the angle of the scapulæ, an entire flatness has replaced the tympany; the level of this dulness is sharply defined by the tympany above, and the metallic note from the coins is not recognizable. On sharply moving the patient the Hippocratic succussion-splash clearly shows that the condition is now hydro-pneumothorax. There are no general symptoms to indicate the presence of pus, and no positive physical sign of this character of pleural effusion exists except through the withdrawal of pus by paracentesis.

Differential Diagnosis.—Pneumothorax is almost always unilateral; cases of bilateral pneumothorax have been described, but they are so unusual as to be among the curiosities of medical literature. From unilateral emphysema contrast in pneumothorax the suppressed respiratory murmur, the existence of the metallic tinkle on auscultation, and the metallic note on auscultatory percussion. Since the pneumothorax is commonly associated with the formation of fluid which is either serum or pus, the condition known as hydro or pyo-pneumothorax usually develops and succussion-splash will be the characteristic phenomenon. The displacement of the viscera in pneumothorax differs from general emphysema and the percussion pitch is lower and the tone more hollow. Finally, the antecedent history of cases of emphysema differ widely from those of pneumothorax.

The prognosis in pneumothorax is very serious, the mortality being reported by Potain as eight cases out of eleven—three were cured. West, of Heidelberg, reports forty-six cases; forty-four died, two cured. The issue of the cases is always doubtful because the primary disease in most instances is phthisis, and from the tendency of the pneumothorax to become pyo-pneumothorax. When the first few days after the accident has occurred are passed in safety the duration of the case may be months or even years. A patient recently died in this hospital whose case was the subject of demonstration before this class for two years. Laennec reported one case in which the patient lived six years.

Dèmarquay and Marotte have shown the innocuousness of air injected into the pleural space and Potain has recently advocated the injection of sterilized air as a method of treatment of this disorder; so that in those rare cases in which pneumothorax has occurred from other causes than pulmonary phthisis, if the accident is not immediately fatal the prospect of recovery may be entertained.

The treatment is chiefly palliative, at the time of the shock; stimulants to sustain the action of the heart and respiration, may be employed, and hypodermatics of morphia to lessen pain. When the area of pneumothorax is small an effort should be made, as soon as the acute symptoms have subsided, to compress the affected side by adhesive strips applied so as to lap the unaffected side, and by limiting chest movement to help secure union between the visceral and costal pleura. This plan of treatment, however, is usually insupportable to the patient and must be abandoned. If an excess of fluid exist, paracentesis should first be practised before strapping the chest.

Potain recently reported three cases of pleural effusion consecutive to pneumothorax of tubercular origin successfully treated by injection of sterilized air into the pleural cavity by the following method. A needle similar to that of a hypodermatic syringe, attached by a fine rubber tube to a reservoir of air which has been sterilized by being passed through a strong carbolic solution and then through cotton, is introduced into the sixth intercostal space while the trocar of an aspirator is plunged into the seventh. The air is then allowed to flow in as rapidly as the fluid escapes, its flow being regulated by means of a clip on the tubing so as to obtain about a normal intra-pleural pressure of six to seven millimetres of mercury as shown by the small metallic manometer attached to the aspirating apparatus. At each operation all the fluid was withdrawn and it was repeated as often as the chest refilled; in one case four, and in another five times. The operation was attended by no discomfort apart from the introduction of the needles, and was followed by great relief from all urgent symptoms. The final results were eminently successful: in all three cases the pneumothorax was cured without retraction of the chest, and in two the phthisical process was arrested. In the third case both lungs were affected and the disease which seemed checked for a time went on to a fatal termination. This method is only applicable when the effusion is serous or sero-purulent and not fetid, and should be deferred until the fluid has become either inconvenient from its weight or dangerous from its volume; it is contra-indicated if there is a large communication with a bronchus. The advantages of the operation are, that the dangers from a large quantity of fluid in the pleural cavity are avoided as well as those arising from a rapid evacuation of a large effusion; that the serious inconveniences of frequently repeated punctures are avoided and the lung is allowed the possibility of slow and progressive expansion. Finally, the cicatrization and cure of tubercular lesions seem to be favored by keeping the affected lung for a long time at rest.

I have described this mode of treatment in detail as reported originally in the *Bull. de l'Acad. de Méd.* of November 17th, and in the *Boston Med. Journal* of September 6th, because it seems a practical method and well worthy of trial. If the original opening in the visceral pleura can be closed, gradual expansion of the lung with obliteration of the pleural sac by adhesions is all that can be expected.

November 7th, the general condition of the patient has improved, the temperature has ranged between 98° and 100° for a week past, respirations 40 to 50, pulse 108, but little cough or expectoration, and increasing strength. The amount of fluid in the pleural sac has increased slightly within the past week, being now bounded above by the angle of the scapula.

EXPLORATORY TREPHINING AND PUNCTURE OF THE BRAIN ALMOST TO THE LATERAL VENTRICLE,

For Intracranial Pressure supposed to be due to an Abscess in the Temporo-sphenoidal Lobe. Temporary Improvement; Death on the Fifth Day: Autopsy: Meningitis with Effusion into the Ventricles.

WITH A DESCRIPTION OF A PROPOSED OPERATION TO TAP AND DRAIN THE VENTRICLES AS A DEFINITE SURGICAL PROCEDURE.

BY W. W. KEEN, M.D.,
PROFESSOR OF SURGERY IN THE WOMAN'S MEDICAL COLLEGE OF PENNSYLVANIA; SURGEON TO ST MARY'S, ST. AGNES'S, AND THE WOMAN'S HOSPITALS, ETC.

EMMA S., aged fourteen years. Eight years ago Dr. John L. Yard first called me in consultation to see her. She then had hip-joint disease on the right side, from which she recovered with a straight leg, though ankylosed, after about three years of treatment. Later she had several scrofulous outbreaks. Six months or more ago her left ear began to discharge, and this has continued ever since. Her general health also has failed, and in spite of her summer holiday in the country she has returned thinner and paler than usual. About two weeks before I saw her she commenced to have pain in her head with some mental dulness, cerebral vomiting, and moderate fever; temperature 99.6° to 101.6°. Soon some little trouble with her speech developed.

I first saw her September 30, 1888, at 8 P.M. Her temperature was 101°; pulse 72; resp. 16. She had vomited food without nausea for several days. She had had headache for several days, but can scarcely localize it accurately. She had had no chill, no convulsions, and no photophobia. Tapping on the left side of the head scarcely elicits pain at any point, but pressure developed distinct tenderness over an area of about two inches in diameter above and in front of the left ear. There is no œdema of the scalp either at this point or elsewhere. The mastoid is entirely free from pain, tenderness, swelling, or œdema. The child has double vision. There is no ptosis. The tongue, when protruded, deviates slightly to the right. The speech is thick. It is difficult to say whether this is due to some ataxic aphasia, or, possibly, to some paralysis of the tongue. The breath is quite fetid. The internal and external jugulars show no tenderness or hardness. There is no word-deafness; unfortunately, word-blindness was not sought for. The left pupil is much larger than the right and is sluggish in its reaction to light.

Mentally she is rather dull and uncomplaining, in marked contrast to her usual disposition. She has had no irritability.

Oct. 1, 2 P.M. Her intelligence has diminished very much—*e. g.*, she seems to apprehend the command to lift her hand, but not to protrude her tongue, and otherwise is very dull, though not sleepy. She has not spoken a word to-day, and only replied "yes," in thick speech, to the many questions we asked her.

Dr. Howard F. Hansell saw her with us to-day, and reports that the vision is unimpaired; the eye-ground shows the veins much congested on both sides, but more marked on the left than on the right, and rapidly developing choked disks. The squint was ascertained to be due to paralysis of the left external straight muscle. The left membrana tympani was destroyed and the canal filled with pus; no dead bone could be discovered. The hearing, unfortunately, was not tested by the watch, but for conversation was only moderately impaired apparently; abdominal reflex was absent; knee-jerk on the left side more marked than the right, but both of them below the normal. She has to-day passed water involuntarily in bed.

Diagnosis.—Intracranial pressure, arising probably from abscess in the temporo-sphenoidal lobe with pressure on the left sixth nerve, and, possibly, on the base of the third frontal convolution. Exploratory trephining was recommended and accepted readily by her parents.

2d. Her condition has to-day grown rapidly worse, as compared with yesterday. She is unconscious, with sordes on the lips and teeth. Last night Dr. Yard prepared her head for operation in the usual way (see the *American Journal of the Med. Sciences*, October, 1888, p. 335), but by an accident he was not able to take the temperature on the two sides of the head.

Operation.—2.15 P.M. Present, Drs. Yard, W. J. Taylor, H. F. Hansell, M. J. Lewis, and Louis Jurist. The operation lasted from 2.45 to 3.32 P.M. No spray was used. During etherization the respiration was shallow and diaphragmatic, so much so, that Drs. Yard and Jurist, who had charge of the patient, sent for me to the room in which she was being etherized, being doubtful whether it was wise to go on. During the operation the pulse was 124, almost too soft to count. Only one-quarter of a pound of Squibb's ether was used.

The ear was first cleaned and filled with boric acid, I then selected a spot three-quarters of an inch in front of the meatus and an inch and a half above Reid's "base-line" (a line drawn backward from the inferior border of the orbit, through the middle of the meatus, and extended to the occiput), as the place for trephining. I made a small incision through the skin and marked this point with a bone gouge, and then made a flap two inches in diameter with the convexity looking upward, so as keep the most favorable blood supply. The set-screw of my one-inch trephine broke, and I was compelled to use a half-inch trephine, which proved to be quite sufficient.

As soon as the button of bone was removed the dura bulged into the opening distinctly. It pulsated, was very tense and elastic to the touch, and its color was dark. Dr. Morris J. Lewis made the following notes of what was done. I plunged a hypodermatic needle of moderate calibre through the dura, downward and a little forward, to the depth of an inch. Some serum was drawn into the glass barrel of the syringe, but as no pus came the

syringe was thrust half an inch further. The suction on it was only ten minims. Small fragments of what I thought was curdy pus were now drawn into the syringe. Subsequent investigation, however, showed this to be some white brain tissue.

1. The dura mater was now opened by a small crucial incision, as I did not intend to close it later. The brain substance immediately bulged to a considerable extent and pulsated.

2. The needle was next introduced directly transversely about one and a quarter inches, but no pus flowed.

3. A grooved director was now substituted for the needle, and was pushed downward and backward to the depth of one and a half inches, till it impinged on the petrous portion of the temporal bone.

4. The grooved director was introduced almost directly downward, till the bone was struck at the depth of one and a quarter inches.

5. The director was next introduced forward, inward, and slightly upward, in the direction of the sella turcica, for a distance of one and three-quarters inches. In this child it almost reached the apex of the temporo-sphenoidal lobe.

6. The grooved director was next introduced downward, and a little forward, till it struck the bone at two inches. No pus was found in any of these six punctures.

7. Thinking there might be an extra-dural abscess, a periosteum elevator was now introduced between the dura and the skull directly downward, until the bone was reached. No pus was found.

The incision was then extended directly backward, and a half-inch button was removed at a point one and a half inches above the base-line, and one and a half inches behind the meatus. The dura was not so dark, nor did it bulge so much, nor was it so tense as at the first trephine opening. The needle was introduced forward, downward, and slightly inward, to the depth of one and a half inches, and, secondly, almost directly transverse, but no pus was found. The dura here was not opened.

I next drew down the flap, and examined the mastoid foramen, but could find no evidence of pus. As the symptoms and physical signs did not point to the cerebellum, I did not trephine there, though I contemplated so doing for a few minutes. I was so convinced that the intra-cranial pressure was due to fluid, and that that fluid was pus, that I introduced a drainage tube transversely, and a little upward, to the depth of one and a half inches, through the first trephine opening, to favor its escape by affording a path of least resistance. The flap was buttonholed for the exit of this tube, and held it firmly in place. Horsehair was placed under the flaps, and catgut sutures introduced. The buttons of bone were, of course, not replaced, nor the dura sewed. A dry sublimate dressing was applied, and the ordinary recurrent bandages used. She was placed in bed in a good physical condition.

Toward the close of the operation the child's respiration was almost entirely diaphragmatic and irregular, somewhat resembling the Cheyne-Stokes type, but not at all marked. In none of the punctures were there any convulsive movements of the right side of the body, other than those that were partially voluntary. Every puncture by the hypodermatic needle sucked up some fragments of white brain-tissue into the syringe.

10.30 P.M. Her condition was very much as it had been the day before the operation. Temperature 101.6°. There has been but slight oozing from the wound. She had taken milk with a little brandy every twenty minutes without any difficulty. She was not entirely unconscious. She had taken up a piece of newspaper lying on the bed, and seemed to make an attempt to look at it, but otherwise she had not shown consciousness. She passed water involuntarily once.

3d. Morning (first day after operation). The moment I saw her when I entered the room I was struck with the improvement in her appearance. Her eyes were open and she took notice of what was going on around her. She had repeatedly taken a tumbler of milk in her own hands and drunk it. Temperature normal. No inference could be drawn from the pupils as the effect of the atropia had not passed off. At the dressing of the wound she showed appreciation of pain. The wound could not look better. A small amount of oozing and some small flakes of brain tissue were on the dressing, but no pus. The wound was redressed more for the purpose of observation than for surgical reasons. She was in every respect better than at any time since I first saw her. Her squint was still preceptible.

3d Evening. Her intelligence is better than in the morning. When I said "good-bye," she held out her hand. She takes fair nourishment. Recognized her mother and tried to talk. Has passed no water since 5 A.M. Lithia water was ordered.

4th. A.M. (second day). Mind not quite so clear as last evening; she noticed the blood-stains on her night-dress, which seemed to cause her distress. Has had no sleep, and has been somewhat restless. Passed water twice. Temp. 100.6°, pulse 120.

10.30 P.M. Temp. 102.4°, pulse 163. Quite drowsy, and took no notice of change of night dress. Passed water twice since this morning. Slept four hours this evening. Took some milk.

5th. 12 M. (third day). Restless all night, no sleep till 5 A.M., since then has slept considerably. Passed water three times in the night. Temp. 103.7°, pulse 150. Dressing changed. The wound looks perfectly well; no discharge; drainage tube removed.

7.15 P.M. Rather more intelligent during the afternoon. An enema moved the bowels freely; shook hands with Dr. Yard when he came in; took no nourishment; passed water twice. Temp. 103.2°, pulse 153.

6th. 10.25 A.M. (fourth day). Has taken very little nourishment; passed water twice; almost comatose; breathing labored. Temp. 104.8°, pulse 172.

6 P.M. Gradually sank and died at this hour.

Post-mortem, Oct. 8th, forty-five hours after death. The wound was well united, though the flaps were easily torn apart. There was no meningitis apparent on removing the skull cap. The bloodvessels were somewhat dilated, those on the right side rather

more than those on the left. Slight œdema was noticed in the track of the middle cerebral vessels. On lifting the frontal lobes a great deal of œdema was noticed which obscured the cerebral substance around the peduncles and pons and was so marked over the medulla and cord that they could not be seen until the fluid had escaped, which it did immediately upon removal. Then, saving some injection of bloodvessels, the brain substance and membranes appeared nearly healthy. The œdema extended distinctly to the fifth, to the auditory and facial nerves, and to a less extent also to both optic nerves, all more marked on the left side. There was not the slightest adhesion at any point, either at the trephine openings or on the under surface of the brain; no false membrane.

At the second trephine opening, the point where the two punctures were made was barely recognizable on the cortex, not the slightest adhesion or inflammation being observed. The posterior puncture was through the middle temporo-sphenoidal convolution at its upper border; the anterior in the superior temporal convolution. The point where the drainage tube had been inserted through the first trephine opening was patulous. It was not, however, surrounded on the external surface of the cortex by any evidences of inflammation.

Transverse sections of the brain were now made, beginning with the cerebellum, which was perfectly healthy at every point. The sections crossing the track of the drainage tube showed not the slightest trace of inflammation surrounding its track. Only the portion of the brain tissue immediately in contact with the tube was slightly discolored, and possibly softened to a depth of not over one-sixteenth to one-twentieth of an inch in thickness. The length of the drainage canal in the brain itself was one inch. *The internal extremity was within one-quarter of an inch of the distended left ventricle.*

The sections of the brain were made about one-third of an inch apart, and showed entirely healthy brain tissue. Although observations were made with great care and each section cleaned by pouring water over its cut surfaces, not the slightest trace could be found of the punctures made by the hypodermatic needle or the grooved director; no laceration of the tissue; no effusion; no softening; no hemorrhage; nothing to give any evidence that the brain had been touched.[1] The lateral, third, fourth, and fifth ventricles were all very much dilated and filled with serum. The posterior horn of the lateral ventricle was three-quarters of an inch in diameter, and the third ventricle one inch in diameter. There was no inflammation of the dura at any point, not even in the track in which the periosteum elevator had been passed between the dura and the skull down to the bone. There was no caries of the petrous bone.

The only other organs examined were the kidneys. The left one was moderately congested, but normal in consistency; the right kidney normal in every respect. A half ounce of urine was drawn from the bladder which was found to be albuminous. There was no œdema of the face nor other part of the body, which was very much emaciated before her illness.

Dr. J. P. C. Griffith made the following report on the specimens which were given to him for examination:

The membranes covering the medulla, and the portion of cord attached to it were much thickened, and adherent to the tissues beneath. Portions were carefully dissected off in water, stained in hæmatoxylon, and examined in glycerine. Under the microscope there were revealed the evidences of a tubercular meningitis; the tissues being thickened and infiltrated with lymphoid elements, while in certain portions tubercles could be distinctly observed.

Remarks.—I have reported this case somewhat minutely on account, first, of the question of diagnosis, and, secondly, the surgical treatment. This last is extremely important as showing first that the brain can be explored thoroughly, repeatedly, and deeply without any apparent injury either to its substance or to its functions; and, secondly, that so far as this case enables us to judge, in cases of intracranial pressure and dropsy of the ventricles, it would be easy in the future to trephine and to tap the ventricles and give exit to the fluid, and possibly effect a cure, without doing any damage to the brain substance.

First, in the matter of the diagnosis, Dr. Yard and I recognized that the trouble was due to intracranial pressure, and the only question was the cause. My own judgment was decidedly in favor of abscess of the temporo-sphenoidal lobe, and for the following reasons:

A scrofulous child, purulent discharge from the ear for six months or more, sudden vomiting evidently cerebral, headache, a tender spot above and in front of the left ear and at no other point, possible aphasia, paralysis of the left sixth nerve, congestion of the optic papilla more marked on the left side, pulse normal, temperature while not normal or sub-normal, but little elevated until a little while before death.

Negatively, I excluded meningitis from the absence of delirium or delusions, the absence of photophobia, of contracted pupils, convulsions, and of facial twitchings, the absence of high temperature, no marked rigidity of the neck muscles, no prior irritability, no injection of the conjunctiva, no grinding of the teeth. I excluded abscess in the cerebellum from the perfect coördination of movements which always existed, and the entire absence of any localized symptoms of cerebellar disturbance. At the operation the examination of the mastoid foramen showed no evidence that the pus had travelled back from the petrous bone toward the cerebellum along the track of the

[1] In the discussion Dr. Osler stated that when examining the specimens with Dr. Griffith, after hardening in Müller's fluid, the line of the puncture was visible. In the first brain we could not see it.

lateral sinus. Although either the presence or absence of pus at this foramen is not a physical sign on which I would rely too much, yet taken with other signs it is probably of value as pointed out by Mr. Barker.

The motor region was excluded by reason of the entire absence of paralysis, the slight possible paralysis of the tongue being due more likely to the direct involvement of the seventh nerve, as it passed through the petrous bone.

Abscesses in the frontal and occipital lobes were excluded by their great rarity and by the absence of any local symptoms. Mastoid disease was excluded, as there was no œdema or other symptoms of local mischief. Abscess between the dura and the skull would probably have produced œdema of the scalp, which was absolutely absent, and the exploration at the operation demonstrated the non-existence of such an abscess. Plugging of the lateral sinus would have produced hardness and other signs in the internal and external jugular veins, and other symptoms of pyæmia. No such changes or symptoms were observed. It seemed, therefore, both by exclusion, as well as by positive evidence, that there was mischief on the left side, and almost certainly abscess of the temporo-sphenoidal lobe. The presence of pulsation at the trephine opening was extremely significant as against the diagnosis of abscess, and together with the elastic tension and bulging would be of the greatest value in enabling us to diagnosticate effusion into the ventricles. These means of diagnosis, however, are only of value during and not prior to the operation.

The results of the operation show that, saving for a slight disintegration of the brain tissue in a very thin layer round the track of the drainage tube, the cerebral substance was healthy. A most remarkable thing to my mind was the entire absence, even after the most careful search, of any evidence of puncture in the brain tissue.

In the various punctures I employed a hypodermatic needle in four of them, and a grooved director in four others. When the dura is intact the syringe must be used, but it should be used with great caution on account of the suction, for, though I had a suction cavity of only seven to ten minims in the barrel of my syringe, yet the brain substance was sucked up into it every time. I cannot but think that the introduction of a grooved director would be safer and certainly, as shown by the post-mortem, did no more injury to the brain substance than the syringe itself, with its certain loss of tissue. The grooved director would allow pus or any other fluid to escape by its deep groove. The sharp point of the needle might readily puncture a vein, a large artery, a sinus, or possibly one of the large nerves, but the blunt end of the director exposes us to no such danger, and invites to a more extended and thorough exploration.

That this is not a merely theoretical objection to the needle is shown by Beck,[1] who relates a case of hemorrhage into the lateral and fourth ventricles as a result of its use, and by Dr. B. A. Watson, who tells me that in his researches on puncture of the heart as a therapeutic measure, such needle-punctures of the vena cava were invariably followed by hemorrhage. Even the introduction of a drainage tube into the brain, in a case operated on by Weir, has been followed by fatal secondary hemorrhage from injury to the middle cerebral vessels.[2] I believe that the grooved director might be fearlessly passed in until it touched the base of the skull, or to the falx or tentorium, provided that important cortical centres, the internal capsule, or the great basal ganglia, are not in its path. It is, I fear, only too probable that these structures would be an insuperable barrier to any such puncture; but even this is a question that can only be decided by trial—a trial, however, that should be most cautiously made, first upon animals and then upon man, and even then in the human subject only when forced upon us by circumstances. I am perfectly well aware that the tendency is to substitute the knife for the syringe, and that v. Bergmann has even formulated it as a rule. This, as an operative procedure, or for superficial exploration, has my entire assent. But for *deep* exploration I am convinced that we shall do less harm by the director; and that as it is less dangerous we shall be more thorough in our explorations with it, and so learn much more than by the knife.

In the use of any instrument, whether a grooved director or a needle, the greatest care should always be exercised to insert it in a direct line, and to withdraw it in the same line so as not, by a lateral sweep, to lacerate the brain substance.

Proposed Tapping of the Ventricles as a Definite Surgical Operation.

As a result of my observations in the present case I would definitely propose in any similar case of dropsy of the ventricles, or of abscess in them, that tapping of them be done as a systematic operation.

In some very brief remarks at the late Washington Congress, I drew attention to the analogy between the cavity of the head and the cavities of the chest and abdomen. In the latter two we recognize various viscera, differing in functions and location, and recognized each by its own physical signs. We recognize, also, their diseases by symptoms and physical signs differing for each organ, and these differences enable us to diagnosticate disease of this or that viscus. In the cavity of the head we have recognized too much only one viscus—the brain. But, I argued, the various cortical areas or centres should be regarded as analogous to so many viscera,

[1] Bergmann: Chir. Behandl. Hirn Krankh., p. 52.

[2] The Medical News, Oct. 6, 1888, p. 401.

fused into one mass physically, differentiated functionally. We can recognize disease of the arm, or face, or speech-centres by the differing locality of the lesions, and by the differing symptoms, as palsy of the face, or the arm, or aphasia, no less than by means similar we recognize diseases of the stomach, or liver, or kidney.

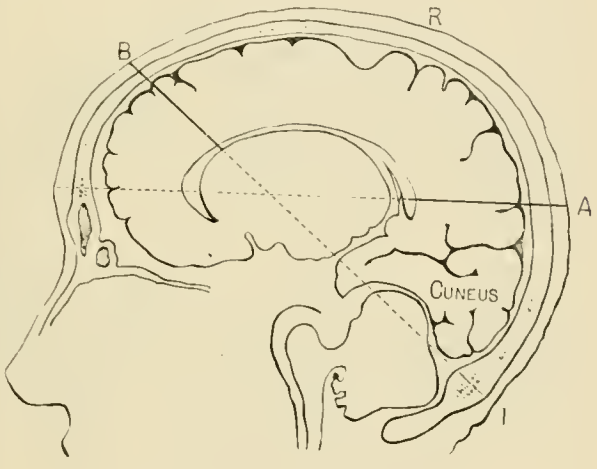
I would go further now, and draw a similar analogy between the serous membrane of the abdomen and that of the brain, and plead for a similar treatment for both in case of similar diseases. As we now open the belly and drain in tubercular peritonitis with such remarkable success, I would propose that we do precisely the same for the brain. That it can be done with precision and without serious injury to the cerebral tissues the history of the present case, I think, abundantly shows; that it is even *more* urgently necessary in the brain than in the chest or belly seems clear when we consider the relative effects of pressure in the two cases. In the chest or belly the walls are more or less yielding, and the viscera hollow or spongy, to a large extent. They can bear great and long-continued pressure with but little damage to their ultimate integrity, or to life, if the pressure be relieved within any reasonable time.

Not so in the cranium. The walls are rigid bone, and the brain can undergo but little pressure, and for a brief time (except it be gradual, as in chronic hydrocephalus) without inviting death. The fatal issue is so uniform that *any* means that holds out a reasonable hope of relief, even though it involve great risk to life, should at least be tried; and the proposal in the present paper seems, at least, to involve but a moderate danger to life with a reasonable probability of success.

It may be objected that much draining of cerebro-spinal fluid would be dangerous. I answer, first, we do not know till we try. Secondly, in my brain tumor case (*American Journal of the Medical Sciences*, Oct. 1888) there was probably a very slight wall between the cavity occupied by the tumor and the lateral ventricle. This wall subsequently ruptured, and gave exit daily to a quantity of cerebro-spinal fluid sufficient to wet an ample sublimate dressing continuously for three weeks. In Mr. Horsley's case of spinal tumor the same abundant drainage continued for a long time. In the *Comptes Rendus* (1888, cvi. 1693) Lucas Championnière reports a case in which no ill results followed such an abundant flow of the cerebro-spinal fluid as to wet the dressings, the pillow, and the bed. Such abundant and long-continued drainings do not, therefore, seem to be a danger. Thirdly, experience may show us that possibly in the head, as in the abdomen, simple evacuation of the fluid without its continuous drainage, may be not only feasible, but best. Of course, for pus in the ventricles the drainage should be prolonged, if, indeed, so fatal a lesion allow of any treatment.

As to the technique, I have made some dissections and trials on the cadaver, with the help of Dr. Wm. J. Taylor, with the following results: We must avoid (1) the motor zone; (2) the neighborhood of the fissure of Sylvius, on account of the middle meningeal and middle cerebral arteries and their branches, and also because access to the ventricle can only be had here through the island of Reil and the basal ganglia. Hence, the first trephine opening in the present case should be rejected as unsuitable. But it must be remembered that it was chosen in this case not to puncture the ventricle, but the temporo-sphenoidal lobe. Only the wide distention and overlapping of the lateral ventricle, in fact, saved me from doing harm, I suspect, by my drainage tube. (3) We must avoid known sense-centres, and utilize, so far as other considerations allow, the so-called "latent zones."

FIG. 1.



(Drawn by Dr. John M. Taylor.)

Antero-posterior section of the head one-half inch from the middle line. R, fissure of Rolando; I, inion; A and B (solid), the lines of puncture, the dotted lines showing their imaginary continuation to the opposite fixed points.

Moreover, the way in which punctures are described in this present paper, and most others, is extremely inexact and unsatisfactory. The exact point of the trephine opening is noted, and then the puncture is described as "downward and forward," "forward and a little inward," etc. I propose to substitute for these loose descriptions, the exact point on the skull at which the line of puncture would emerge were it prolonged.

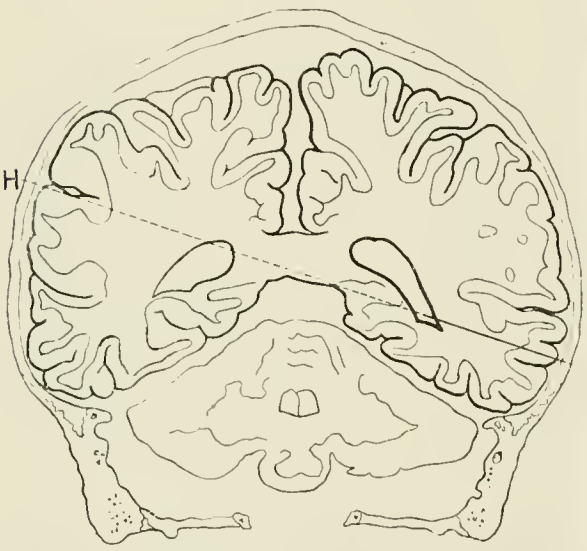
Provisionally, therefore, and until experience will show us better, I would propose three routes as practicable.[1]

[1] Dr. Harrison Allen (The American Journal of the Medical Sciences, July, 1873, p. 224) proposed at autopsies to examine

I. Trephine half-way from the inion (the external occipital protuberance) to the upper end of the fissure of Rolando, half to three-quarters of an inch to either side of the middle line. Puncture toward the inner end of the supraorbital ridge of the same side (Fig. 1, A). The puncture will pass through the precuneus, and the normal ventricle will be struck at some point in the posterior horn at from two and a quarter to two and three-quarters inches from the surface of the scalp.

II. Trephine at one-third of the distance from the glabella to the upper end of the fissure of Rolando, and half to three-quarters of an inch to either side of the middle line. Puncture in the direction of the inion (Fig. 1, B). The puncture will traverse the first frontal convolution well in front of the motor zone, and the normal ventricle will be struck in the anterior horn at about two to two and a quarter inches from the scalp.

Fig. 2.



(Drawn by Dr. John M. Taylor.)

Transverse section of the head one and a quarter inches behind the meatus. The continuous line shows the line of puncture, the dotted line its imaginary continuation to the opposite side of the skull.

III. Trephine one and a quarter inches behind the meatus, and one and a quarter inches above Reid's base-line. Puncture toward a point two and a half inches directly above the opposite meatus (Fig. 2). The puncture will traverse the second temporo-sphenoidal convolution, and enter the normal lateral ventricle at the beginning, or in the course of the descending cornu at a depth of about two to two and a quarter inches from the surface.

the fluid in the ventricles "by a vertical incision made from the vertex of the brain about six lines to the outer side of the great longitudinal fissure," an incision that will always reach the ventricles, but would injure the motor centre.

I have endeavored to give these points for trephining less in inches than in proportionate parts between fixed points, which is the better method. In the third route the measurements are for an adult skull, and are to be somewhat reduced for children. The depth necessary for the puncture can only be stated approximately (*a*) on account of the point of emergence into the ventricle varying with slight differences in direction; (*b*) on account of different thickness of the skull, and overlying soft parts; and (*c*) variations in the diameter of the entire skull from youth to age, and also in different adults. All these are measurements to a normal ventricle. In a distended ventricle from effusion the distances would be proportionately less.

The posterior route has the advantage of better drainage. But whether this will be really an advantage is a question. Experience may prove that evacuation of the fluid without drainage may be best. It avoids the cuneus and will not therefore produce hemianopsia.

The anterior route has two disadvantages: first, the scar on the forehead, and, secondly, unless great care is used in directing the puncture and its depth, the corpus-striatum may be injured. Compared with the danger of the disease the first objection is slight, and in a distended ventricle the second would lessen *pari passu* with the degree of the distention. The advantages are that it is high enough to avoid the frontal sinus, injures no known centre, and if evacuation and not drainage be desired this will easily give it.

The lateral route has the great advantage that, in a case like the one here reported, in which there might be a reasonable doubt as to whether there was an abscess of the temporo-sphenoidal lobe, or dropsy of the ventricles, both explorations could be made from one trephine opening. It could either be made to favor drainage if dependent, or to hinder it by lying with the operated side up. It penetrates a possible centre for hearing of the opposite side, but as it has been utilized for puncture in a number of cases of abscess, in the temporo-sphenoidal lobe, and no ill result has followed as to hearing, this objection would seem to vanish. At the ventricular end of the puncture it has the danger of possible injury to the thalamus, but this, I suspect, in a distended ventricle would not be very great. On the whole, I should at present favor this route until we find a better one.

An inch or a half inch trephine opening having been made, the dura should be examined. If it pulsate, bulges in the wound, and is tense and elastic to the touch, it will confirm the diagnosis; should it be tense, elastic, and bulging, but not pulsate, abscess or tumor should be suspected and sought for. The diagnosis of dropsy of the ventricles having been confirmed, the dura should be incised conically

and the grooved director now be introduced in the direction, and about the depth above indicated, unless fluid is found more superficially. If the first puncture does not reveal fluid, a second or a third may be made. When found, it should be evacuated by the introduction of a dressing or hemostatic forceps. I should then introduce a drainage tube for twenty-four hours or more, according to circumstances. The rest of the treatment would be the usual one in brain cases.

A STUDY OF SOME OF THE PYOGENIC BACTERIA AND OF THE GERMICIDAL ACTIVITY OF CERTAIN ANTISEPTICS.

BY ROSWELL PARK, A.M., M.D.,
PROFESSOR OF SURGERY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF BUFFALO.

AT the present day, after the researches of Scheurlen, Rosenbach, and others, it seems hardly necessary to take any position in defence of the statement that there is no suppuration without the previous presence of some bacteria, and the writer prefers not to enter upon this part of the question at all; but there are a few points in connection with the action of pyogenic bacteria and their growth in the presence of the various antiseptics, to which he would like to call attention.

For present purposes we may speak of the three or possibly five varieties of staphylococcus, and the two varieties of streptococcus known to pathologists, disregarding most of the other ten to fifteen forms of bacteria known to be concerned in the possible production of pus. The writer has been studying the physical properties of these two generic forms in connection with the clinical phenomena attending their appearance. His own researches have led him to agree thoroughly with Ogston as to the biological and pathological differences between these two forms. From his own researches he had about arrived at conclusions which had been already carefully summarized by Krantzfeld in a thesis published two years ago in Russian, but which had only recently come to his knowledge through translation. Without endeavoring to give all the facts upon which these conclusions are based, the essential items may be stated as follows: All the staphylococcus forms, including the pyogenes albus and aureus and the citreus albus and flavus, grow more rapidly than the streptococcus; they grow better in the absence of oxygen; they more easily enter the blood-current, and are by it more quickly disseminated; thus phlegmons caused by staphylococci pursue a more acute course both in time and in intensity of disturbance, and the various cases of septicæmia and pyæmia developed in consequence thereof seem to be of a more rapid or overwhelming character. In cultures the staphylococci remain active for a long time; old cultures of them emit a well-marked odor much like that of starch paste, as Krantzfeld has noticed, and this odor can be frequently recognized in old

dressings which have become saturated with pus. The streptococcus forms grow more slowly, seem to require more oxygen, and manifest a disposition for the lymphatic vessels rather than for the blood-vessels; it is well known that the streptococcus erysipelatosus is propagated mainly in the lymphatic current.

Phlegmonous inflammations caused by streptococci are either of the nature of true erysipelas, when caused by its specific streptococcus, or take the form of a diffuse cellulitis, in which, if pus form, it does so more slowly. The phlegmons caused by the staphylococcus are usually localized, even if extensive, whereas those in which the streptococcus is found are quite likely to be connected with multiple or somewhat distant abscess formations. For example, in a case of erysipelas or erysipelatoid inflammation of the palm of the hand, we are quite likely to get an abscess in the axillary glands, a thing which would be quite uncommon if the staphylococcus-forms alone were at fault. With regard, however, to their powers of systemic poisoning there is, perhaps, but little difference; both may alike cause septicæmia and pyæmia—through the action of specific phlebitis and the dispersion of septic thrombi, or through a poisoning of the system by ptomaines. Nevertheless, when a systemic infection is caused by streptococci, the abscesses seem to be confined rather to the serous membranes; for example, Heubner's multiple infectious inflammations

of the serous membranes of children, and Volkmann's acute purulent synovitis. When this systemic infection is caused by staphylococcus, we see during the active period of growth—that is, during adolescence, that there is a tendency to inoculation of the pyæmic process in the bone, and then we have clinical manifestations of acute infectious osteomyelitis, whose acuteness and ravages in some cases are well known. One who has seen many of these cases will be quite likely to agree with Krantzfeld and Rodet, that acute infectious osteomyelitis represents a form of non-traumatic pyæmia.

During the past year and a half the writer has, in connection with his former assistant, Dr. Matzinger, carefully investigated the biological character of pus from fifty-two different patients, and presents below a table giving a summary of the results of his examinations. The method has been similar to that generally adopted, a drop of pus being removed on a sterilized needle at the moment of its evacuation, transferred to gelatine or agar, and then carefully developed through successive generations until its bacteria could be identified. Only one opportunity of examining pus from hypopyon presented itself. This has been of especial interest, because it has been stated by some writers that pus, in which bacteria were present, could not disappear spontaneously. In this particular instance the anterior chamber was tapped, and the pus evacuated was examined with the result given below. The anterior chamber, when filled with pus, was not further disturbed and the pus in time disappeared by apparent absorption.

Simultaneously with these experiments another series was carried on to see the inhibitory power of various antiseptic substances, either recent or old. Jellies were prepared containing the percentage or proportion of the drug experimented with, as stated below. The bacteria experimented with were the pyogenic and some of the other specific forms, as well as one or two of the chromogenic. The table presented herewith will show the result obtained after careful exposure and cultivation in the thermostat for a sufficient length of time. It will be observed that iodoform makes a very poor showing when studied in this light, and this leads me to reiterate a statement frequently made in other connections, that oxide of zinc has all the good properties of iodoform and scarcely any of its disadvantages. In every way in which I have tested it, I have found it to yield, experimentally and clinically, just as good, if not better results.

It will be seen also that hydronaphthol and boric acid appear to best advantage under these tests. This also bears out personal experience, since the writer has perhaps never been disappointed in the use of either of these drugs; while for nearly two years he has been using hydronaphthol solutions for every purpose for which he previously used carbolic acid.

It is intended to make a further systematic study of other antiseptics, but it is hoped that these data will have a sufficient value to justify their publication before the list has been completely gone through with.

The results above reported were presented in slightly different form to the American Surgical Association at its meeting in September last.

THE TOE REFLEX.

By WHARTON SINKLER, M.D.,

Attending Physician to the Philadelphia Orthopœdic Hospital and Infirmary for Nervous Diseases, and Neurologist to the Philadelphia Hospital.

About two years ago I showed at the Philadelphia Neurological Society a patient in whom I demonstrated what I called "the great toe reflex." I had seen this phenomenon several times before and have since then studied it more fully.

The "toe reflex" is met with only in cases in which the knee-jerk, ankle-clonus, and other tendon "reflexes" are strongly developed. It is elicited in the following manner: The patient lying on his back with his legs extended, the observer grasps the great toe and flexes it strongly; there immediately follows involuntary flexion of the foot, then flexion of the leg occurs, and lastly, the thigh is flexed on the pelvis. Usually the whole limb returns at once to the position of extension. It seems to make no difference whether the toe be flexed suddenly or gently and gradually: in either case the same series of movements as above described follows. Flexing all of the toes at the same time causes the same result. The order and manner of the act are very much like the result of irritating the sole of the foot —"the plantar reflex."

I have recently studied this reflex in a case in which the question of the influence of pain is removed. The patient is a woman in the nervous wards of the Philadelphia Hospital, who has complete paralysis of motion and sensation below the sixth dorsal vertebra. There is an angular curvature at this vertebra, the result of a fall from a window. Below this point there is no sensation to pin-pricks, nor is there bleeding from the punctures. The knee-jerk is grossly exaggerated, but the ankle-clonus cannot be developed on account of the muscular rigidity. The plantar reflex is excessive on both sides. On flexing the toes, either the great toe alone or all the toes together, the foot is quickly and strongly flexed, then the leg is drawn up, and finally the thigh is flexed on the abdomen. The patient is entirely unconscious of the movement either by reason of pain or from any sense of the leg moving.

In lateral sclerosis, in which the knee-jerk is excessive, and in some cases of old hemiplegia, the "toe

reflex" is generally well marked; but it is most strikingly present in cases of pressure disease of the cord, either from injury of the spine or caries.

I have called this phenomenon a reflex because it has seemed to me like one, but it may in part be explained as the result of a tendon pull. For instance: Flexing the toe pulls on the flexors of the foot, which in turn contract, drawing the foot upward; but the flexion of the leg and thigh are not capable of the same explanation.

The "paradoxical muscular contraction" of Westphal somewhat resembles the toe reflex, but differs from it in many respects. The former is a contraction of a muscle after it has been suddenly relaxed. For example, if the foot is grasped and passively flexed on the leg, the tibialis anticus may contract and keep the foot flexed for some minutes.

MEDICAL PROGRESS.

Creolin-iodoform.—To render iodoform disinfectant and deodorant, JAKSCH, in No. 40 of the *Pharm. Post*, recommends admixture with creolin. One to two per cent. of the latter well rubbed up with iodoform makes a somewhat brownish powder of a mild aromatic odor, soluble in alcohol and in ether; water takes up the creolin, leaving the iodoform undissolved. This combination is applied to wounds, ulcers, abscesses, etc., with results at least not less favorable than from pure iodoform; it would seem as though this preparation would diminish secretion in a greater degree as well as stimulate the granulation process.—*Wiener medizin. Presse*, No. 42, 1888.

Gonorrhœa in the Female.—A useful article on gonorrhœa in the female is published in the current number of the *Lyon Médical*, by M. HORAUD. The remarks are based upon 5090 cases of the disease which had come under the observation of the author. Discussing the microbic origin of the disease, he says that Hallier, of Jena, in 1872, described a micrococcus in the gonorrhœal discharge, and even in the blood of patients who had been attacked with gonorrhœal rheumatism. But the honor belongs to Neisser of discovering, in 1879, the true microbe of gonorrhœa, and of pointing out the method of isolating it, and of proving its connection with the causation of the disease. To this microbe Neisser gave the name of gonococcus, which has since been retained. Every discharge from the urethra, vagina, uterus, anus, or the blood of the menses or the lochia, can occasion urethritis in man, but gonorrhœa only follows when the discharge contains gonococci. The purulent ophthalmia of newborn children is only of a gonorrhœal nature when it is contracted from a mother suffering from gonorrhœa; hence it is to be assumed that it is only in certain cases of ophthalmia neonatorum, in the pus of which gonococci will be found.

The author enters fully into the subject of how to collect pus for examination for the gonococcus from the female generative organs. Urethral gonorrhœa may persist a long time in women—some months, and even years. He has seen patients the pus from whose urethra still contained gonococci at the end of four and ten months, and of two years, without reinfection having taken place to account for the disease. No cases of auricular blenorrhagia, nor of nasal or buccal, had come under his observation. A short time ago, however, he published a note of urethral gonorrhœa in a man which had been contracted during a coitus *ab ore*. The woman from whom the contamination came, and who had lent herself freely to this kind of occupation, submitted to a minute examination, but no buccal lesion was detected, nor were there any traces elsewhere about her of gonorrhœa. The author concluded that the contagion had been derived from the gonococci deposited in the mouth during a previous coitus.

In the treatment of gonorrhœal discharges he speaks highly of nitrate of silver, both in solution and in the solid form. Even weak solutions of the drug of 0.30 of a gramme to 100 grammes of distilled water are successful in reducing old chronic discharges. From comparative trials which he has made of nitrate of silver and of sublimate solutions, both in cases of urethral gonorrhœa and purulent ophthalmia of infants, he is confident that the former drug is in every respect superior, and yields better results.—*Medical Press*, Oct. 31, 1888.

Treatment of Bright's Disease.—Avoid moist climates and sudden changes of temperature. Avoid highly seasoned food and eggs; pursue as far as possible the milk diet; cut off wine, beer, and brandy. SENATOR allows veal and pork, vegetables, fruit, and milk, but prohibits beef. Wine and water for a beverage.

SEMMOLA follows the preceding rules, with the addition of the following to be taken as a drink:

R.—Iodide of potassium	. .	1 part.
Phosphate of sodium	. .	2 parts.
Chloride of sodium	. .	5 "
Water		1000 " —M.

BAMBERGER insists on milk diet exclusively and gives iron:

R.—Sulphate of iron,		
Bicarbonate of sodium,		
Extract of dandelion	. .	āā 5 parts.—M.

Make sixty pills, and give three in the morning and three at night.

He also prescribes quinine obtained from the infusion of Peruvian bark.—*Révue Général de Clinique Thérapeutique.*

The Removal of Warts by Carbolic Acid.—PROF. B. FRÄNKEL, in the *Wiener medizinische Presse*, Oct. 1888, recommends the following method for the removal of warts: The skin surrounding the wart should be covered with cotton, and thus protected. Then, by means of a glass rod, apply the liquid carbolic acid to the wart and allow it to dry. No pain is perceptible. In the course of two or three days a part of the wart will fall off. Renew the application until all has been removed.

Antipyrin as a Uterine Sedative.—WINDELSCHMID (*Allg. med. Ctrl.-Ztg.; Union Méd.*) prescribes enemata of thirty grains of antipyrin before or during menstruation in cases of dysmenorrhœa. In two obstinate cases he has known this treatment to prove particularly satisfac-

tory, three doses being given (at intervals of twelve hours between the first and second, and of twenty-four hours between the second and third). He notes profuse sweating and slight ischuria as among the inconveniences of the method, and adds that it has sometimes been necessary to give a glass of wine or milk to avert imminent collapse.

Rivière (*Gaz. Hebdom. des Sci. Méd. de Bordeaux; Union Méd.*) has found the same drug very efficient in allaying after-pains, in doses of fifteen grains by the mouth. A single dose proved enough in twelve out of twenty-eight cases, and two doses, at an hour's interval, in twenty out of thirty-eight cases. When it fails, he says, retention of the placental débris or the like is to be suspected. He states that the drug is not eliminated by the milk.—*New York Med. Journal*, Nov. 17, 1888.

Antipyrin in Diphtheria.—A case of diphtheria, in a child of five years, is reported as cured by the use of this drug locally. Although the classic treatment had been vigorously followed, and the throat carefully cleansed, the membranes spread and completely covered the pharynx. A solution of antipyrin in water, 10 : 100, was applied, the patient making a perfect recovery.—*Gaz. Hebdomadaire des Sciences Médicales.*

Nephrectomy.—Schmidt, of Cologne, before the Surgical Section of the Sixty-first Congress of Naturalists, clearly and concisely reports Bardenheuer's results with nephrectomy from 1879 to 1888. During a period of time in which the kidney was extirpated thirty-five times, nephrotomy was performed but twice. This is explained by the fact that the radical operation was performed in twenty-three instances for tuberculosis, abscess, pyonephrosis, and pyelitis. Only in four cases was operation indicated by tumors; the kidney was removed in eight for hydronephrosis, cystic kidney, and injury to a ureter during amputation of the uterus. In the operation Schmidt recommends the single or double trap-door flap and packing, with subsequent secondary union. Eight patients died during the first two weeks, two later; in only one death is the operation said to have been responsible—on the other hand, a contracted kidney existed, so that nephrotomy was indicated. In two cases, sepsis, which was present before the operation, caused death, in one collapse; a child of three months died in thirty-six hours with convulsions, another from scarlet fever, one patient from metastatic carcinoma, one from amyloid degeneration. Both nephrotomies (for acute traumatic hydronephrosis and for pyonephrosis) terminated fatally.

In suppuration of the kidney (tuberculosis, abscess of the kidney, and pyonephrosis) there is mostly a typical form of perinephritic abscess forming between the adipose capsule and the kidney, so that the whole tumor assumes the shape of the organ; ulceration, externally, is rare in these cases, whereas the perinephritic abscess in a wider sense, suppuration of the capsule, is more likely to ulcerate through. Schmidt and Bardenheuer consider extirpation indicated in suppuration of the kidney, as this condition is the primary affection and the perinephritic abscess the secondary, and even at the operation it cannot usually be determined whether the abscess is simple or tubercular, or whether several foci of disease are present. Bardenheuer cuts directly through the thickened capsule into the renal tissue and shells out the abscess, permitting the capsule to remain; by this means, on the one hand, infection is more readily prevented, and on the other the firm capsule prevents the walls of the cavity collapsing.

Pyelitis, hydronephrosis, and pyonephrosis have a common etiological relation to permanent or transient, total or partial closure of a ureter. The last condition is often occasioned by parametritis; if indurated masses are present, instead of catheterizing the ureter, this should be treated extraperitoneally. Should a ureter be cut in extirpating the uterus, the corresponding kidney should be removed by the lumbar incision. In the discussion, Sprengel, of Dresden, related that he had recently removed a large hydronephrotic kidney from a child of four months by lumbar incision conjoined with an incision at right angles, extending anteriorly. A cure resulted.

Krönlein objected to indiscriminate extirpation and accorded nephrotomy its proper position.—*Berlin. klin. Wochenschr.*, Oct. 15, 1888.

Expectorant Mixture.—

℞.—Terpine . . . . . 10 grammes.
Glycerin . . . . . 60 "
Dissolve by the aid of gentle heat.

The dose is regulated by the amount of terpine it is desired to give, there being 15 grains of terpine to a spoonful of this mixture. It may be given in any syrup. —*Revue de Thérapeutique*, October, 1888.

Treatment of Sweating of Hands and Feet.—Unna recommends for this affection, when the parts are cold, that before the patient goes to bed he should bathe the affected parts with hot water to which has been added some irritating substance, such as camphor, mustard, or vinegar. Then, after drying, the part should be enveloped in an ointment which will cause hyperæmia, such as one of turpentine and ichthyol, each five parts, to oxide of zinc ointment, ten grammes. In the morning the ointment is to be washed off and the parts are to be rubbed with ice-cold water, the friction being continued till hyperæmia and warmness of the skin are induced; then the skin is to be powdered with a powder containing mustard flour. If the feet are affected, the stockings should be powdered before they are put on. Where the parts are warm, the hot and cold baths are to be omitted and ichthyol is to be used; lukewarm baths in the evening, followed by two and a half per cent. ichthyol ointment, washing off with lukewarm water and ichthyol soap in the morning and leaving on some of the dry soap-suds, is the method of treatment.—*New York Med. Journal*, Nov. 17, 1888.

Glycerin Suppositories.—Boas (*Pharm. Ztg.*, No. 80) recommends hollow suppositories of cocoa butter, to contain five to thirty minims of glycerin. In cases in which glycerin proves the appropriate remedy, fifteen minims suffice to produce a copious evacuation. The indication for the use of glycerin is atony of the large intestine, whereas, in cases of obstipation dependent upon atony of the stomach or upon defective digestion of the small intestine, other laxatives may take the place of glycerin.—*Munchener medicin. Wochenschr.*, Oct. 16, 1888.

A New Antiseptic.—From extensive researches and experiments, Dr. Berens concludes that the fluosilicate of sodium is a better antiseptic than chloride of mercury or phenic acid, for preventing the development of bacteria, and it is also a powerful deodorizer. He uses it in gonorrhœa in a 1 to 2 per cent. solution with a marked amelioration of symptoms in three days' time. The same success attends its employment in catarrhal conjunctivitis and purulent ophthalmia. He recommends its use in leucorrhœa, suppuration of the middle ear, and in mucous fluxes generally.—*Gaz. Hebdomadaire des Sciences Médicale.*

Incompatible Antiseptics.—The *Journal de Médecine de Paris* points out the incompatibility of the following commonly prescribed substances:

Corrosive sublimate and iodine.
Corrosive sublimate and soap.
Phenic acid and iodine.
Phenic acid and permanganate of potassium.
Iodine and soap.
Salicylic acid and soap.
Salicylic acid and permanganate of potassium.
Oil, soap, or glycerin, and permanganate of potassium.

Trentment of Sycosis.—Unna, in the *Monatsschrift für prakt. Dermat.*, No. 11, 1888, gives his plan of treatment of folliculitis barbæ, or non-parasitic sycosis. He regards shaving as a very important part of the treatment. This is to be followed in bad cases by the constant application of his carbolic-mercurial or resorcin-plaster muslin; or, if the patient will submit to a nightly treatment only, a zinc-sulphur salve muslin is to be worn during the night, followed in the morning by epilation of the pustules, washing of the part, and the application of a five per cent. alcoholic solution of resorcin to each affected follicle. The whole series of his "reducing agents," such as sulphur, ichthyol, resorcin, pyrogallol, and chrysarobin, may be used at night in ointments of two to five per cent. strength, or ichthyol may be employed in ten per cent. strength as a fomentation. Mercurial ointment with ten per cent. of carbolic acid and up to one per cent. of sublimate is also useful. If the patient will not allow the beard to be shaved, it will be harder to cure the disease, and we must proceed by the removal of each affected hair, washing out the suppurating hair follicle, and the application to it of a zinc-sulphur or weak resorcin-sublimate salve. Scarification does harm, and general epilation should not be practised. Only the diseased hairs should be plucked out. The rhinitis which is often present should be treated by the nasal douche with a one per cent. solution of ichthyol. For some time after the disease is practically cured the face should be shaved with sublimate soap, each hair that is diseased should be plucked and the follicle touched with an alcoholic solution of resorcin, and every night the face should be anointed with a resorcin or sublimate ointment or paste.—*New York Medical Journal*, Nov. 17, 1888.

Contribution to the Study of the Influence of Antipyretics upon Diabetes.—Dr. Volkoff (*Thèse de Petersburg*, 1888, and *Vratsch*, No. 27, 1888) undertook, in the clinic of Prof. Botkine, a series of experiments upon four diabetic patients, to prove the effect of various antipyretics upon this malady, with the following results:

Antipyrin, administered to these four patients gave excellent results, namely diminution of thirst and of the amount of sugar and urea eliminated—in short, marked improvement.

Acetanilide, given to three patients had no effect whatsoever; as much as sixty grains a day were taken.

Sulphate of thallin, administered to the same patients who were given antipyrin, and in the same doses, diminished the amount of sugar, but for a short time only.

Phenacetine, taken in the same doses of twenty grains, proved ineffective.

Salol, given to one patient in twenty grain doses, three times daily, diminished thirst, and the amount of sugar and urea very perceptibly.

Volkoff ascribes the difference in action of these various preparations, to the difference of the etiological character of this disease. According to his opinion, antipyrin proves only of service when the malady is due to a central nervous lesion. One of the patients on whom antipyrin had acted beneficially, died in his clinic, and the autopsy revealed a brain lesion as the cause of the disease.—*Bulletin Général de Thérapeutique*, Oct. 1888.

Antiseptic Pastilles in Diphtheria.—Vaumond (*Wiener medizin. Presse*, No. 42, 1888) recommends the following as a prophylactic in diphtheria, especially for smaller children who cannot gargle and in whom applications to the pharynx are difficult:

R.—Acid. boric.	20 parts.
Sodii benzoat. . . .	1 part.
Ol. thymi	½ to 1 part.
Sodii biborat. . . .	20 parts.
Acid. citric	12½ "
Ol. limonis . . .	1½ "
Ol. menthæ	½ part.—M.

Each pastille should weigh thirty grains and contain one-third of a grain of boric acid and one-thirtieth each of benzoate of sodium and of oil of thyme. As a solvent and basis, glycerin, water, gum, and sugar are used, and to give the mass consistence some gelatin is added.

Poisoning by Chromate of Lead.—Dr. Berthet read before the Société des Sciences Médicales de Lyon a paper upon the subject of poisoning by chromate of lead. The patient, a seamstress, used for her work yellow cotton; she was taken ill in the latter part of August with the following symptoms: Vomiting, albuminuria, cerebral excitement, etc. Patient died shortly afterward in a comatose condition, having previously suffered repeated epileptic attacks. The autopsy revealed congestion of the various viscera, especially of the lungs and kidneys. Chemical analysis proved a large deposit of lead in the brain.

Dr. Cornevin calls attention to the fact that chromate of lead is often used to color butter.—*Lyon Médical*, Oct. 28, 1888.

For Burns.—

Iodoform	4 parts.
Extract of hemlock . . .	2 "
Phenic acid	1 grain.
Unguent. rosæ	30 parts.—M.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, DECEMBER 1, 1888.

CREOLIN IN OBSTETRIC PRACTICE.

THE ideal antiseptic for practical use has yet to be found. An agent potent to destroy the causes and accompaniments of disease and favoring physiological processes is greatly needed. Bichloride of mercury fulfils best of known substances the first indication, but is distinctly noxious to living tissues. Carbolic acid, boracic and salicylic acids, and thymol have points of excellence, but lack the efficiency of mercury in pathological conditions.

Early in the present year creolin attracted the attention of German obstetricians and surgeons, by whom it has been extensively used. The substance, when concentrated, is a brownish-black oily fluid, of tarry odor, and aromatic, burning taste; it is obtained from English pit-coals by distillation. Easily soluble in alcohol, ether, and chloroform, with water it forms a homogeneous, slightly alkaline emulsion: further knowledge regarding its chemical composition is wanting at present.

Experience with intra-uterine injections of bichloride of mercury, in dilute solutions, has led continental obstetricians to regard its use in this manner as distinctly dangerous. In the clinics at Giessen and Prague this use of mercury has been abandoned. Sommer, writing of the experience of the Charité of Berlin, reports a mortality rate from this source sufficiently high to call attention to the fact. Virchow has demonstrated mercurial nephritis in parturient women, and has emphasized the dangers of its use in the anæmic and those in whom the parenchyma of the kidney is unsound. Géhé and Turgard have reported, recently, accidents from intra-uterine douches of mercurial solution. Boxall has called the attention of English obstetricians to the limitations to be observed in the use of mercurial injections. Credé and Winckel, in preparing a text-book for midwives, entrust them with carbolic acid, but not with bichloride of mercury.

A practical comparison of creolin and bichloride of mercury has been recently made by MINOPOULOS, in the Munich Frauen-klinik (*Münchener med. Wochenschrift*, No. 45, 1888). His material was 280 parturitions, equally divided between the two antiseptics. The results were, with bichloride of mercury: two cases of severe septic infection, thirteen cases of mild infection; with creolin, no severe infection, seventeen cases of mild sepsis. It was observed that the larger proportion of cases of mild infection occurred when creolin was used in one-half per cent. solution: this solution is, probably, too weak. A one per cent. solution was found especially useful in cases of fetid lochia, and a two per cent. solution as a stimulant and alterative in vaginal ulcers. These cases included the complications of pregnancy and parturition, and afforded a fair comparison.

Experiments upon bacteria by Esmarch and Eisenberg have shown that creolin, in one per cent. solution, retards the development of bacteria more efficiently than carbolic acid; in five per cent. solution it destroys pathogenic bacteria: creolin soap disinfects the hands more thoroughly than bichloride (1 to 1000) soap. Creolin does not injure the hands, and instruments of those who use it; it is an excellent deodorant. It has shown, up to the present time, no noxious properties, whether used externally or taken into the stomach. It deposits an insoluble tarry residue, when undisturbed for some time, which is the greatest practical objection so far observed to its use. Several preparations of creolin, domestic, English, and French, are available for obstetric practice.

The results obtained in surgery and obstetrics by others who have used creolin, invite the attention of the American profession to this antiseptic, and urge a trial of its virtues.

ADULTERATED AND IMPURE MILK.

The difficulties in the way of protecting the milk-supply of a city from adulteration and sources of

dangerous contamination are by no means trifling. Proper laws and ordinances proscribing adulteration under penalties, and their enforcement by a rigid inspection service may do much to prevent the more common forms of sophistication. But there is a danger, not so easily averted, in the possible contamination of the milk by pathogenic germs accidentally conveyed from different sources at the dairy or directly imparted by sickly cows, such, for example, as suffer from tuberculosis. It is not practicable to supervise continually all the dairies that supply a large city. The rigid enforcement of laws against tuberculosis in cattle will eradicate one source of the evil, but the accidental contamination of milk by disease germs is not so easily guarded against. Close supervision of the dairies would reduce the evil to a minimum, but this is difficult of execution. There is a want of knowledge upon this subject which should be supplied by instructive tracts issued to all those whose business it is to provide and deal in this important article of food.

Too great a risk is assumed in trusting to the honesty and intelligence of the milk purveyor or to the uncertain administration of laws for the protection of the supply. To this confidence many a young life has doubtless been sacrificed. Milk inspection is strongly to be commended, and no effort should be spared to render it as complete as possible; but no matter how satisfactorily conducted, it is the part of prudence to take the precaution of sterilizing all milk by boiling or steaming, a positive safeguard of easy application which physicians should feel it their duty to recommend day by day.

The United States cruiser "Boston" arrived last Saturday in New York Harbor with yellow fever on board. There are three persons sick, one of whom is Surgeon W. I. Simon, who is in a most precarious condition. Four deaths occurred on board during the sail northward from Port au Prince, Hayti. The Boston encountered a four days' gale of wind, and the consequent pitching of the vessel militated greatly against a favorable course in the disease in the cases of Surgeon Simon and of the four enlisted men who died.

The Vienna Medical Society has elected Dr. John S. Billings, of Washington, an honorary member.

Dr. H. D. Schmidt, the distinguished pathologist, who for many years has been connected with the Charity Hospital in New Orleans, died on the 23d ult.

Professors von Bergmann and Gerhardt were recently the recipients of an ovation from the medical students of Berlin, who formed in procession and marched past their residences.

Professor Du Bois-Reymond attained his seventieth birthday a few days ago, and the medical students made preparations to give him an ovation on the morning of the anniversary; but desiring to avoid all personal homage, he passed the day out of Berlin. A large number of messages of congratulation from all parts of Germany were forwarded to him.

Dr. Heinrich von Bamberger died at Vienna on the morning of November 9th, after a short illness. Born at Prague, December 27, 1822, he studied medicine in that city, receiving his degree in 1847. Part of his student-years were passed at the Vienna University, where Skoda and Rokitansky were then teaching. Subsequently he became second-assistant to the Public Hospital at Prague, and during the years 1851–1854 he acted as assistant to Prof. Oppolzer, at Vienna, and in the spring of 1854 was made Professor of Special Pathology and Therapeutics at the University of Würzburg. Here Bamberger developed great literary activity. In 1872, upon the death of his teacher Oppolzer, he was made his successor, in the chair of Special Pathology and Therapeutics at the University of Vienna. His principal works were: his *Treatise upon Diseases of the Heart* (Vienna, 1857); on the *Diseases of the Chylopoietic System*, published in 1855, and a second edition in 1864, which was translated into Dutch and Italian. In his death the Vienna school has lost one of her most distinguished exponents.

REVIEWS.

A Text-book of Pharmacology, Therapeutics, and Materia Medica. By T. Lauder Brunton, M.D., D.Sc., F.R.S. Adapted to the United States Pharmacopœia, by Francis H. Williams, M.D. Third edition. 8vo. pp. 1305. Philadelphia: Lea Brothers & Co., 1888.

Perhaps no book has been presented to the profession which aims and succeeds in giving so much of the three branches of pharmacological lore as does the one before us. From the fact that another edition has already been called for, we may fairly conclude that the book is increasing in popularity on both sides of the Atlantic,

which is not only complimentary to its author, but indicates that the medical profession is beginning to appreciate books which give more than a mere *résumé* of empiricism, and is beginning to understand the value of scientific deductions when made by a writer so thoroughly capable as is Dr. Brunton.

The new edition has been improved in so many ways that we have not space to mention them all in this brief notice. The most important of them, however, is the section on the action of drugs upon the eye. Antipyretics and their modes of action are also more fully considered, and by the use of small type for matters which are practically of little interest to general students, and yet are occasionally wanted for reference, a certain amount of space has been gained. Though the present edition contains 120 pages more than the second, the use of thinner paper has prevented much increase in the bulk of the volume.

We can cordially recommend the book as one of value to the physician who wishes to be brought into intimate touch with the recent advances of scientific therapeutics, and while we think it unfortunate that more of the space is not absorbed by consideration of the direct application of remedies to disease, we cannot but regard it as a work of which the author may be justly proud.

SOCIETY PROCEEDINGS.

MONTREAL MEDICO-CHIRURGICAL SOCIETY.

Stated Meeting, November 2, 1888.

The President, William Gardner, M.D., in the Chair.

Dr. Bell exhibited a case of

EXCISION OF THE KNEE

in a man aged forty-five years, cured in one dressing. The femur was rounded off to fit into a concavity in the tibia, as recommended by Dr. Fenwick, and the bones were held together by two nickel-plated nails. The first dressing was removed in five weeks. The specimen of diseased bone removed from the knee-joint was also presented; this showed large pieces of necrosed bone in several parts of the lower end of the femur.

Dr. Bell also exhibited a patient who had received an injury of the knee which had caused a

SEPARATION OF THE LOWER EPIPHYSIS OF THE FEMUR.

This had united in a bad position, so that the knee was very much bent inward, and the lower end of the shaft of the femur protruded through the skin. The parts were cut down upon, osteotomy performed, and the leg straightened. The result, as shown to the Society, was an admirable one.

Dr. Shepherd exhibited a patient who had suffered from

COMPOUND FRACTURE OF THE OLECRANON.

The separated fragments of bone were sutured with silk, the result being bony union. The patient, a man aged twenty-five years, whilst working on board a ship, was struck on the elbow of the left arm by the fan of the ventilating apparatus; this split the olecranon process vertically, and opened up the joint. When he came to the hospital the wound was covered with dirt, and on separating the lips of the wound it was seen that the olecranon process was split into two portions longitudinally, and the joint was opened. After cleansing the wound, the separated fragments of bone were brought together with two silk sutures and the wound closed, a small drain being left at the lower end. The dressings of gauze and jute were left on for three weeks, and when removed the wound was perfectly healed and the bone found united. The patient went to work a month after the accident, but for some time the movements of the joint were rather limited. The accident happened in July last. At present he has as good motion in the injured elbow as in the other.

Dr. Stewart exhibited a patient suffering from

PROGRESSIVE HEMIATROPHY OF THE FACE,

and gave the following account of the case: The patient, a boy aged fourteen years, had always been in good general health. No history of any facial atrophy. In those parts of the face innervated by the left trigeminus, especially by its two lower branches, the skin, subcutaneous tissues, the muscles, and the bones of the left side of the face are greatly wasted. The muscles appear to have suffered less than any of the other structures. The left half of the tongue is wasted, but the palatine structures on the same side are as well developed as they are on the right; the left nostril is large on the atrophic side, apparently owing to wasting of the turbinated bones and mucous membrane. The special senses are fully as acute on the left as on the right side. There is no disorder of common sensation, the senses of touch and temperature are equally acute on both sides. Repeated measurements, taken with the differential calorimeter, are negative. The angle of the mouth is slightly drawn to the atrophic (left) side. The electrical reaction to the faradic and galvanic currents is normal. In fact, it takes fewer milliampères to bring about contraction on the atrophic side; this is, no doubt, due to the wasted skin of that side offering less resistance to the passage of the current.

The wasting was first noticed about two years ago. During the first few months it made rapid progress, but during the past year patient says he is not aware of any marked progress. Two years before the commencement of the atrophy the patient had the left half of his face and left ear severely frost-bitten. It was suggested that probably the profound irritation which the sensory nerves sustained as the result of this, had induced changes in the nuclei of their origin.

REVERSION IN A PIGEON WITH TUBERCULOSIS.

Dr. T. W. Mills exhibited specimens from a pigeon the subject of general tuberculosis. He said the specimens were of both physiological and pathological interest. The pigeon was a perfectly white Jacobin, bred by himself from a pair of red birds, and he asked if it was a case of Albinism, a "spert," or an instance of reversion, as understood by Darwin, or what breeders term "throwing back." Albinism is well known among wild animals (rabbits, squirrels, etc.), and "sperts," or the appearance of variations not to be accounted for on any well-recognized principles also occur. Upon the whole, Dr. Mills thought this was a case of reversion. A white cross has

been known to show itself in pigeon-breeding after nine years of careful breeding. The subject had been considered important by Darwin, for it was largely upon the evidences of reversion to forms and markings peculiar to wild species that this naturalist founded his views that our domestic animals were derived from a few wild forms.

The bird shown had died two days previously, after ailing for about three weeks. A post-mortem examination showed that the organs contained tubercles in every stage of development and degeneration. The moulting season is a very trying period for birds. Dr. Mills related an observation he had made to illustrate this; a young cockerel, getting its second feathers, was noticed to be bleeding in the region of the tail. Examination showed that the blood was oozing from the roots of the new feathers. The abundance of blood diverted to the skin, and a corresponding demand for nervous energy in this quarter, explained why other parts should suffer, and illustrated the general views he entertained as to the part played by the nervous system in the vital processes, and the practical importance of maintaining the balance of function so often disregarded both by brain-workers and by muscle-users (athletes). The case seemed to him very clear.

The specimen also illustrated two principles that seemed to hold in regard to tuberculosis among the lower animals: (1) The extreme rapidity of the process; and (2) the extensive character of the lesions. This bird had been ill only three weeks, and was fairly well nourished at death. The tubercles were very widely distributed, the organs inflamed and bound together by recent adhesions. Owing to enlargement of the organs and pressure the apex of the heart was squeezed to such an extent that it must have been functionless, while the immediate cause of death was, in all probability, mechanical interference with the action of the heart.

Dr. Shepherd said he was much interested in the case of reversion exhibited by Dr. Mills, and said these are not at all uncommon in the human family. There is in nearly every person's anatomy some form of reversion to an earlier type. As bearing on these reversions of color, he instanced the occurrence of a red head in a family in which it had not been seen for several generations. He also mentioned a case which had lately come under his observation, viz., that of a cow having two rudimentary metacarpals developed in the fore limb, these being the rudiments of second and fifth toes.

Dr. Smith asked Dr. Mills if such a pigeon as he had shown was fit for food; he stated that no doubt many birds that were offered for sale on the market were subjects of tuberculosis.

Dr. James C. Cameron reported a case of

NERVOUS(?) DIABETES, WITH HIGH TEMPERATURE, IN A PUERPERAL WOMAN.

The patient, aged twenty-two years, multipara, was admitted into the Montreal Maternity, October 10, 1888, in active labor. Her first child was born in May, 1886. During present pregnancy she suffered much from morning sickness, occasional hemorrhages, and painful micturition. Her matrimonial relations had not been happy; her husband left her some time before admission; she was an inmate of the Sheltering Home. She is subject to very violent outbreaks of temper. Labor was short and uneventful, lasting altogether six and a half hours; her convalescence was normal for the first week; about that time she was fretting about something, subsequently it turned out to be an expected letter. On the morning of the eighth day her temperature was 99.4°, and in the evening rose to 100.6°, and the next morning was 102.2°. The urine was examined and showed a trace of sugar. Lactation was well established and was normal; appetite good; tongue clean; lochia normal; and urine not increased in amount. Fehling and Pavy's tests used to detect the sugar. There was no great thirst. At times her temperature would run up to 105°, and as the temperature increased so did the amount of sugar; the temperature seemed to rise with the least excitement, and the pulse was never high, even when the temperature was 105°.

Dr. Cameron went on to say that sugar had been frequently found in the urine of puerperal women during lactation, and M. Blot was the first to claim that its presence is then physiological. He asserted that sugar could be found in half the observed cases of pregnancy; that it begins to appear coincidently with the milk, increases in quantity as the milk increases, and disappears when lactation ends; and that these phenomena are observable in other mammalia. M. Leconte, on the other hand, disputed Blot's conclusions, denied the existence normally of sugar in the urine of nursing women, and said that Blot mistook uric acid for sugar. Beneke and others, however, have confirmed Blot's observations.

Dr. Cameron said that in his case sugar was not found till after lactation had been fully established; it increased as the temperature rose and the milk became scanty, but as the temperature fell the milk again became abundant, and evidently lactation had nothing to do with the appearance of the sugar. That the nervous element had much to do with the production of the sugar, he had no doubt, as when nervous phenomena began sugar increased, and when they disappeared the sugar also disappeared. On the 27th sugar was absent, and the patient was preparing to leave the hospital that day, but when Dr. Cameron made his visit he told her she had better remain a few days longer; she immediately began to cry and fret, and although her temperature did not rise sugar reappeared in the urine.

The reader of the paper said he could quite exclude septic trouble and local mischief, troublesome lactation, sore nipples, constipation, digestive troubles, and other causes which sometimes cause rise of temperature. Attention was directed to a chart which was exhibited, and which showed the peculiar action of the temperature, rising during waking hours and falling during sleep, without corresponding variation in pulse.

That the temperature caused the glycosuria, or the glycosuria the elevation of temperature, was not at all likely, both conditions seemed rather to have been due to some peculiar nervous influence.

Dr. T. Wesley Mills, in speaking of the cases detailed to the Society by Drs. Stewart and Cameron, referred to the views he had recently presented on the relation of the nervous system to the vital processes, at the late meeting of the Canadian Medical Association, at Ottawa, and also at the Washington Congress in September. He thought it would greatly widen our conception, and give truer views both of physiological and path-

ological processes, if vital processes were regarded as a related whole, the parts of which could not be isolated and placed out of relation with the rest. That such had grown up in our midst was the result of book treatment, and had no foundation in nature. What is "nutrition?" Can it be considered apart from secretion, heat-production, etc.? Dr. Mills maintained that it could not without the danger of getting artificial conceptions. Were these trophic nerves? was a question subordinate to: Does the nervous system in mammals regulate the entire metabolism, or only certain phases of it? If it regulates secretion, he did not see, apart even from special evidence, how the conclusion could be avoided, that it regulates heat-production, etc., for these processes are only *phases* of an inseparable whole while life lasts. It would appear that physiologists had substituted their own artificial conceptions for the real state of the case as it exists. In one sense all nerves are trophic. Dr. Cameron's case was a remarkable but not isolated instance of the truth of the view that heat-production is under the influence of the nervous system; and if so, why not the entire metabolism of the body?

If the sugar in the urine in this case was really grape-sugar, it was another evidence for such a general view as he was advocating. The narrow views as to diabetes being due to disorder of the liver only, must be abandoned. We are satisfied with explanations that are so simple and also artificial; we constantly forget how complex the relations among the different parts of the body are.

Dr. Lapthorn Smith said he had seen the temperature rise as high as 103° F. after drinking a cup of hot tea. He had seen the receipt of bad news cause an elevation of temperature.

Dr. Ruttan said that milk-sugar in the urine of nursing women is not uncommon. Lactose will answer to Fehling's test, and only the fermentation test will distinguish between milk-sugar and grape-sugar.

Dr. George Ross said that the striking observations of Dr. Cameron were of the greatest interest; he was not aware of similar ones. Elevation of temperature in connection with nervous causes seems to be true, and the nervous system in the puerperal state is especially liable to disturbances, and also after fevers, such as typhoid; *sudden* elevations of temperature are common during the convalescence from typhoid, and are of no very serious import. This elevation is quite different from the gradual rise which indicates a relapse. The sudden elevations are usually produced by emotional causes.

It is not usual to have high temperature with glycosuria. The fact that the temperature dropped at night and became elevated during the day, was significant of nervous disturbance; also that these symptoms disappeared under bromide of potassium.

Dr. Reed related a case of atrophy of the muscles of one side of the face without atrophy of the other tissues. Glycosuria was caused by the arrest of the flow of milk. He would like to ask if the sugar was estimated from the whole quantity of urine passed. He spoke of a case of very high temperature caused by the shock of a railway accident.

PHILADELPHIA ACADEMY OF SURGERY.

Stated Meeting, November 5, 1888.

The President, D. Hayes Agnew, M.D., in the Chair.

UNDESCENDED TESTICLE; PURULENT INFLAMMATION OF OVERLYING GLANDS.

Dr. Thomas G. Morton presented two testicles recently removed. The first was from a patient, aged twenty-four, who had been affected with a hernia into the left scrotum since birth, and the testicle upon the same side had not descended into that pouch at any time that he could remember. He had never worn a truss or received any treatment for either condition, nor had he in any way been troubled thereby until within a few weeks, when inflammation had been set up in the inguinal region apparently without cause, save that he had slightly strained himself some three weeks before. He presented an abscess of the corresponding groin which seemed to have origin in the lymphatic glands of that region which in turn appeared to have had origin in the tearing of an attachment of the undescended testicle at the time of strain, as that injury was said to have marked the onset of his present difficulty.

There was no history of chancre or palpable evidence of its former presence. The testicle could be plainly outlined by carrying a finger along the inguinal canal. I obtained his consent to operation and made an incision over the abscess, drained it of about an ounce of pus, excised the affected glands and then came down upon the testicle lying in the canal but now fused with all the anterior structures by inflammatory products. It was freed from all attachments, a ligature of catgut cast about the cord, and the organ removed. The wound was now thoroughly curetted, washed with powerful sublimate solution, and closely sutured, leaving in a rubber drain. No unfavorable symptoms followed the operation, the drain was removed upon the fifth day, and he is now quite well. The specimen showd itself to be an undeveloped testicle surrounded by a tunica vaginalis altered by inflammatory changes; the testicle itself being about the size of a cherry. The hernial sac was not opened and Dr. Morton thought best not to interfere with the rupture until, perhaps, at a subsequent time.

Dr. Morton also showed a second specimen, illustrating

TUBERCULAR DISEASE OF THE TESTICLE,

that day removed. This one was taken from a colored man, aged thirty-five, at the Pennsylvania Hospital. For the past few months he had suffered with pain in the testicle and cord of the right side, and had twice during that time been operated upon for hydrocele of the corresponding tunica vaginalis. The much enlarged organ and a portion of the cord were removed by the usual method. Upon section both cord and testicle presented typical cheesy deposits, one large central collection and numerous smaller foci.

Wm. B., aged thirty-nine, colored, married, has had syphilis for past seven years. Two years ago he noticed that the left testicle was enlarged and painful. This increased in size until one year ago, when a hydrocele was diagnosticated and tapped, with but little decrease in size of tumor. Pain has been much worse for past three

weeks, and patient has sense of dragging in scrotum. When admitted but a slight amount of fluid could be detected. Dr. Morton opened the scrotum, evacuating an ounce or so of dark fluid; he found the testicle diseased and removed it. Cord much enlarged and many evidences of chronic inflammation present.

CORRESPONDENCE.

INAUGURATION OF THE PASTEUR INSTITUTE.

(*From our Special Correspondent.*)

The inauguration of this institution took place on November 14th, in the presence of the President of the French Republic, who presided, assisted by the Presidents of the Senate and House of Representatives, as well as by the Secretaries of War, of the Interior, of Public Instruction, of Finance, and of Commerce; members of the Academy of Sciences and of Medicine, etc. This solemnity took place in the library hall of the Pasteur Institute, which hall contains six busts in marble of the largest donors to the enterprise—the Emperor of Russia, the Emperor of Brazil, Mme. Boucicaut, Mme. Furtado-Heine, Comte de Lauberpin, and Baron Alphonse de Rothschild.

The first speaker was M. Bertrand, Permanent Secretary of the Academy of Sciences. After remarking that the 14th of November, 1888, would never be forgotten in the history of medicine, he said: "During the past forty years, my dear Pasteur, you have permitted glory to come to you, without moving a step toward it. Amongst so many routes, by which often one reaches for it, you yourself know but one, the route of truth."

M. Bertrand then made a most touching study of the early life of Pasteur, and he recorded how one of their mutual classmates, Verdet, had prognosticated about Pasteur; "Pasteur," said he, "knows not the limits of science—I am afraid that he will work hard in vain—he likes insoluble questions." Could any one have estimated him with more sagacity? "The problems which, for half a century, have occupied your mind continuously, giving you no intellectual rest, are no more insoluble to-day. It is to thank you in the name of humanity, to rejoice ourselves in the name of science, to glorify us all in the name of France, that we are united here to-day."

Professor Grancher was then introduced; his speech, being a *résumé* of the work done by Pasteur since the announcement of the method, we shall give in full:

Mr. President of the Republic and Gentlemen: The communication made by M. Pasteur to the Academy of Sciences on October 26, 1885, in which he announced that young Meister had been successfully inoculated with the antihydrophobic virus, created a deep sensation among the scientific world. It was, indeed, the first direct application to man of a general method of treatment of virulent and contagious diseases, and we can easily understand the enthusiasm and hopes of some, and the scepticism, even the hostility, of others.

After Meister and Jupelle, the wounded came to M. Pasteur and his assistants in such numbers that they had to organize a service accessory to the antihydrophobic treatment: matriculation of patients, dressing of wounds, correspondence, etc., so much so, that the year 1886 was absolutely absorbed by the amount of work required for the vaccination of 2682 persons, French and foreigners, each person receiving on an average from fifteen to twenty inoculations.

At that moment, M. Pasteur felt the imperious necessity of a journal, or official organ of the laboratory, which would publish every month the statistics of his vaccination; unluckily his health, seriously attacked by his fatigues and emotions, obliged him to leave Paris toward the end of the year 1886; and the *Annales de l'Institut Pasteur*, started by M. Duclaux, professor of biological chemistry at the Sorbonne, only appeared in January, 1887.

However, the adversaries of M. Pasteur's method, did not fail to profit by our silence, and as we had a few failures during the year 1886, they easily spread the rumor that our laboratory hid its cadavers, and that our dead were legion. They went even so far as to say that the new method would give hydrophobia instead of curing it.

In the beginning of the year 1887, the Academy of Medicine took up the question, and we were then enabled to combat by facts and numbers these calumnious reports which excited the public mind and frightened our patients. At the same time, the learned societies at Naples, Vienna, and St. Petersburg, took up the discussion of this subject, and the war between the Pasteurians and the anti-Pasteurians was a serious one.

In those scientific discussions in which the attack and the defence were equally vivid, everything has been said for and against the antirabic method of vaccination; its adversaries sustaining that the method is inefficacious and dangerous according to the case presented; its partisans, on the contrary, claiming that antirabic vaccination is devoid of danger and marvellously efficacious.

The battle, which was suspended for several months, was taken up again in July, in the presence of M. Pasteur, who answered his contradictors with his well-known gallantry. It was brought forward by the report of the English Commission which M. Pasteur presented to the Academy. This official commission, composed of the most celebrated scientific men of England, having a young and clever physiologist, Mr. V. Horsley, as reporter, arrived in Paris in a very incredulous spirit. After having made a very serious study of the facts presented, they returned to England and repeated the experiments of M. Pasteur; the experimental control lasted more than one year. The conclusion of the Commission, to the great disappointment of our adversaries, was, textually, that "M. Pasteur had discovered a preventive method of hydrophobia comparable to the one of vaccination against variola."

The discussion at the Academy was ended by the following words of M. Charcot:

"Yes, the inventer of antirabic vaccination can to-day, more than ever, march forward, head erect, and pursue the accomplishment of his glorious task, without allowing himself to turn for one single moment because of the outcries of systematic contradiction or the insidious murmurs of disparagement."

These words were listened to and remembered by all, and the year 1888 has been a pacific one.

Gentlemen, before presenting to you my statistics, I would like to say to you what were the causes, to my

mind, which have brought about such an hostility against antirabic vaccination.

You know that M. Pasteur is an innovator, that his creative imagination, regulated by a strict observation of facts, has overthrown many errors and built up in their place a new science. His discoveries on ferments; on the development of the infinitely small microbes causing contagious diseases, and on the vaccination of these same diseases, have been for biological chemistry, for the veterinary art, and for medicine, not only a regular progress, but a radical revolution.

Well, revolutions, even those imposed by scientific demonstrations, leave behind, wherever they pass, vanquished who do not pardon easily. M. Pasteur has then in the world many adversaries; without counting those Frenchmen at Athens who do not like to see the same man always just and always successful; and, as if his adversaries were not numerous enough, M. Pasteur makes additional ones by the implacable vigor of his dialect and by the absolute form which he sometimes gives to his thought.

This form can be dangerous, especially in medicine, where nothing is absolute, and where exceptions to the rule are always numerous. Well, M. Pasteur, by a habit of mind, neglects willingly these contingent facts, which could not, it is true, prevail against law, but which, when it touches a medication applied to the human species, merits to be counted. He has, then, purely and simply proclaimed the efficacy of his method for the treatment of hydrophobia, without making reserves as to the possibility of partial failures; while, if he had been a physician, he would have instinctively taken this precaution, foreseeing the possibility of failure. He did not do that, and exposed himself to the attacks of rational medicine.

To comprehend the opposition of medicine to the discoveries of M. Pasteur, it suffices to examine the movements which have agitated it for the past fifteen years. We hardly knew that in certain diseases, the blood, the humors of the body, and the tissues were occupied by microörganisms, when M. Pasteur, led by his discoveries of ferments, threw himself into this new path for him and for us. And what discoveries he made one after another! He enlightens us; no, he dazzles our eyes accustomed to the semi-daylight of Hippocratic medicine.

See M. Pasteur in the presence of the microörganism of carbuncle of animals. Not only does he make its biology, not only does he prove to us that it is the unique cause of carbuncle, but he educates, he disciplines this infinitely small entity, and teaches it to serve against itself and to become its proper vaccine virus. The experiment of Pouilly le Fort, which had been prepared for a long time by MM. Pasteur, Chamberland et Roux, is known all over the world.

When M. Pasteur, at the London Congress in 1881, announced his great discovery of the attenuation of virus and the vaccination of chicken cholera and carbuncle, one of the most competent men in bacteriology, M. Koch, is reported to have said: "It is too fine to be true;" and three months later, in the first number of the *Mittheilungen*, of Berlin, M. Koch contradicted Pasteur. Since then, however, he has recognized that attenuation and vaccination are correct facts and of great scientific value; but he still refuses to believe the practical value of these vaccinations, although the vaccine of carbuncle extends in every country where carbuncle exists—in France, Italy, Hungary, Spain, India, and Australia.

What better proof do we need of its practical and scientific value? This opposition did not trouble M. Pasteur, who said to us, "Well, let them not believe in the attenuation of virus and vaccination, we shall have ten years advance on them."

The study of carbuncle is hardly finished, when M. Pasteur begins with hydrophobia. Here, for several years, with the aid of M. Roux, he made experiment after experiment, and arrived at still more surprising results. The microbe of hydrophobia has escaped observation up to date, but it certainly exists. Knowing it only by its effects, M. Pasteur has found the way to utilize it as vaccine. And, moreover, M. Pasteur has proposed vaccination after dog-bite—that is, after infection. Physicians, up to now, have always accepted the dogma that when a virus, whatever it may be, has penetrated the human organism, it is beyond our reach and we must await its results. The resistance of physicians to so much subversive news is then quite comprehensible. To recognize that we have first learned and then taught errors, requires outside of personal and impartial new facts, a certain freedom of mind which is not always found, even in most distinguished men.

M. Pasteur, luckily for him and perhaps even for us, is not a physician. Experimenter, without any preconceived ideas or influence of a special school, he has created by the side of rational medicine, which he ignores, a new medical science which his contradictors themselves ignore. This medicine is founded on the idea that this morbid spontaneity does not exist for infectious diseases, and that the laws of general pathology are common to men and animals. How many physicians, however, have been brought up to believe the contrary. This being the case, how can we be astonished at their opposition and their rebellion? I, for my part, think their scepticism very excusable, as it proceeds from traditional ideas, that is, from the spirit of preservation.

It must not be forgotten, and M. Pasteur does not forget it, that at the critical hour, a great many physicians, men of science whose authority was universally recognized, have helped the right and favorable side of the scales to come down. Of the first rank, Vulpian, who not only had followed Pasteur, but who had pushed him to the antirabic vaccination. Vulpian fought and died on the battlefield defending with a fiery eloquence the new method.

Besides Vulpian, Brouardel, Charcot, Verneuil, Chauveau, and Villemin have honored themselves in sustaining the course of progress and preparing its triumph.

M. Pasteur had then the good fortune to find, even at the hour of defection and weakness, a double fulcrum: on one side the great number of patients who never hesitated; on the other, the encouraging words of our most eminent masters. Many other physcians believed in the scientific faith of M. Pasteur, I cannot name them nor do I know them all; but they kept quiet, and our adversaries made such a noise in the press and academies, that the antirabic vaccination was thought to be a thing of the past—to be dead. The method lives, gentlemen. It is prosperous, for there exist to-day, counting the one in Paris, more than twenty antirabic institutions dissemi-

nated throughout the entire world. There are seven in Russia: in Odessa, St. Petersburg, Moscow, Warsaw, Charkow, Samara, and Tifflis; five in Italy: at Naples, Milan, Turin, Palermo, Bologna, these last two having been recently created and sustained by the King; one in Vienna; one in Barcelona; one in Bucharest; one in Rio de Janeiro; one in Havana; one in Buenos Ayres; finally, in Chicago and Malta two new laboratories are being organized. The Antirabic Institute of Paris is in continuous relation with these laboratories, the chiefs of which have all, but two, come to Paris to study the method of M. Pasteur, to apply it to their patients with its progressive improvements.

From the origin we have classified our patients into three sections A, B, and C. The section A contains all the persons bitten by animals recognized to have been hydrophobic by absolute experimental proof. In section B are inscribed all the persons bitten by animals declared to be hydrophobic by certificates of veterinary surgeons; it is the most crowded section. Finally, section C contains the persons bitten by animals suspected to be hydrophobic. Suspicion here results from the circumstances under which the bite has been given; an unknown dog crosses a village, bites a few children and animals, dogs and sheep, and then disappears. If those persons present themselves at the Laboratory, we inscribe them in section C. This section becomes more and more restricted, for we are very severe in our selections, and I think I can safely state that 98 per cent. of the persons we admit for vaccination have been bitten by mad dogs.

Our *general* statistics comprise these three sections, A, B, and C, united in one section. It is subdivided into a *particular* statistic to each one of the sections A, B, and C, and into a *special* statistic for the bites of the head, face, extremities, and trunk.

The number of persons that were treated in Paris, during the years 1886–7 and the first half of 1888, amount to 5374. In 1886, when we had a great number of foreign patients, we inoculated 2682 persons; 1778 in 1887; and 914 up to July 1, 1888.

The percentage of mortality, counting even the deaths of those that were taken with hydrophobia on the first day after the treatment, is for 1886 1.34 per cent.; in 1887 1.12 per cent.; and in 1888 0.77 per cent.

But it would be right to separate from the table of mortality, the persons who died from hydrophobia within fifteen days that follow the treatment; for vaccination, to be efficacious, must be terminated before the virus of the biting dog has begun incubation in the nerve centres. We know that the virus of common hydrophobia, introduced directly on the surface of a dog's brain, incubates from fifteen to eighteen days before it produces its effects. In patients who die from hydrophobia during the fifteen days that follow the treatment, this last has been useless, it having been applied too late; it has not failed because the condition of its efficacy had not been realized.

In separating those cases from the number named—and no physician will oppose this—the percentage of our deaths, notwithstanding the treatment, comes down for 1886 to 0.93 per cent., for 1887 to 0.67 per cent., and for 1888 to 0.55 per cent.

Our mortality decreases gradually, and this is due to the progressive improvements brought to our first method of treatment. We now make a more energetic, more prolonged, more intense treatment, using M. Pasteur's expression, and the treatment yet remains inoffensive. This different efficacy of the antirabic vaccination, according to the one or the other formula, is the most palpable proof of its therapeutic efficacy. The Russian scientific men who combated the antirabic vaccination in Odessa and at St. Petersburg, took this fact into consideration, when they stopped their opposition, M. Gamaleia having shown to them the two very different tables of mortality, according to the method employed.

At Odessa, the first or simple treatment applied to 136 persons, gave a mortality of 5.88 per cent.; while the *intensive* treatment, applied to 997 persons, has given a mortality of 0.80 per cent.

Dr. Bujwid, Chief of the Laboratory at Warsaw, made similar observations; this gentleman, who is here present to-day, will not contradict me when I say that when he called here to study antirabic vaccination he was very sceptical. A student of Koch, and already a very able bacteriologist, he studied with us several months, then continued in his private laboratory at Warsaw, where he performed antirabic inoculation. M. Bujwid studied the simple treatment, stopping at the solution of spinal cord of six days. 195 persons were vaccinated by this method, with a mortality of 4.1 per cent. On the contrary, the *intensive* treatment applied to patients who had suffered from a really severe and dangerous bite (30 persons had been bitten in the face, and 4 by hydrophobic wolves), gave the most encouraging results. Out of 370 persons vaccinated up to the 1st of September last, not one single case of death occurred; so that M. Bujwid, who was an unbeliever for a long time, has become a most convinced partisan of the method. Our particular statistics for each section, A, B, and C, bring us to the same conclusions. The mortality in section A, which contains persons whose bite has certainly had a virulent character, hardly differs from the mortality of section C, which includes persons bitten by animals which were only suspected of having hydrophobia. For the three years, 1886, '87, and '88, the mortality in section A is 1.36 per cent., counting all deaths; and only 1.09 per cent., counting deaths that have occurred fifteen days after the treatment. In section C this mortality is 1.30 per cent. and 0.54 per cent. This similitude in the rate of death for these two sections apparently very different, proves two things: 1st. That the greatest number of biting animals had been suffering from hydrophobia. 2d. That persons of these two sections (A and C) must be treated with the same severity.

The special statistics for the bites of the face, of the hands, and extremities, prove in their way the efficacy of antirabic vaccination. We know that in old statistics the average mortality for all bites were 10.15 and 20.1 per cent., according to the observer; and that the mortality from bites of the head and face reached up to 80 and 88 per cent. In our statistics, the mortality after bites of the head or face is 3.84 per cent., if we count all deaths; it is really only 1.82 per cent., if we separate the deaths that have occurred within the first fifteen days following the treatment. Hence, in this kind of bite, half of the deaths occur during the first fifteen days that follow the treatment, which is a new proof of their excessive gravity. But this dangerous period passed, the treatment is nearly as efficacious for them as for ordinary

bites. We explain our favorable results in these cases by the very energetic character of the vaccination of persons bitten in the head or face.

The great difference which exists between our statistics of 1.82 per cent. and the number of the classical statistics, 80 to 88 per cent., is so large, that it is really impossible not to admit the favorable influence of the antirabic vaccination.

The foreign statistics are in accordance with ours at St. Petersburg; the laboratory which has been started by His Imperial Highness Prince Alexander of Oldenburg, who keeps it up at his own expense, has vaccinated from July 13, 1886, to September 13, 1888, 484 persons, with an average mortality of 2.68 per cent.

From the explanations given to us by Dr. Kraiouchkine, physician to the antirabic laboratory, it results that his death-rate, somewhat higher than ours, is due to the fact that bites are extremely severe in character in his region.

At Odessa, in the laboratory under the charge of Professor Metschinikoff, Dr. Gamaleia has vaccinated:

In 1886, 324 persons by different simple methods. Death-rate 3.39 per cent.

In 1887, 345 persons by the *intensive* treatment. Mortality 0.58 per cent.

In 1888, 364 persons by the *intensive* treatment. Mortality 0.64 per cent.

During these three years 1135 persons have been treated by the antirabic method, with a mortality of 1.41 per cent.

At Moscow, the Antirabic Institute, founded under the protection of Prince Dolgoroukowa, has vaccinated, in 1886, 107 persons by the simple treatment; death-rate, 8.40 per cent. In 1887, 280 persons by the intensive treatment; death-rate, 1.27 per cent. In 1888, 246 persons by the intensive treatment; death-rate, 1.60 per cent.

In Warsaw, M. Bujwid has inoculated 297 persons by different simple methods. His average mortality has been 3 per cent. 370 persons by the *intensive* method. Not one person has died up to date. (It is sixteen months since he began this intensive treatment, and two months since he made his last inoculation.)

At Samara, Dr. Parchenski has vaccinated 53 persons, 4 having been bitten by wolves. The mortality, which was very high here, 5.67 per cent., is explicable by the fact that the treatment, according to the explanations given us by Dr. Parchenski himself, had not been sufficiently energetic and prolonged.

At Charcow, and probably for the same reasons, but we have not been able to get any clear statement, 233 persons have been vaccinated with a death-rate of 3.80 per cent.

At Milan, Dr. Baratieri has vaccinated 335 persons; 2 died notwithstanding the treatment; death-rate, 0.60 per cent.

At Palermo, Prof. A. Celli had vaccinated from March 1 to September 30, 1888, 109 persons without one case of death.

At Naples, Professor Cantani has been obliged to close his laboratory on account of the financial question, the city authorities having refused to support the laboratory. The laboratory was closed from January to August, 1888. In that city, the adversaries of M. Pasteur were very numerous, and had succeeded, notwithstanding a vote of confidence and encouragement on the part of the Academy, to divide public opinion and set the city authorities against M. Pasteur's method. But during this period of seven months, nine deaths occurred as a result of hydrophobia in Naples, and then the city authorities promised financial help for the opening again of the laboratory; the government of Italy, as well as the province of Naples, has also promised to help the work, and the laboratory has again opened its doors. 246 persons have been vaccinated in Naples, 199 since the day of opening of the laboratory (Sept. 22, 1886) up to January, 1888; and 34 since the reopening. The death-rate after vaccination has been 1.5 per cent.

In Havana, in the Antirabic Institute of Dr. Santos Fernandez, Dr. Tamayo has inoculated 170 persons, of whom 50 were bitten by animals which suffered from undoubted hydrophobia. The mortality was 0.60 per cent.

At Rio de Janeiro, in the vaccinating laboratory due to the initiative of the Emperor of Brazil, Dr. Ferreire dos Santos, has vaccinated 53 persons, with no case of death up to now.

Gentlemen, I cannot overlook the statistics of the district of the Seine (which comprises the city of Paris), which is the object of a yearly special report to the Board of Health. The report of 1887 has been made by Dr. Dujardin-Beaumetz, who has obtained his documents at the Prefecture of Police, and for the vaccinated persons at the laboratory of M. Pasteur. Well, in 1887, the number of persons bitten and vaccinated is 306, out of which two died, death-rate 0.76 per cent.: on the other hand, seven cases of hydrophobia have occurred amongst the 44 persons who have not reported for vaccination, which gives us a death-rate of 15.90 per cent.; a ratio which is accepted by MM. Pasteur and Brouardel as being the average of the death-rate by hydrophobia in Paris before the introduction of vaccination. M. Dujardin-Beaumetz concludes: "I know no evidence more striking of the value of the method of inoculation."

The report of M. Beaumetz contains another conclusion not less interesting—that is, that hydrophobia is a disease that administrative sanitary measures can combat. He recalls the fact that in Germany hydrophobia has nearly disappeared, which is owing to the very intelligent prophylactic measures taken. Hydrophobia is, indeed, never spontaneous, it is always transmissible from one animal to the other, and of all animals the dog is certainly the most susceptible,

The following numbers will indicate what intelligent prophylactic measures might do. In December, 1887, the number of persons bitten by hydrophobic dogs was 32; it came down to 25 in January, 1888; then suddenly went up to 61 in February; 57 in March; 56 in April; 67 in May. At that moment the police authorities formulated an order that any dog found running in the street, without his master, would be seized This order was vigorously enforced, and we find in June only 46 persons bitten; in July 29; in August 19. In September a more liberal order in favor of dogs was emitted, and the number suddenly rose to 38. When we observe this rapidly decreasing rate under sanitary measures, does it not seem certain that with a little more perseverance on the part of the public authorities, and a little good will on the part of the population, we might be able to reduce the number of cases of hydrophobia in France, as in Germany, to almost nothing?

You know, gentlemen, that Pasteur's Institute has been founded not only for the treatment of hydrophobia, but also for the scientific study of the means to combat practically the diseases which affect the human species; diphtheria, typhoid fever, phthisis, etc. The extensive laboratories which will be opened to French and foreign physicians, will be for humanity a source of blessing, and a strong means to diffuse and export French science.

M. Christophe, Governor of the Credit Foncier, then exposed in a very able speech the financial situation of the Institute.

Finally, M. Pasteur's son read the following speech for his father, who was too much impressed by all that had been said to be able to read it himself:

Mr. President of the Republic, and Gentlemen: The one who will write in twenty years from now our contemporary history, and will search amidst the war of political partisans the secret thoughts of France, will be proud to be able to say that in the first rank of its preoccupation, public teaching in every degree has been placed. From the village schools to the laboratories of superior studies, all have been either founded or renewed. Student or professor, every one has taken part in it. The great masters of the university have comprehended that if it was necessary to allow primary and secondary education to flow like large rivers, it was also needful to occupy one's self with the spring, namely, superior studies. They have given to this education its deserved place; such an education can only be reserved for a small number; but from this small number, and its select brains, will depend the prosperity, the glory, and, finally, the superiority of a nation.

This is what will be said, and what will be the honor of those who have originated and seconded this great movement? For myself, gentlemen, if I have had the happiness to be led in some of my researches to the knowledge of certain principles which time has consecrated and rendered fruitful, it is because I have never been refused what was necessary for my work. And the day when I foresaw the future which opened itself before the discovery of the attenuation of virus, I addressed myself directly to my country, that it should permit me, by the force and generosity of public initiative, to construct laboratories which not only would apply themselves to the prophylactic method of hydrophobia, but also to the study of virulent and contagious diseases, on that day France has given our hands full. Collective subscriptions, private liberalities, generous gifts due to fortunes that scatter their favors like the ploughman who sows his wheat; all have contributed, even to the workingman who took from the salary of his daily hard work.

While this French concentration was taking place, three sovereigns gave us an evidence of their effective sympathy. His Majesty, the Sultan of Turkey, desired to be amongst our subscribers; the Emperor of Brazil, this emperor, man of science, inscribed his name with the pleasure of a colleague, said he; and the Czar of Russia saluted the return of the Russian subjects who had been treated by us, by a really imperial gift. To the Russian physicians who will work in our laboratories, and are already present amongst us, I address to the Czar our compliments of respectful gratitude.

How these sums have been centralized at the Credit Foncier de France, and the use made of them, you have just heard from the report made by M. Christophe, but he has not told you with what an attachment he has managed this National property.

Before placing the first stone of this Institution the Committee of Subscription had decided, against my will, that this Institute should bear my name. My objections persist against a title which reserves to a man the homage due to a doctrine. But if I am confused by such an excess of honor, my gratitude will be the more profound and complete. Never has a Frenchman addressing himself to other Frenchmen, been so touched as I am at the present moment.

This great house is, then, an existing fact, and one could say of it that there is not a stone in it which is not the sign of a generous gift. All the virtues have united themselves to elevate this home of work. But, alas! I feel the terrible melancholy of a man entering it "vanquished by years," who has no more around him his masters, not even one of his war companions, Dumas, Bouley, Paul Bert, Vulpian, who have been with you, my dear Grancher, the counsellor of the first hour, the most convinced and most energetic defenders of the method.

However, if I have the sorrow to say: They are no more, after having valiantly taken part in the discussion which never originated with me, but which I had to endure; if I am as sad at their absence as I was the day after their death, I have at least the consolation to think that what we have sustained together will not perish, our scientific faith is shared by contributors and disciples here present.

The department for the treatment of hydrophobia will be under the direction of Professor Grancher, who will be assisted by Drs. Chantemesse, Charrin, and Terrillon. The Secretary of Public Instruction has authorized M. Duclaux, my oldest student and assistant, to-day professor at the Faculty of Science, to deliver his lectures on biological chemistry, which up to now had been given at the Sorbonne, and will be given hereafter in our Institute; he will be chief of the laboratory of general bacteriology. M. Chamberland will direct bacteriology in its relations to hygiene. Dr. Roux will direct the studies of bacteriology applied to medicine, and two Russians, learned men, Drs. Metschinikoff and Gamaleia, will kindly help us in our work, and the domain of morphological bacteriology and comparative bacteriology will belong to them.

You know, gentlemen, the hopes we have in the researches of Dr. Gamaleia. I purposely use the word, *hopes;* for the application of the process to man is far from being done yet; but the greatest difficulties have been left behind.

Constituted, as I have just told you, our Institute will be at the same time a dispensary for the treatment of hydrophobia, a centre of researches for infectious diseases, and a centre of learning for the studies belonging to bacteriology. Only of recent origin, but born already armed, this science has obtained such a force by its recent victories, that it gains all the minds. This enthusiasm, which you have felt from the earliest hour, keep it, my dear assistant, but give it, for an inseparable companion, a severe control. Never advance anything which cannot be proven in a simple and decisive manner. Have the religion of critical spirit. Reduced to itself alone, it is not an originator of ideas, nor a stimulant of great things. Without it everything is incomplete. It always has the

last word. What I ask you now, and what you shall ask at your turn of the disciples you shall form, is that which is most difficult for the inventor. To think that one has found a very important scientific fact, to have the fear to announce it, and to constrain yourself for days, weeks, sometimes even years to combat yourself, to seek to contradict your own experiments, and to proclaim your discovery only when you have spent on your experiments all the contrary hypotheses; yes, this is a hard work. But when, after so many efforts, one has arrived at certainty, one feels one of the greatest joys that a human soul can experience, and the thought that he will contribute to the honor of his country renders this joy still more profound.

If science has no nationality, the man of science must have one, and to it must he report the influence which his works must have in the world.

Should it be allowed to me, Mr. President, to terminate by a philosophical thought, brought on by your presence in this hall of work, I would say that two contrary laws are to-day present, a law of blood and death, which imagining daily new methods of fighting, obliges people to be always prepared for the battlefield; and a law of peace, of work, which thinks of nothing else but to save man from the scourges which daily overpower him.

One hunts for violent conquests, the other for the relief of humanity. This one places a human life above all the victories; the other sacrifices hundreds of thousands of lives for the ambition of one man.

The law of which we are the instruments, even searches in the carnage to heal the bloody evils of this law of war. The dressings inspired by our antiseptic methods can preserve thousands of soldiers. Which one of these two laws will overcome the other. God above knows it. But, what we are able to assure is that French science shall have done its best in following this law of humanity in extending the frontiers of life.

The President of the French Republic then rose, and after having remarked that M. Pasteur had asked honors only for his assistants, he nominated Professor Grancher and Professor Duclaux, officers of the Legion of Honor, and Dr. Chantemesse was created knight of the same order.

THE PASTEUR INSTITUTE

has been erected by a subscription of persons all over the world; the rich as well as the poor workman have contributed to the success of this enterprise, and over five hundred thousand dollars have been collected for that purpose. The building, according to the proper wish of Pasteur, is not attractive by its architecture, but was built with the object of being useful to those who would seek information under its roof, and not for the tourist.

Pasteur's Institute has been divided into six departments, viz.: department for the treatment of hydrophobia; department of general bacteriology; department of medical bacteriology, which will be divided into two sections; first, section on methods, second, section of research; department of morphological bacteriology; department of bacteriology applied to hygiene.

The department of hydrophobia is the most important section, for the present, at least; every day, in the morning, from sixty to eighty persons are inoculated, and in the evening from twenty to thirty; no Sundays are allowed for holidays, and the inoculators are always to be found at their duty.

The chief of the department of hydrophobia is Professor Grancher, of the Paris Faculty of Medicine.

Two physicians assist Professor Grancher; they are Dr. Chantemesse, physician of the Paris Hospital, who has drawn attention, during these past years, especially to his researches on the microbe of typhoid fever, and Dr. Charrin, chief of the General Pathological Laboratory of the Faculty of Medicine. Two surgeons are also attached to the same Institute, Prof. Terrillon, of the Faculty of Paris, and Dr. Drengrueber, surgeon of the Paris Hospital.

Every day, for the use of the department of hydrophobia, about ten rabbits, ten guinea-pigs, and two or three dogs are sacrificed in the preparation of the virus. The way in which the inoculations are made as well as the preparation of the virus, we shall relate, hereafter, in another letter.

Department of General Bacteriology.—This department is devoted to the general study of microbes, pathogenic, and non-pathogenic; the chief of this department will be Prof. Duclaux, one of the first students of Pasteur; he is to-day professor of biological chemistry at the Sorbonne, and his chair is now transferred, by order of the Secretary of Public Instruction, to the Pasteur Institute.

Department of Medical Bacteriology.—This department has been divided into two sections.

1st. Section of Methods. In this section the pathogenic microbes will be especially studied—all those that contribute to the etiology of contagious and virulent diseases, such as tuberculosis, typhoid fever, diphtheria, measles, scarlatina, pneumonia, cholera, etc. The chief of this section will be M. Roux, a well-known student of Pasteur, to whom he has rendered very great services during his studies of hydrophobia.

2d. Section of Research. This second section will be under the direction of M. Gamaleia, of the microbiological laboratory at Odessa, who lately has become well known by his researches on the vaccine of Asiatic cholera; he is of Russian nationality.

The *Department of Morphological Bacteriology*, whose specialty will be the study of the natural history of microbes, is also under the direction of a well-known Russian, M. Metschinikoff, director of the bacteriological institute at Odessa.

The *Department of Bacteriology applied to Hygiene* will be under the direction of M. Chamberland, another well-known student of Pasteur, who took a large part in the researches of his master on the carbuncle vaccinations.

It is hardly necessary to add that the above laboratories are open, free of charge, to all who desire to come to study. Two sorts of laboratories will exist in each of the above departments:

1st. A laboratory of study for the physicians who shall come to acquire a sufficient knowledge of bacteriology, which will enable them to practise their profession more in accordance with the present state of medical science.

2d. A laboratory of research for those who have already a general knowledge of bacteriology.

PARIS, November 16, 1888.

THE AMERICAN PUBLIC HEALTH ASSOCIATION.

(*From our Special Correspondent.*)

The Sixteenth Annual Meeting of the American Public Health Association just held at Milwaukee, brought together a large number of representative sanitarians and health officers, to consider some of the most important subjects that can be presented to public and professional attention. While papers and reports on other subjects were not excluded, the Executive Committee had designated as the subjects for discussion and elucidation: I. The Pollution of Streams; II. The Disposal of Refuse Matter of Cities; III. Animal Diseases Dangerous to Man; and IV. Maritime Quarantine and Regulations for the Control of Communicable Diseases,

The first meeting was held on November 20th at Athæneum Hall. The Report of a Committee on the Pollution of Water Supply, by Surgeon Charles Smart, of the Army, as Chairman, well introduced the series of papers and reports to follow. It was an able presentation and summary of the reasons why the pollution of streams and other bodies of water was not consistent with their use for potable water. The report argued against reliance on methods of chemical purification, and while admitting the improvement of sewage by dilution, aëration, etc., it contended that this did not assure a satisfactory purity.

The paper went on to show at length that although aëration doubtless did measurably promote the oxidation of organic matter under such and similar circumstances, yet the very process which, through the production of ammonia, led to its nitrification, was the concomitant, not to say the breeder and nurser, the propagator and multiplier of the various bacteria and bacilli which are known to be the causes of malarial, typhoidal, and other epidemic diseases. And it was furthermore shown that neither the stagnation of "settling basins," as at St. Louis, nor yet the huge filters of Atlanta remedied this, the real evil. For it is neither the stench nor even the discoloration which is the true index of a given water-supply's impotability, from a sanitary standpoint. Homœopathic dilution can get away with the former; alum, iron, lime, and other precipitants can, with filtration, produce water of crystalline purity to the naked eye; but neither method can starve or coagulate the lively bacterium into innocuous desuetude. Dr. Smart, therefore, held with the English authorities: "Rivers which have received sewage, even if that sewage has been 'purified' before its discharge, are not safe sources of potable water."

There was no recognition of the facts shown by Percy Frankland and confirmed by others, as to the rapid elimination of bacteria under methods of chemical purification and aëration. The paper was able and well represented the views of those who take the high, safe ground that all forms of sewage must be excluded from every water supply used for drinking purposes. But it scarcely gave due credit to facts, just as well established, which go to show that where such a perfect supply cannot at once be made available, great benefits can be derived from the intervention of long distances of flow and from artificial methods of aëration and purification. We are, nevertheless, glad to have the perfect ideal held up, since the sin of using bad water is one of the vices of cities. The report was well discussed by Prof. Vaughan, Prof. Rohé, Dr. H. P. Walcott, and others.

The Presidential Address of Dr. C. W. Hewitt, of Minnesota, in the evening, was characteristic, desultory, impulsive, assertive, it was in many respects suggestive and practical. With pointed emphasis, he outlined the details of sanitary administration. Especial stress was laid on the need of daily, practical, and, so to speak, petty activity of health officers, so that by clearing away minor abuses, one by one, and preparing for larger exigencies, panics may be avoided. Practical suggestions were made as to many of these details. As the address of Surgeon Sternberg last year presented the more scientific basis of sanitary work, this address was representative of those who salute themselves as practical, administrative sanitarians, and look with only patronizing consideration upon those who study deeper the problems of life, and yet do not forget to proceed effectively to administrate in accord with both knowledge and experience. Both have their sphere of usefulness and both, in time, come to the point in a working association like this.

The well-known opposition of Dr. Hewitt to the National Board of Health did not prevent him from recognizing the desirability of some restricted form of national health power. He urged "the need of a more intelligent and far-seeing—that is to say, a less red-tapy and offensively centralized—co-operation and independence of local, state, and national health boards; insisting that the first was the integral unit, and that the last should properly be evolved out of the demonstrated and experienced needs of the second. In other words, that the highest efficiency of local boards, rural as well as urban, is of the last consequence, and that the true function of the national board should, on the one hand, be to facilitate and cement the interdependent helpfulness of the state boards among one another; and, secondly, to provide for a thorough extra-national system of sanitary inspection in connection with our consular system.

A paper by Dr. Crosby Gray, Health Officer of Pittsburg, was valuable, because it gave the results of a very careful topographical, chemical, and biological examination into the cause of a six per cent. higher death-rate of the south side of that city. He traced it to the water supply of that part of the city, as drawn from the Monongahela River, which receives a vast amount of pollution. He reckoned the loss to the city during the past year at $480,000, as based on accurate statistics of cases as given.

Dr. H. B. Baker, presented remarks on the classification of diseases, in which he took exception to present methods and thought that if the bacteriologist would present a classification from his stand-point, and so the meteorologist, the chemist, and the etiologist, we would have valuable material for a re-classification.

The paper of Dr. Kilvington, of Minneapolis, was a valuable *résumé* of the experiments thus far had as to burning garbage, excreta, etc., by means of furnaces. The matter was before the Association last year, and many details given as to a score or more of such crematories in England and that of Mann, so successfully used in Montreal. To these he added accounts of the Milwaukee Destructor; the Rider Destructor, of Pittsburg; and the Engel, at Minneapolis, also in use at Des Moines. We have had occasion in the past year to examine the evidence as to the feasibility of this mode of refuse disposal, and feel sure that it will be found available in

many of our cities. The Association made an examination of the one at Milwaukee, which has recently been considerably changed in order to use some more modern improvements devised by Mr. Forrestal. Dr. De Wolf, Health Officer of Chicago, while approving of this method, also drew attention to the Buffalo Distillery Crematory, which extracts lubricating oils in the process of burning, and so in part pays expenses.

As a matter of course, quarantine came in for its full share of attention. Dr. Rauch discussed chiefly land quarantine, and repeated the substance of his essay before the Illinois State Board. He made a practical application of it to yellow fever, and denounced the exclusion of refugees. He did not prove his assertion "that a continuous temperature of not less than 70° F. is necessary for its origin and spread." While it is well recognized that it is a disease of warm climates, it is not safe to assert that persons having contracted the fever cannot have it and be the centres of an epidemic, without a continuous temperature of over 70° F. Even were this so, there is not a city in the Middle States that does not for days reach this and not infrequently in September. There was much of value in the paper after it had been thoroughly sifted by the best authorities in the Southern States who have fought, not at long range, this fearful scourge.

Dr. Rutherford, Health Officer for the State of Texas, and Col. Hadden, of Memphis, ably defended their methods of quarantine, and well disputed the position taken by Dr. Rauch.

An excellent paper was presented by Dr. Jerome Cochrane, the Health Officer of Alabama, from a recent, though oft-repeated, experience. He claimed yellow fever as a communicable disease, requiring most thorough methods of isolation in the hands of a thoroughly equipped local board. He would resort to depopulation and refugee camps only on the careful judgment of the local health authorities, as such removal, although theoretically good, is often impracticable.

Papers of merit were presented by Mr. Payne, of the Signal Service, on "Climatology and Health;" and by Dr. A. W. Bell on "Sanitary and Medical Service on Immigrant Ships."

Dr. D. E. Salmon, of the Bureau of Animal Industry, read a valuable paper on "Tuberculosis," showing that the two chief sources of supply were the floating and dried materials from diseased lungs and the use of the milk and flesh of tuberculous cattle.

A paper by his assistant, Dr. Theobald Smith, of Washington, "On the Origin and Sources of Disease Germs" was a valuable contribution to bacteriology.

The Lomb prize for the best paper on "Five Food Products Illustrated by Practical Receipts" was awarded to Mrs. Mary J. Hinman, now in attendance at the University of Strasburg. Seventy essays were presented.

While there were some local defects of arrangement and the attendance was not so large as at some previous meetings, some valuable papers and discussions were furnished.

The next annual meeting will be held at Brooklyn, N. Y.

Milwaukee, November 23, 1888.

THE CERTIFICATION OF A PATIENT'S DISEASE.

To the Editor of The Medical News,

Sir: A question has recently come before me involving certain relations and rights between doctors and their patients, that I should like to lay before you and your readers for further information, if it should be thought worthy of consideration. I must confess that I feel surprised to find myself in so small a minority.

The Medical Association of the District of Columbia is a voluntary body, composed of all the medical practitioners of the district who are in good standing, and deals with questions of ethics alone. The resolution embodied in the circular quoted below was adopted at a recent meeting by a vote of 21 to 4.

The circular reads as follows (as it is in print and sent to all the members, it is, of course, in no sense a confidential communication):

"My Dear Doctor: At an adjourned meeting of the Medical Association of the District of Columbia, held the evening of the 13th inst., Article XXVII. of the regulations was so amended as to read as follows, viz:

"'Article XXVII.—In certificates on account of illness given to employés in the public offices, or others, respecting absence from official duties, the disease shall not be specified; neither shall the name or nature of the disease be divulged by any written description or statement of its symptoms given to the patient himself, nor by any specification of the disorder, nor by any disclosure which may be construed into an evasion of the meaning of this regulation.'

"I am directed by the Association to forward a printed copy of the above article, as amended, to each member." —Signed by the Secretary.

In considering this article the question is not whether in giving certificates of any kind to a third party, the doctor shall state the nature of the disease under which the patient is suffering; although this question is open to consideration—in cases of life insurance, etc., where the patient himself desires it, or under other peculiar circumstances. A case in point has recently occurred where a patient desired, and deserved, relief from duty on the petit jury; he was given a doctor's certificate that he was suffering from a disease which disabled him from jury duty. As no further particulars regarding the disease were given, he was retained on the jury and, when locked up with his eleven associates in a case requiring long consideration, sent to his physician for a more explicit certificate. In reply, a personal letter was sent to him, stating that he was suffering from a form of *itch* which was contagious.

In considering this article the question is not whether the doctor shall disclose or withhold, under any circumstances, details prejudicial in any way to the patient; but simply as to whether the doctor is not bound, as a business transaction, to give a patient by word of mouth or in writing, such details as the patient may ask for regarding the nature of his disease, to do with as the patient may see fit. If the patient can prove that such a refusal is prejudical to his welfare, pecuniary or otherwise, may the patient not obtain satisfaction by a process of law?

The causes which led to the passage of the article in question have nothing to do with the question involved, but it may be worth while to refer to them. It will be

noticed that the application is made only to public official duties. The government departments have pretty generally adopted a rule requiring the nature of the disease to be stated in all certificates for absence on account of sickness, thus casting discredit on the physician's statement of simple disability, compelling references to morbid conditions which are either not creditable, or, as in the case of women, of whom so many are in these departments, are of a nature not suitable to be made a matter of record or discussion in public offices; or compelling the physician to disregard truthfulness in the interest of his patient, and to make use of a politic evasion—in other words, to lie about it. The latter is evidently distasteful to the members of the Association, so they have made this issue. I sympathize fully with my colleagues, but I do not see how they can maintain the position they take in this Article XXVII.

Yours very truly, L.

Washington, D .C

NEWS ITEMS.

A Long Distance Consultation by Telegraph. — The Canadian Pacific telegraph was last Sunday week brought into service in a way that not only afforded a good illustration of the extent of the system, but furnished a unique example of the possibilities of modern science.

Lord Ennismore, heir to the Earldom of Listowel, is lying at the point of death in the hospital at Victoria, British Columbia, with typhoid fever, accompanied by other complications. A telegraphic circuit was formed from London to Victoria, by the Mackay-Bennett Cable and Canadian Pacific Railway telegraph, and Sir Andrew Clarke, of London, was placed in direct consultation with Dr. Hannington, in Victoria. A conversation lasting three hours, concerning Lord Ennismore's condition, was carried on.

An unbroken circuit was worked from Victoria to the cable office in New York where the telegrams were repeated to London. Replies were received in three and four minutes. Lord Ennismore, though still in a dangerous condition, is reported as somewhat better.

Influenza.—This malady, known in France as the *grippe*, is just now epidemic in London, and possibly elsewhere in the British Isles. It is quite distinct from the ordinary "cold in the head," to which it stands in much the same relation as cholera does to summer diarrhœa. It is not, strictly speaking, infectious, although it occurs in epidemic form. The victims are stricken down simultaneously, often by hundreds and even thousands. The first great epidemic occurred as far back as 1580, and spread all over Europe. Since that time epidemics have broken out at irregular intervals, differing only in extent from their mediæval predecessors.

The most marked feature of this really redoubtable, though not necessarily fatal, malady is the intensity of the nervous phenomena, and the prostration which it leaves behind. It is related that some years since the entire crew of a man-of-war cruising in the Channel were incapacitated within a few hours to such an extent, and with such impartiality, that the vessel had to hoist signals of distress and obtain assistance to navigate it. When it invades a town, the disease does not, as with infectious maladies, start from a limited area, but conquers the whole population at one fell swoop. The rapidity with which it travels is also remarkable. The epidemic of 1847 in one month skipped from Spain to Newfoundland, and from New Zealand to Valparaiso, Syria, Africa, and even to Hong Kong. It usually travels from east to west, but does not appear to obey any general law, and although in some instance outbreaks have seemed to be consequent on sudden changes of temperature, they have supervened in all seasons and in all climates.

Apart from the ordinary symptoms of catarrh, respiration is often extremely embarrassed, and sometimes death results from positive "paralysis of the lungs." This interference with the pulmonary function may perhaps explain the prostration which persists long after the principal symptoms have disappeared, and incapacitates the sufferer from work for a period of time varying from one to three weeks. It is comparatively rare in England in its aggravated form, and therefore often gives rise to unnecessary alarm.—*Medical Press*, October 24, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM NOVEMBER 20 TO NOVEMBER 26, 1888.

McClellan, Ely, *Major and Surgeon.*—Having reported to the Division Commander, on the 23d inst., as required in par. 15, S. O. No. 261, current series, A. G. O., is assigned to duty as Attending Surgeon at these headquarters, and as examiner of recruits at Chicago, Illinois, from that date.—*Headquarters Division of the Missouri, Chicago, Illinois*, November 24, 1888.

By direction of the Secretary of War, leave of absence for four months is granted Richard C. Newton, *Captain and Assistant Surgeon.*—Par. 16, *S. O. 272, A. G. O., Washington*, November 21, 1888.

By direction of the Secretary of War, the leave of absence granted John Van R. Hoff, *Captain and Assistant Surgeon*, in S. O. No. 134, November 1, 1888, Department of the Missouri, is extended one month.—Par. 3, *S. O. 274, A. G. O., Washington*, November 23, 1888.

By direction of the Secretary of War, the leave of absence granted Marshall W. Wood, *Captain and Assistant Surgeon*, in Special Orders No. 257, November 3, 1888, from this office, is extended ten days.—Par. 12, *S. O. 270, A. G. O., Washington*, November 19, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING NOVEMBER 24, 1888.

Heffinger, A C., *Passed Assistant Surgeon.*—Ordered to the U. S. S. "Kearsarge."

Bryant, Patrick H., *Assistant Surgeon.*—Ordered to the Naval Hospital, Brooklyn, New York.

McMurtrie, Daniel, *Surgeon.*—Ordered to the U. S. Receiving Ship "Vermont."

Drennan, M. C., *Surgeon.*—Detached from the "Vermont," and ordered to the "Atlanta."

Winslow, G. F., *Surgeon.*—Detached from the "Atlanta," and placed on waiting orders.

McClurg, W. A., *Passed Assistant Surgeon.*—Detached from the "Tallapoosa," and ordered to the "Kearsarge."

Von Wedekind, L. L., *Assistant Surgeon.*—Ordered to the "New Hampshire."

Heffinger, A. C., *Passed Assistant Surgeon.*—Detached from the "Kearsarge," and ordered to the "Tallapoosa."

Stephenson, B. F., *Surgeon.*—Detached from the Navy Yard, Boston, and ordered to the "Wabash."

Oberly, A. S., *Medical Director.*—Ordered to the U. S. S. "Richmond."

Jones, W. H., *Surgeon.*—Detached from the U. S. S. "Richmond," and placed on waiting orders.

ORIGINAL ARTICLES.

GLYCERINE ENEMATA AND SUPPOSITORIES IN CONSTIPATION: BASED ON A TRIAL OF THEM IN 234 CASES.[1]

BY J. P. CROZER GRIFFITH, M.D.,

ASSISTANT PHYSICIAN TO THE HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA, PATHOLOGIST TO THE PRESBYTERIAN HOSPITAL.

THE treatment of constipation is often one of the most difficult questions which present themselves to the attention of the physician. Undoubtedly hygienic and dietetic measures, or such internal medication as tends eventually to produce natural, regular, and unaided evacuations, form the measures which are most to be sought after. There are, however, cases in which the movement of the bowels is urgently demanded, and no time for any systematic treatment is allowed; and other instances present themselves where, owing to a congenital or acquired utter intractability of the intestines, a palliative treatment, consisting in the periodical artificial production of alvine discharges, is the only course left us.

It is in these two classes that the internal administration of laxative medicine and the employment of rectal injections find their proper sphere. Which of them is to be chosen depends, of course, on the exigencies of the case. Very often, certainly, the enema is greatly to be preferred, since it avoids the general disturbance of the gastro-intestinal tract, and the pain and impaired digestion which may ensue. The employment of large injections of water, with or without soap, turpentine, oil, molasses, etc., is frequently both inconvenient and unpleasant; and it was with considerable pleasure, therefore, that I first noticed the recommendation of glycerine by Anacker.

Further research shows, undoubtedly, that the use of glycerine for this purpose was but an old and largely forgotten custom. I have been unable to discover who first devised this treatment, but I have learned that the late Dr. A. H. Smith, of this city, was constantly in the habit of prescribing injections of it; and his former associate, Dr. H. A. Slocum,[2] still uses it with success. Dr. William Pepper[3] has also prescribed it in numerous instances. Eustace Smith[1] refers to the value of the injection of from 40 to 60 drops of glycerine in the constipation of infants, and calls it "an old-fashioned plan lately revived;" and Cadogan-Masterman,[2] while administering a teaspoonful of glycerine, per rectum, to a case of herniotomy, heard the nurse remark: "That was Mr. Warden's favorite plan; he said it was better than all the pills in the world." And this physician, says the writer, died sixteen years ago. Vámossy[3] searched the German text-books with reference to this matter, but only found that Bernatzik[4] stated that glycerine had been used as a laxative and antiseptic clyster; that Daude[5] had given injections of it as a protective and emollient to the mucous membrane of the rectum in dysentery; and that Vogl[6] recommended it for the same purpose in inflammatory diseases of the rectum.

I find the soothing action of glycerine as a local application in dysentery referred to in the *National Dispensatory*, and the drug is also spoken of as a feeble and uncertain laxative; but neither in this work nor in the *United States Dispensatory* is its rectal administration to aid defecation alluded to, and the text-books on *Therapeutics* by Wood, Ringer, Brunton, and Bartholow are silent on the subject. Nevertheless, in Quain's *Dictionary of Medicine*, Oliver, in the article on "Constipation," recommends the injection of a small quantity of glycerine into the rectum.

The history of the present interest in this matter is as follows: A Dutch proprietary medicine, known as "Oidtmann's Purgatif," patented by Dr. Oidtmann, of Maastricht, had attained surprising repute in Holland and Germany for the treatment of constipation. A small metal syringe, holding about 3 to 5 grammes, accompanied the bottle, which contained a grayish-black, slightly greenish fluid, thicker than water, feeling somewhat oily, and having a strong and peculiar odor, which has been compared to that of mouse urine. What was claimed for the preparation it undoubtedly performed; namely, that when about one-half a teaspoonful of it was introduced into the rectum, there was produced a prompt, easy, complete, and painless evacuation.

There was no tenesmus, but a slight sense of irritation of the anus remained for about a quarter of an hour after the movement.

How great a renown the "Purgatif" was obtaining was shown by its widespread employment by the laity, and by the fact that even some physicians were prescribing it, while more than one chemical examination of it was made. Analyses by Birnbaum,[1] Mylius,[2] Rupp,[3] Steensma,[4] Anacker,[5] Guldensteenden-Egeling,[6] and that made by the authority of the *Land-Medicinal-Collegium*[7] of Saxony, were published; the researches of Guldensteenden-Egeling being particularly careful and exhaustive. Though these differ considerably as regards the nature of the other ingredients, all but that of Mylius agree in declaring glycerine to be the main constituent. This writer simply confesses his inability to discover of what the medicine is composed.

Whether glycerine was also the *active* ingredient could only be determined by clinical experiment, and Anacker,[8] after a series of trials, found that it was, and that 1½ to 2 grammes of it, introduced into the rectum, acted as quickly and thoroughly as did the "Purgatif." He believes that in this method of employing glycerine we have a valuable addition to our armamentarium, applicable to all cases of constipation except those in which there is ulceration of the rectum. The action of glycerine he considers due to its hygroscopic qualities. By abstracting water from the mucous membrane it produces a hyperæmia of the lower parts of the bowel, and, through the consequent excitation of the nerves, an increased peristaltic action.

A little later than Anacker's paper, and without reference to Oidtmann's Purgatif, a publication of Unger's[9] recommended the employment of glycerine in the form of suppositories with soap and *Rhamnus frangula*; and stated that physicians had given them, as thus prepared by him, with very satisfactory results. In an article[10] appearing nearly a year later he changes the formula considerably, while increasing the glycerine and diminishing the soap, as he says that there is no doubt the former is the active agent. He believes that the glycerine excites the mucous glands to greater secretion, and repudiates the theory of increased reflex peristalsis, as suggested by Anacker.

Vámossy[1] was induced by the communication of Anacker to administer enemata of glycerine to 150 cases of the most different diseases, varying in age from six to seventy years, all of whom had been constipated for at least two days. A small syringe made for the purpose was employed, and 2 c.cm. (equivalent to 2.5 grammes) of glycerine injected. Evacuation of the bowels followed after one to two minutes as a rule, and the stools were always soft and formed; no case of a fluid stool being witnessed. Only in rare instances, as in obstinate habitual constipation or where cerebral hemorrhage had occurred, was the evacuation delayed for one-half hour. Defecation was painless, and no uncomfortable sensation remained afterward. It was noticed that the greater the fecal mass in the intestine the more energetic and complete the action of the enema seem to be. The author agrees with Anacker as to the *modus operandi* of glycerine in the rectum. Should pain or burning in the rectum be produced by a too powerful action of the glycerine—as he has heard has occurred in delicate individuals in private practice—he advises that the drug be diluted with one-half its volume of water.

Seifert,[2] though bitterly opposed to patented medicines, had Oidtmann's Purgatif so constantly forced on his attention, that he tested its power, and found that it fully met the claims made for it. Having heard of Anacker's discovery of the active constituent, he tried glycerine enemata in 26 cases, besides children, and found that 3.5 c.cm at once produced a copious evacuation, without leaving any disagreeable sensation. In no case did he see the drug lose its effect, though sometimes given regularly for many months.

Boas[3] has likewise used this treatment in a long series of cases with good results. In patients with hemorrhoids, however, the insertion of any syringe may be productive of pain. At the best the use of a syringe is not altogether pleasant, is difficult for the patient himself to employ, and cannot always be prescribed in private practice. The author has accordingly devised another form of administration, and has in 20 cases employed hollow suppositories of cacao-butter, each containing 1 gramme of pure glycerine, this dose being found sufficiently large, and acting in fifteen to twenty minutes. He never found it necessary to use more than one suppository, though there would be no objection to giving two.

Kröll[4] also favors the employment of cacao-butter suppositories containing, at least, 2 grammes of glycerine. The evacuation takes place in five to fifteen

[4] Therap. Monatshefte, p. 506, November, 1888.

minutes. He has used them in 50 cases, and with only 1 failure. While he has often seen glycerine injections produce an unpleasant sensation in the rectum, he has never known the suppositories to have this effect. He considers glycerine especially adapted to cases of constipation from insufficient peristalsis of the large intestine, caused by congestion of the portal system, or occurring in those leading sedentary lives or confined to bed. The treatment does not lose its effect by repetition.

Gerstacker[1] took careful notice of 55 cases in which he employed enemata of about 2 grammes of glycerine. The results were very satisfactory, defecation taking place shortly after the injection. The average time required was eight and one-half minutes, the shortest two minutes, and the longest six hours. Usually there was but one stool, and this soft; eleven times it was hard, and four times there were repeated evacuations. In no instance was there any unpleasant sensation after the evacuation. The author uses a small metal or glass syringe, to which he attaches a piece of rubber drainage tube one-half metre long. This device, he thinks, removes the objections raised by Boas, since the patient can very conveniently and without assistance give himself the injection while lying on the back.

Schindelka[2] has had very favorable results with glycerine enemata in 100 horses, 5 grammes always producing an evacuation.

While believing that suppositories have a decided advantage over enemata, Dietrich[3] considers those recommended by Boas to have the disadvantages of being too large, and of inserting into the rectum too great a proportion of comparatively inert matter. He therefore describes and offers for sale a suppository composed of ninety parts of glycerine and ten parts of a hard stearine soap; and says that according to the report from various physicians who have tried them in numerous cases, they produce a natural, easy, and prompt action, the bowels being opened within ten minutes.

Novotny[4] has administered enemata of ½ to 1 fluidrachm of glycerine to 200 patients with the most diverse diseases, and in all but three or four a good stool was produced within a few minutes, though in a few cases two to three hours elapsed. There was not a disagreeable symptom in a single instance. In about a third of the cases a second liquid stool followed the first formed one. He has had cases of obstinate constipation yield almost immediately to this treatment, after having withstood the most powerful purgatives.

Subbotić,[1] after numerous trials of glycerine by enema, confirms the favorable opinion of others. It was always promptly efficient if the rectum contained feces. When, on the other hand, the rectum was empty, repeated injections failed to induce a passage. He considers that this is entirely in accord with Anacker's explanation, and is a proof that the action of glycerine is confined to the lowest section of the bowel, and that it is unable to stimulate the upper portions to propel the feces downward.

Reisinger[2] reports his experience with 115 rectal injections of glycerine, 101 of which were successful, usually in two to fifteen minutes, though the evacuation was sometimes delayed for one to two hours. The cases were of the most different diseases. The stools varied from the consistence of diarrhœa to quite decided solidity. The only unpleasant secondary effects noted were the complaints of slight burning in the anus in two cases. Post-mortem examinations were later made on five of the cases, but in every instance the mucous membrane of the rectum was found to be destitute of any change which could have been produced by the injections. As regards the manner in which glycerine provokes the evacuations, it is evident it is not through a mechanical irritation, since the injection of an indifferent chemical substance (solution of albumen) had no effect at all. Neither does the author share the views of Anacker, since he found that concentrated solutions of sulphate of sodium introduced into the rectum had no such effect as the glycerine has, though they have the power of abstracting water. It is more probable, therefore, that there exists a direct chemical action of the glycerine on the mucous membrane of the rectum.

Ullmann[3] has made a careful, critical study of the effect of glycerine enemata, and the relation of the successful administrations to the disease, the habits of the patients, etc. In the great majority of 174 cases the stools were hard, and in only seven were they watery. Subsequent constipation was seen in about one-third of the patients. Diarrhœa followed in six patients, all of them suffering from tuberculosis. A slight burning in the anus was not infrequent after defecation, but pain of any moment only occurred in five patients. Like Subbotić, he noted the almost invariable failure of the glycerine in cases in which the rectum was empty, and the feces were contained in the bowel above it; and with him believes that the inverse of peristalsis is limited to the lower section of the large intestine. He agrees with Unger that the evacuation is due to a profuse hypersecretion produced by the glycerine. He recommends the injections when it is desired to

empty the rectum quickly, or when general peristalsis is to be avoided. Their habitual use is improper, as there may be danger of causing inflammation. The amount used was 3 to 6 grammes, and the evacuation generally followed in three to fifteen minutes.

From England comes the report of a trial of glycerine by J. Althaus,[1] who announces his success with it in a large number of his own cases, while several other physicians have told him of their satisfaction with the plan of treatment. The evacuation of the bowels takes place almost immediately, or within a few minutes, and there is no pain or discomfort, unless it be a little throbbing felt in the rectum for a few moments afterward. M. Prowse[2] states that glycerine is quite effectual when diluted with an equal quantity of water. W. Easby[3] cannot speak too highly of it as a laxative enema, having used it frequently of late, though his first trial of it was about two years ago. He gives one fluidrachm with a little water in a syringe holding about half an ounce. C. J. R. McClean[4] has employed it by enema in a number of cases with very satisfactory results; using a common glass urethral syringe. J. Bunting[5] does not find glycerine diluted with water act nearly so well as when pure. C. Palmer[6] administers it with a syringe in the shape of a small India-rubber ball with a vulcanite nozzle. W. B. Roué[6] describes, with an illustration, a small graduated glass syringe holding 3 drachms, and adapted for glycerine enemata. The vulcanite nozzle is two inches long, and of sufficiently large bore to admit the easy entrance and exit of the glycerine. G. A. Carpenter[7] tabulates the results of 214 injections of 1 to 2 drachms of glycerine in 63 children of from one to eleven years of age. The method was uniformly successful, and in no case did it invariably fail. The enemata are easy of application, prompt in action, and unattended by the slightest discomfort. He considers them superior to the drugs ordinarily employed for constipation.

An American report on the rectal use of glycerine as a laxative is that of E. R. Mayer,[8] who has employed enemata of ½ drachm with very general success, and has also used the drug in hollow suppositories of cacao-butter, or enclosed in gelatine capsules. A slight degree of rectal irritation followed the repeated use of the capsules. In a case of painful hemorrhoids enemata of glycerine not only emptied the bowels more thoroughly than compound licorice powder had done, but appeared to give more relief to the pain than all the local treatment previously employed. The author then reports an interesting case of extreme tympanites in peritonitis unrelieved by injections of soap, water, and turpentine, in which 2 fluidounces of glycerine introduced high into the rectum gave great relief by the discharge of a large amount of flatus within twenty minutes, followed later by a fecal evacuation. Contrary to the views of Subbotić, he believes that glycerine has a local action not only on the lower bowel, but that by its peculiar power of diffusing itself it rapidly spreads past the sigmoid flexure to some of the coils of the small intestine. In this way a large amount of fluid is mingled with the feces, and finally a general peristalsis is produced.

I. N. Love,[1] also, has used glycerine enemata in many cases, and with uniformly satisfactory results; finding it particularly useful in infants and mothers in whom a constipated habit has persisted after the birth of the child. By giving the injection at the same hour every day the unaided regularity of the bowels may be brought about. In a few cases of hemorrhoids and of severe rectal irritation he had better results with glycerine than with the purgatives and sedative ointments previously used.

The marked success met with in the first few cases in which I used this treatment was reported in a brief note[2] published last spring. Since that time the results have continued to be so good, that glycerine enemata or suppositories have largely supplanted other aperient rectal medication in the medical wards under my charge, as well as in other wards of the University Hospital. The collection and preservation of records of cases have been tedious and troublesome, and I am largely indebted in this report to the patient care of Drs. Leidy, Kirby, Wood, and Hay, of the resident medical staff. Up to the time when enumeration had been discontinued there had been 234 cases of constipation, occurring in the most varied medical and surgical diseases, to whom over 530 rectal administrations of glycerine had been given. When enemata were employed the amount used was usually 1 to 2 fluidrachms, though 1 fluidrachm was generally found sufficient. This was sometimes injected pure, sometimes mixed with a small quantity of water; the effect being much the same in either case. In some instances 20 minims (25 grains) of glycerine were enclosed in a gelatine capsule, and inserted into the rectum, and answered well in many cases. A solid suppository, made by incorporating glycerine with paraffine, was devised by Dr. Leidy, and gave satisfaction in some instances, but required to be kept from moisture, and in a cold place. By far the greatest success with suppositories, however, was obtained with those

made with glycerine and soap, which I will presently describe.

The results of the glycerine treatment were most encouraging, as there nearly always followed a full, easy, and painless movement within a few minutes after its employment. The average time required after the enemata was probably five to ten minutes, though the effect was sometimes not evident for fifteen to thirty minutes, and in one case was delayed one and a half hours. Very frequently the evacuation was almost immediate. In a case of convalescent typhoid fever, for example, whose constipation, lasting three and a half days, had not been relieved by an injection of warm water, an enema of 1 drachm of glycerine produced such an immediate effect that the nurse had hardly turned away from the bed before the patient called for the bed-pan. The thought naturally arises that such prompt results must certainly be due to a strongly irritating action on the mucous membrane of the intestine. I would, however, call particular attention to the fact that this does not appear to be the case. My experience agrees with that of the writers already quoted, that it is rare that pain in the abdomen or rectum, or other symptom of real irritation precedes the evacuation or remains after it, as is so often the case after stimulating aqueous enemata have been used. In a few cases I have recorded a stinging in the rectum attending the injection, or a burning sensation, lasting a few minutes after the bowels were opened. It was found that this did not occur if the glycerine was mixed with a small quantity of water. In a few other instances there was actual rectal pain, due not so much to the action of the glycerine as to the passage of not sufficiently softened feces.

All that has been said regarding enemata of glycerine applies as well to the effects of suppositories, except that the latter require somewhat longer to operate, owing to the time needed for their solution in the bowel. They are also somewhat less certain in their action, on account of the medicament contained in them. Glycerine usually produces but one stool, and this is soft rather than liquid. It is for this reason that the remedy sometimes fails in obstinate constipation, the very hard scybalous masses not being softened enough. Yet, I am by no means certain that, even in most cases of this kind, soap and water have, as a rule, any superiority, for both the enemata and suppositories of glycerine were often found useful in the enforced constipation following gynecological operations, such as perineorrhaphy, where it was desired that the feces should be soft, and that straining be avoided. There were instances, too, and that not infrequently, in which glycerine produced an easy passage, but in which soap and water either effected no movement at all, or did not soften the scybala sufficiently to prevent painful evacuations. This method of treatment was found particularly valuable in cases in which opium in large doses had been administered during a considerable period. It failed in no such instance, though turpentine with soap and water was often ineffectual. I cannot speak from experience as regards the contra-indication to the use of glycerine in ulceration of the rectum, to which Anacker alludes. The local employment of it in dysentery, already referred to, would indicate that it is not necessarily to be avoided as a laxative when an ulcer exists. I have never seen the drug lose its effect after continued use, and have not found it necessary to increase the dose, nor does there seem to be any tendency to constipation remaining after the treatment is discontinued.

Glycerine is not, of course, an infallible remedy, and, like all other aperients, will sometimes fail utterly, even in cases in which it has been at other times effectual. My experience with it has, however, been sufficiently extended to justify the conclusion that in it we have a safe, prompt, and reliable means of obtaining an evacuation of the bowels; more convenient of employment, and more pleasant to the patient than are large aqueous injections, and certainly superior to them as regards the absence of irritation of the rectum.

Finally, I would again call attention to the administration of the drug in the glycerine and soap suppositories referred to, as an elegant means of exhibiting the remedy in private practice. I have made a somewhat extended trial of these, modelled after those manufactured by Dietrich. Messrs. Henry C. Blair's Sons, apothecaries, of this city, have taken great trouble in perfecting the method of their preparation, and now offer them for sale. 50, 66, and 75 per cent. of glycerine, with soap, was not found reliable. Finally, by using an especially hard castile soap 90 per cent. of glycerine was incorporated in suppositories weighing 52 grains each, and these were efficient in the majority of cases. It is to be remembered that the total amount of glycerine in each (46 grains) is not quite two-thirds of that generally used for an enema (viz., 1 fluidrachm, 75 grains). If, therefore, a case does not easily yield to one of them, there would be no objection to giving two at a time. These suppositories are made after the shape recommended by Dr. Dixon,[1] and have accordingly all the advantages peculiar to this form. They are very hygroscopic, but when wrapped separately in tin-foil keep very well, and I can imagine no more elegant method of producing an intestinal evacuation than by their use. Very neat little suppositories for babies, holding 10 or more grains, are also supplied. Mr. James J. Ottinger, apothecary, of this city, has sent me samples of 90 per cent. glycerine supposi-

[1] Therap. Gaz., April, 1888.

tories made with a dry stearine soap, and now offered for sale. He has succeeded in preparing them in such a way that the covering of tin-foil is dispensed with. They are not very hygroscopic, even on exposure to air for some weeks, and present a handsome appearance. I have not myself had any experience with them. Messrs. Parke, Davis & Co. also manufacture 90 per cent. soap suppositories. samples of which they have sent me. I have not yet had the opportunity of trying them.

Though glycerine suppositories are somewhat less certain than are the enemata, yet they are not only much more convenient for private practice, but, owing to their rather slower action, I found them entirely unproductive of discomfort, even in the occasional instances in which the enemata have caused slight burning. The largest rectal gelatine capsules hold not more than 25 grains; an amount too small to be generally useful. Their action is uncertain, and even when two are given at a time, a movement does not occur for thirty to forty minutes. Another objection is that, if sold already filled, they rapidly soften and allow the glycerine to escape. The hollow cacao-butter suppositories are not to be recommended on account of the size required to hold a sufficient quantity of glycerine, and the large amount of inert matter employed. I cannot, therefore, but consider those made with soap the most eligible form.

123 SOUTH EIGHTEENTH ST., PHILA.
Nov. 28, 1888.

IS THE ELECTRIC LIGHT INJURIOUS TO THE EYES?

BY GEORGE M. GOULD, M.D.,
OF PHILADELPHIA.

BEFORE proceeding to the direct answer of the question, it may be well to glance at the larger one that refers to the relation of the electric light to general hygiene.[1] Most every one has a general impression that the electric light is much superior to other methods of artificial illumination, so far as concerns our general health and comfort, but few could give a reason for the faith that is in them. They will come out of a theatre, music hall, church, etc., with headaches, lassitude, exhaustion, their bodies bathed in sweat, all resulting in colds, and a multitude of major and minor affections, and never utter a word of protest or complaint against the culpable and parsimonious management that permits the vitiation, poisoning, and superheating of the atmosphere by a thousand gas-jets. It is certainly not too much to urge, as has been done (14), that the matter should be under the control of the law, and that electric lighting is of political importance on a par with the supply of pure water and drainage. The following figures, from a trustworthy source (14), are so eloquent that they need no comment or explanation:

TABLE.

Burnt to give light of 12 candles equal to 120 grains per hour.	Cubic feet of oxygen consumed.	Cubic feet of air consumed.	Cubic feet of CO_2 produced.	Cubic feet of air vitiated.	Heat produced in 100 lbs. water raised 10° F.
Cannel gas,	3.30	16.50	2.01	217.50	195.0
Common gas.	5.45	17.25	3.21	348.25	278.6
Sperm oil,	4.75	23.75	3.33	356.75	233.5
Benzole,	4.46	22.30	3.54	376.30	232.6
Paraffin,	6.81	34.05	4.50	484.05	361.9
Camphine,	6.65	33 25	4.77	510.25	325.1
Sperm candles,	7.57	37.85	5.77	614.85	351.7
Wax candles,	8.41	42.05	5 90	632.25	383 1
Stearic candles,	8 82	44.10	6 25	669.10	374.7
Tallow candles,	12.00	60.00	8.73	933.00	505.4
Electric light,	None	None	None	None	13.8

It is thus seen that, as compared with the electric light, gas consumes over seventeen times as much air, vitiates three hundred and fifty times as much, and then, adding insult to injury, gas heats the foul residue twenty times as much as the electric light would do.[1]

In a recent address before the British Association,[2] Mr. Preece shows that gas absorbs 68 watts, whilst electricity (arc) absorbs only 5, and the glow light but 3 watts, as the energy required to produce a light of one candle-power. He also shows that in London the cost of producing one candle-light for one thousand hours is, for gas, 30 cents; oil, 16 cents; electricity (glow), 18 cents; and arc, 3 cents.

There is, therefore, no excuse for longer delay in introducing this superior form of illumination into public meeting places. The long-suffering public should arouse their masters to a knowledge of their duty in this respect. The latter have no longer even the excuse of financial expense.[3]

But there has grown up a somewhat popular notion

[1] For those especially interested in the subject, besides the references given, relating to the relative production of heat, carbon dioxide, and other combustion-products, and their influence upon health, the following may be of service: Cohn, Untersuchungen ueber Tages und Gas-Beleuchtung, Berl. klin. Woch., 1885. Cohn, Ueber den Beleuchtungswerth der Lampenglocken, Wiesbaden, 1885. Cohn, Studien, etc., Vierteljahresschrift f. öff. Gesund., Bd. xv. Heft 4. Pettenkofer, Archiv f. Hygiene, Band 1, p. 210. Reuk, Centralblatt f. Electrotechnik, 1885, p. 210.

[1] From experiments made in the hall of the Birmingham Festival (14) it was shown that when gas was used the temperature near the ceiling rose from 60 to 100 degrees after three hours' lighting. This was equal to adding 4230 persons to the full audience of 3100. The vitiation of the air was equal to that produced by 3600 additional persons. When electricity was used the temperature rose only 1½ degrees in seven hours, and the air was, of course, not vitated at all.

[2] See Science, Sept. 28, 1888.

[3] As to this aspect of the question see some most interesting and suggestive extracts from Lodge's Modern Views of Electricity, in Science, Sept 28, 1888, p. 153.

that the electric light is hurtful to the eyes, and one finds, even in the literature of the subject, some very absurd prejudices and nonsensically windy disquisitions concerning the noxious action of the mysterious "chemical rays" said to predominate in the electric light spectrum.

Having had a number of patients who persisted in ascribing certain ill-defined ocular affections to the action of the electric light, I determined to see what evidence existed of the supposed noxious influence. The following is the report of the cases published of ocular troubles resulting from an exposure of the eyes to the electric light, and of the conclusions deducible from their consideration. I may say that, so far as my own experience is concerned, I found in my patients who complained of the electric light, that their ocular troubles could usually and easily be accounted for by some error of refraction, overwork, etc.

The question of nomenclature may be noticed in passing. The term *electric ophthalmia* has been proposed and used of the ocular affections to be described. But the popular use of the word ophthalmia confines it almost exclusively to conjunctival troubles, whilst if not others, there are evidently retinal lesions in these cases. Moreover, there is no sense in the term electric ophthalmia. Electric light ophthalmia would be less criticisable, though still very objectionable. Electric sunstroke, electric light sunstroke, etc., are highly ridiculous in themselves, besides importing into the agency the element of heat, as certainly present in sunstroke, as it is certainly absent in the ocular injuries of the electric light. We, therefore, must use some circumlocution to describe these cases.

I proceed at once to give a condensed *résumé* of the cases so far reported in which the electric light was the cause of ocular troubles. They number twenty three, though several cases are evidently included in Defontaine's account.

1. Terrier (26)[1] cites a letter of Professor Gariel stating that Foucault, in 1843, was attacked with a severe ophthalmia, due, according to his own belief, to the electric light. No particulars are given.

2 and 3. Two chemists, according to Professor Charcot (2), following some experiments in fusing certain substances with a 120 cell Bunsen battery, were seized during the night with pains in the eyes, luminous sensations, and erythema or "electric sunstroke of the face." The ocular troubles were less severe than the cutaneous erythema. There was desquamation of the affected skin in four days. Charcot attributed the injury to the chemical rays, and recommended spectacles of uranium, which substance retains a large proportion of these rays.

4. Little (12) reports the case of a gentleman, who in experimenting in a laboratory, with the electric light, neglected upon one occasion to protect his eyes with his dark glasses. His right eye was exposed to the light. He was blind for a few minutes, and for several days thereafter he had great photophobia and headache. Two months after this accident the physician was consulted on account of dimness of vision and dark spots before the right eye, whose acuteness was $\frac{20}{L}$. Ophthalmoscopic examination showed the optic nerve and adjacent retina affected. Tinted glasses and rest were ordered. No subsequent history.

5 and 6. A case is reported by Rockliff (9) of a workman whose duty it was to adjust the carbon points of a 3000 candle Siemen's light. He used no protecting spectacles, and was for some moments "seized with paralysis of the retina." He had often been troubled with lachrymation, photophobia, pains, and swollen eyelids. These he treated himself by the application of cold compresses. Once, however, this was insufficient, and the distress and swelling of the lids increased. The eyes were hot, red, and the swelling and injection extended to the forehead. The pains were intense within and about the globes. The conjunctivæ were scarlet, the photophobia and lachrymation excessive. The cornea was not affected. The symptoms disappeared in forty-eight hours under lead lotions and systemic purgation. His assistant was also, but less severely, attacked with conjunctivitis, etc.

7. Emrys-Jones (11) reports the case of a patient, who, in making some experiments, had to approach within a few inches of an arc lamp, thus exposing his unprotected eyes for some twenty minutes to the light. There followed a dazzling sensation, and colored circles seemed to surround the street lamps. Early the next morning there was great pain in the eyes, and a great flow of tears. The photophobia and conjunctivitis continued until the subsequent day, when complete relief is said to have followed the instillation of atropine.

8. In a second case of Emrys-Jones (11) the patient seems to have experimented with the electric light, frequently looking at it through a narrow opening between his fingers, though often neglecting even this precaution. With a light of a 2000 candle-power the consequences were only temporary, when viewed from a distance of a dozen feet, and when the gaze was not continuous. If the eyes were not protected by smoked glasses, and were brought within eighteen or twenty-four inches of the arc, the duration of the exposure being one or two minutes, a certain degree of inflammation resulted. A too strong current, producing a violet light, or an insufficient one, producing an orange light, results in less trouble to the eyes than the normal current strength—white, tinted with a sky-blue. Irregularity of the light is more dangerous than when it is steady. The patient reported that his first symptom was a sensation as of a multitude of duplicates of the arc; or, with movements of the eyes, a blinding glare, very confusing for a time, and forming a sort of screen before objects. At first the image was the same color of the arc, but soon this gave place to the complementary color which persisted longer, and which disappeared very slowly. When this had entirely passed away it could be recalled by rapidly opening and closing the eyelids. The severity of the lesion was proportionate to the length of time afterward that the patient could thus reproduce these images. If this were during one

[1] The reference numbers throughout the article refer to those of the bibliography appended.

hour, the patient knew that the inflammatory symptoms would finally ensue, and so he proceeded at once with the remedies that would serve to cut short the attack. The patient had had three separate attacks, accompanied by the usual symptoms of a feeling as of dust in the eyes, lachrymation, intolerable pain, etc. Lotions of sulphate of zinc and opium were used. Patient had not noticed any swelling of the lids.

9. Nodier's case (7) was that of a naval officer whose duty it was to experiment with the electric light. The light was equal to 1600 Carcel jets, surrounded by a glass 40 cm. from the focus, and the officer's eyes were subjected to this light for two hours without protecting spectacles. This was followed soon by headaches and pains in the eyes. The next day the conjunctivæ were red; there were lachrymation, sclerotic hyperæmia, pericorneal circles, myosis, photophobia, muscæ volitantes. These symptoms disappeared slowly in three days. Both eyes were affected alike, and there was no erythema of the skin. The diagnosis was hyperæmia of the retina and conjunctiva. The treatment consisted in zinc collyria, tepid compresses, and rest.

10. In a similar case reported by Nodier (7) the light was only equal to 300 Carcel jets, and the symptoms were light. There were slight cephalalgia, pricking sensations of the eyes, profuse lachrymation. The hyperæmia, pericorneal circle, sclerotic congestion, myosis, and photophobia were only of one eye. The attack passed off in twenty-four hours. The treatment consisted in atropine instillations, belladonna ointment above the orbit, compresses, etc.

11. Dr. Dujardin (26) describes the case of an electrician whose occupation was to charge the accumulators, and who subjected his eyes to the influence of a strong spark. There was photophobia and redness of the bulbar conjunctiva for twenty-four hours.

12. In a communication of Dr. Martin to Dr. Terrier (26) the case of M. L. is described. He had been present at the electric welding. He had worn protecting colored glasses, but in order to see more exactly he had taken them off for a moment. No evil results were felt until night, when he was seized with intense heat of the face and eyes, lachrymation, and such great pain in the eyes that he was unable to open them, and believed himself blind. The pain increased to real torture, the face was injected, the skin thick and rough, and hot. Tears flowed down the cheeks, the lids were swollen so that they could not be opened, the spasmodic closure of the same, and contractures of the facial muscles being increased by the attempts of the physician to examine the eye. By the aid of cocaine, it was found that the white of the eye was but little injected, the cornea intact, the pupil contracted. The palpebral conjunctiva was scarlet, but not swollen, the vision normal. Soothing collyria and cocaine were administered, and the ocular symptoms gradually disappeared in a day or two. The skin of the face was affected more than a week.

13. Sous (23) records the case of M. D., who, though protecting his eyes with dark blue glasses, often looked closely at an incandescent light used to illuminate the work. During the night he was seized with violent pains in the eyes. His eyes and orbits seemed filled with coals of fire. There was intense photophobia, not a ray of light being permitted by the patient. A cherry-laurel water lotion was prescribed, and recovery followed in two days.

14 to 20. Terrier (26), quoting a letter of Dr. Faucher, cites the cases of Messieurs Faucher, Morin, and four assistants, who, from the effects of the intense light in some experiments, had an intense congestion of the conjunctivæ for three days, together with very painful sensations of heat, dryness, and as if foreign bodies were in the eyes. One of the workmen had also an intense "electric sunstroke" of the hands and face.

21. According to Terrier (26), a Mr. N., of Lille, after being present for one and one-half hours during the welding of some metals by electricity, remarked immediately that his eyes were very red. The injection of the eyes and erythema of the face continued that day, and during the evening he noticed malaise, heaviness of the head, and feverishness, with painfulness of the eyes. During the night, there were intolerable pain and intense photophobia, with lachrymation, which continued for a day or two; he was able to return to his work in four days. The treatment consisted in applications of ice and cocaine instillations.

22. Defontaine (22) describes the "electric sunstroke" of the workmen employed in the electric steel-welding works at Creusot. The intensity of the light is equal to about 10,000 Carcel lamps. The men do not approach nearer than fifteen to thirty feet, and though there is at this distance no heat, they begin to feel, within two hours, a burning sensation in the exposed skin of the face and neck, described by one of the men as exactly like that previously experienced by him in a veritable case of sunstroke. The skin is sensitive to the touch, and of a reddish bronze hue. Though the eyes were protected with glasses so dark, that seen through them the disk of the sun was hardly distinguishable, there soon followed a temporary blindness of a few minutes, and for an hour or more thereafter objects seem to be suffused in a decided yellowish saffron hue. The conjunctiva was very hyperæmic, and this lasted for forty-eight hours. There was the extremely painful sensation, as of a foreign body under the lids, and lachrymation was excessive. Cephalalgia and insomnia with slight feverishness were noted. Within the next five days there was desquamation of the entire face in large sheets.

23. Terrier (26), in describing a similar case to the last, notes especially that vascularization of the conjunctiva was particularly noticeable in the part exposed by the opened lids, and when the conjunctiva was covered by the lids there was hardly any injection. It may also be remarked that, unlike all others, he found the pupils dilated. They were little sensitive to light.

If from a review of these cases we try to make up a clinical picture of the disease, we at once strike upon the etiology, and therein lies the greater part of the differences that have arisen in the discussion of the subject. To this *vexata questio* we must direct our attention.

The first fact that strikes our attention is that the subjects were nearly all scientific experimenters, or workmen about the light who were compelled to approach either very near the same or to leave their eyes a long time subject to the influence of the rays. So far as I have found, there is not a single well-authenticated instance of ocular trouble from the use

of the electric light as a simple illuminant. It is a fact well known that we may blind ourselves permanently by staring into the sun, and yet diffused sunlight is, of course, the natural stimulus of the eye. Whatever prejudice may linger in some minds against the electric light properly used as an illuminant may therefore be dismissed as absolutely without clinical proof.

We next notice that the cases cited occurred in those not protecting their eyes in any way, or insufficiently. With this fact we come to the consideration of the real cause of the lesion. It has been ascribed to the supposed excess of chemical (blue, violet, and ultra-violet) rays in the electric light spectrum. Let us see how far this is true.

Rendering the yellow rays equal in the spectra, Meyer (*Centralblatt für Electro-technik*) has analyzed the spectra of the two forms of electric light, with solar light as a term of comparison, with the following results:

	Gas.	Incandescent lamp.	Arc lamp.
Red . . .	4.70	1.48	2.09
Yellow . . .	1.00	1.00	1.00
Green . . .	0.43	0.62	0.99
Blue . . .	0.23	0.21	0 87
Violet . . .	0.15	0.17	1.07

It is thus seen that all three lights are reddish-yellow as compared with the sun, and that even the arc light is poorer in blue rays than sunlight. This, of course, relates to the visible portion of the spectrum. As to the ultra-violet portion, Mengeaud (13) says that M. de Chardonnet photographed the spectrum of an incandescent lamp (like Edison's) and found that it did not exceed that of the visible spectrum. This may have been either because of the absorption of the ultra-violet rays by the crystal globe surrounding the lamp, or because the short rays are not produced. If, therefore, these investigators are to be relied upon, and there seems to be no reason for doubting them, there is absolutely no ground for the great burden of complaint that has been brought against the violet and ultra-violet rays of the electric light. They either do not exist or, if so, they are in less quantity than in sunlight. The recommendations of Javal (6) and Fieuzel (6) to use yellow spectacles to shield the eyes from the baneful effects of the short waves, thus fall flat.[1] Cohn calls attention to the fact that the blue rays are not harmful to the eyes, Graefe and oculists of all times having habitually recommended bluish-tinted glasses.

[1] Another reason urged for the adoption of such lenses is that they obviate the chromatic aberration of the eye, by which, theoretically, the focus of the red rays is behind that of the violet. But Helmholtz could not find that visual acuteness was at all lessened by this chromatism. Javal says it is, and that artificial light is insufficient, widens the pupil, and makes the chromatism of the eye perceptible. He would therefore shorten the spectrum, but not by blue glasses which cut off the red end and thus lessen the amount of light-stimulus; but by yellow glasses, that cut off the blue end. It is a case of hypercriticism and supersubtlety.

The theory of M. de Chardonnet (17) holds that all the ocular media absorb more or less the ultra-violet radiation, and that to this absorptive power is due the fatigue of the eye. He found (18) that the crystalline has especially the function of intercepting the ultra-violet radiation, but this brings doubly into view the absurdity of the theory; there is no question in the reported cases of lenticular trouble; it is chiefly retinal or conjunctival, if not entirely so. Not only are there no ultra-violet rays to absorb, but the body that absorbs them is an insensitive, unaffected organ.

Over-refinement is carried a step further in the theory of Regnault (19), who ascribes the ocular troubles caused by the electric light to the fluorescence developed in the media of the eye by the action of the violet and ultra-violet rays. He showed that the mammalian cornea is manifestly fluorescent, and the crystalline also, and to a high degree; that the phacocine or central portion of the crystalline is not so; that the hyaloid membrane is the only tissue of the vitreous having a weak fluorescence; and that the retinal fluorescence is weaker than that of the crystalline.

I think we may throw out all theories that explain the lesions as due to a greater or less proportion of the waves of the different parts of the spectrum. Since time began our eyes have been accustomed to all colors, and, besides, the waves deemed especially harmful are innocent by comparative non-existence. To what then shall we credit the trouble? I believe it is due simply to the intensity or amount of the stimulus which, from the natural and physiological stimulus of diffused sun or electric-light illumination passes, by closeness or by duration of observation, into pathological irritation and even a quasi-mechanical injury. It is simply a question of degree. From the delicate tint of a cold blue through to the more powerful waves of the red end of the spectrum, up to direct gazing at the electric light or the sun, and to the effect of a sheet of lightning (that has produced blindness) it is only a question of intensity or quantity of the self-same stimulus. A temperature of 98° F. is pleasant to the body, but one of twice that amount coagulates its albumins. There is in Italian a gruesome word, the sad record of a savage age: *abacinare*—to hold a heated glowing vessel close before the eyes until vision is destroyed, or but a shimmer of light is left. The idea was not to burn the eyeballs, but to destroy the retina by the intense stimulus. Czerny[1] focussed direct sunlight upon the retinæ of animals. There followed coagulation of the retinal albumin, destruction of the rods and cones, and severe inflammation of the retina and choroid, ending in atrophy of the retina. When

[1] Sitzungsberichte der Wiener Akadamie der Wissenschaften, Bd. 56, Abth. 2, S. 409.

gaslight was used these results did not take place, but, though tinted glass was interposed, the effects always ensued with sunlight. Deutschmann[1] showed essentially the same fact by inserting in the path of the sun's rays a glass tube filled with cold water, some 20 cm. long. The destruction of the retina was the same as if the warm rays had not been intercepted. The descriptions of cases of snow-blindness—*e. g.*, those of Graddy[2]—read almost exactly like those I have summarized. The same may be said of those cases of injury from exposure to sunlight such as described by Drs. W. Norton Whitney,[3] Sulzer,[4] Haab,[5] Deutschmann,[6] and others who describe retinal injuries from the observations of eclipses, etc., despite the use of protective blue glasses. There is central scotoma, reduced vision, loss of color sensation, photophobia, etc. In Whitney's cases there was a pearl-white spot at the macula, as if its albumin had been coagulated. Briere[7] had a case of complete blindness from the reflex of a lightning-flash from the white street, and Little (12) had a case of blepharospasm lasting thirteen days, from a lightning-stroke.

It is to be noted that the effects of the electric light are not because it is more intense than sunlight. It is, in fact, far less intense than sunlight. Multitudes of people impelled by curiosity have gazed at the ordinary arc or glow lights without a single case of ocular injury. Hardly one would be able to look into the sun in the same way. All the cases of ocular injury from the electric light are due to gazing at it at very short range and for a long time. Compared to daylight, the electric light lessens colors, for red, blue and yellow, one to two, three, and, for red, even four. In the establishments for electric welding the great intensity or number of the light waves is so high that not only are the delicate retina and conjunctiva injured, but the skin wherever exposed is inflamed and desquamates from a short exposure to the near and powerful stimulus exactly as it would if exposed to the sun's rays upon a hot summer day.

Another proof that the injury is due, not to a different proportion of the long or short waves, but simply to their great quantity, lies in the fact that the ocular trouble is exactly proportional to the intensity of the light, or, what amounts to the same thing, the nearness of one's approach or duration of exposure. This is particularly clear in case No. 8. I have elsewhere[8] endeavored to show that the retinal intermediate of light and color sensation is a molecular vibration responding, and proportional to the wave-length and number of the received ether-waves—or, in other words, that the retinal function is a delicate and high differentiation of the temperature-sense. Now, just as a certain degree of heat or molecular vibration is grateful and necessary to the general nerve end-organs, but a much higher degree is destructive of them, so it is the same with the retina. Every fact adduced above, together with the symptomatology and pathology of sun-blindness, snow-blindness, etc., goes to show the truth of this conception. Excess of physiological activity everywhere runs into pathological activity. The light of the ordinary glow or arc lamps when diffused, or not looked at directly, is not injurious to the eyes. Neither is it injurious if looked at from a distance (several feet, or thirty, according to its intensity), unless the gaze be fixed upon it for a length of time that more than compensates for the distance. The injury is proportional to the intensity of the light, to its distance, and the duration of the exposure. It may be said that there is absolutely no danger from the use of the diffused light as an illuminant. They who have the care of these lights—scientific experimenters and workmen in the welding-works—such must protect their eyes with colored glasses, whose function is simply to arrest the great part of the numbers of the light-waves, so that the intensity of their action is reduced. It matters not whether the long or the short waves are intercepted,[1] so enough of them are cut off to reduce the general average to a standard approaching that of diffused daylight, the normal stimulus of the eye. The indication is for a London smoked or dark-blue tinted lens, the depth of whose shade should be proportional to the nearness of approach and the intensity of the light.

As to the symptomatology of the ocular affection, there is the greatest unanimity in all the cases. If the light has been very intense and the exposure at short range, there will probably be a temporary "paralysis of the retina," lasting one minute or several, and accompanied by blepharospasm. There may be a blinding glare, positive and negative after-images, central scotomata, or other chromatic sensations, as of colored circles about objects, etc. In any case, what may be called the typical symptoms appear in from two to twenty-four hours after the exposure. There is then always photophobia (with blepharospasm) pronounced and intense. Lachrymation is always present, and the third unfailing symptom is pain in the eyes, which, probably, also extends to the head. The intolerable ocular pains are usually accompanied by a feeling as of particles of sand under the lids, and these particles seem large, recognizably distinct, and unendurable. The

[1] See case 8.

conjunctiva, especially when exposed to the direct action of the light, is congested, usually intensely so; there is sclerotic hyperæmia, pericorneal circles, and myosis.[1] During the attack ophthalmoscopic examination is scarcely possible, and would probably show nothing of importance, since the symptoms are almost entirely those of a reflex neurosis, due to conjunctival irritation. The attack lasts from one to three, or even more, days, and may be cut short by the rational indicated treatment.

The prognosis is good; no case of permanent injury having been so far reported.

As to the treatment, a mydriatic should be used to set at rest the ciliary muscle, and cocaine to relieve the pain, the irritation, and reflex spasms of the muscles. Astringent collyria are wholly useless, and might prove injurious. Cold compresses have been usually employed, but I should use hot ones if a case were presented to me.

As regards the pathology of the affection, Nodier (7) ascribes the conjunctival hyperæmia to the retinal lesion by reflex action, that produces spasmodic contraction of the muscular fibres of the iris and ciliary body, whence results compression of the irido-choroidal venous trunks with venous stasis, or reflux, of these and of the conjunctival vessels. Nodier had not had any such experiences as those described in cases 12, 14, 22, 23, in which the skin of the face, neck, or hands was affected. Case 23 is particularly instructive, as showing that the conjunctiva was injured by the direct action of the light, and only where it was exposed to the same. Heimann[2] thinks the conjunctivitis (*sic*) is due to the pressure of the lids on the eye in the spasmodic action of the orbicularis under intense light. The whole matter seems simple enough and easily explicable. The fact that photophobia, lachrymation, pain, etc., are not symptoms of retinal lesions and inflammations, seems to make Nodier's assumptions purely gratuitous. These symptoms are the infallible results of irritation of the external tissues, the conjunctiva, cornea, etc. This irritation certainly exists in electric light injury: it affects all exposed parts, and is most intimate, penetrating, and severe. It simply results in vaso-motor paralysis by pure reflex action, and there follow as inevitable and necessary consequences the outflow of tears, the vascularization (not conjunctivitis) of the conjunctiva, etc., the blepharospasm, the photophobia, and the pain.

Summing up the conclusions reached, I should say that:

1. As regards general hygiene, the superiority of the electric light over gas as an artificial illuminant is so overwhelming as to admit of no discussion. It is incontestably the light of the future, and the public should not rest until its meeting-places, such as theatres, halls, reading-rooms, churches, etc., are lit by the most perfect system at its command.

2. A study of the published cases of injury of the eyes by the electric light shows that not one was due to the use of the diffused light as an illuminant.[1] The popular prejudice against such a use of it is absolutely without justification. All the cases reported were of scientific investigators, etc., or workmen about the light, who approached it very closely, gazed at it protractedly, and without protecting colored spectacles

3. The ocular injury is due, not to the supposed preponderance in the electric-light rays of violet and ultra-violet (chemical or actinic) waves, but simply to the greater number (intensity) of the usual length light-waves.

4. The symptoms of the ocular injury are possibly immediate temporary "retinal paralysis," blepharospasm, central scotomata, chromatopsia, after-images, etc. Within twenty-four hours there come on intense photophobia, lachrymation, ocular pain, a feeling as of foreign bodies beneath the lids, conjunctival hyperæmia and congestion, pericorneal circles, etc.

5. The attack usually lasts but two or three days; the prognosis is excellent; the treatment is simply cocaine and atropine instillations and cold or hot compresses.

6. Workmen and experimenters who must approach closely to the electric light should protect their eyes by smoked or tinted glasses, the depth of the tint being greater where the light is more brilliant, the proximity greater, or the exposure longer. In the welding-works the workmen must be particularly careful about this, and must also not expose the skin of the face, neck, and hands to the action of the light. The precaution may not be amiss to advise the curious against testing their eyes by gazing at the ordinary arc and glow lights at short-range.

THE ARREST OF HEMORRHAGE FOLLOWING EXCISION OF THE TONSIL.

By RICHARD J. LEVIS, M.D.,
of Philadelphia.

Persistent hemorrhage after excision of the tonsil is extremely rare, but such instances are occasionally reported, and the subject has recently been discussed and means for its arrest suggested. There have occurred cases in which the methods usually recommended would be entirely impracticable.

I have seen but a single case in which profuse and dangerous hemorrhage continued after the operation. In that instance an unnecessary entire removal of the tonsil had been effected by the form of guillotine that draws out the mass before the cut is made.

At my first visit to the patient, a male adult, he had bled freely for some hours and was blanched and exsanguinous. Various inefficient expedients had been resorted to, including the application of cold and temporary pressure. Of course, there had been used Monsel's solution—the vilest of the abominations called styptics—a class of remedies which declare the inefficiency of the surgeon, and have caused more hemorrhage by masking its source and by loss of time, than they ever arrested.

After excavating from the mouth and fauces the masses of hard, black clots produced by the iron solution, the cut surface was seen bleeding freely.

All bleeding was instantly arrested by simply passing an ordinary tenaculum firmly through the tissues of the base of the tonsil, and giving the instrument a decided twist. The torsion effected, compressing the oozing vessels, was maintained by closing the patient's jaws on the handle of the tenaculum as it protruded from the mouth. The jaws were then securely held together by a firm bandage about the head, from the chin to the vertex.

Before resorting to the expedient with the tenaculum, it had been my intention to transfix the base of the tonsil with a curved needle, place a ligature tightly behind it, and leave it in position, after nipping off its point, and bringing the end of the thread out of the mouth.

After the arrest of the hemorrhage the patient rested through the succeeding night, experiencing apparently no annoyance from the presence of the tenaculum.

I may remark, in illustration of another expedient for arrest of hemorrhage after tonsillotomy, that at my visit on the next morning I was prepared, in case hemorrhage should recur on the removal of the tenaculum, to pass one or more ligatures through the base of the tonsil, and for this purpose had ready for use needles of short curve, fixed in needle-holders. A concentric constriction of the base, thus made, would effectually prevent any possible hemorrhage.

In this case no hemorrhage followed on removal of the tenaculum, after it had remained twelve hours in position.

In a case of hemorrhage after excision of the tonsil, recently reported, the operator was able to seize the tissues with a volsella and apply a ligature. In occasional cases the difficulty or impossibility of thus applying a ligature to isolated vessels is due to the flatness of the surface and the lack of loose tissue to be grasped.

Considering how full is the arterial supply of the tonsil, it is remarkable that hemorrhage does not frequently occur in the operation of its excision. On injecting, in the cadaver, the vessels supplying the tonsil, I have been impressed with its varied vascularity, derived mostly from the inferior laryngeal, the lingual, and the palatine arteries; and I wonder if it is always realized that the internal carotid artery actually touches the base of the tonsil, especially when that vessel, describing a curve, with the convexity inward, as it frequently does, seems really to bear against it.

THE TREATMENT OF PERITONITIS.[1]

BY ARTHUR V. MEIGS, M.D.,
PHYSICIAN TO THE PENNSYLVANIA HOSPITAL.

THE question how to treat peritonitis is one of the greatest importance, and upon the decision eventually reached will in the future depend the lives of many patients. Should the leaders of our profession decide that the administration of saline purges is the best treatment, and this be for a few years taught in the schools, the ordinary practitioner will soon acquiesce. If such a consummation is to be deplored, now is the time for us who are of the contrary way of thinking, to protest.

To me it seems clear that before any conclusion can be reached, it must first be acknowledged that peritonitis, as ordinarily seen, diagnosticated, and treated by physicians, is so different from the lesion or disease which has been successfully dealt with by surgeons by the administration of saline purges, that it must be recognized that, from the standpoint of therapeutics, the two questions are as far apart as though they were two widely differing diseases.

As a therapeutic measure, no one disputes the wisdom, under some circumstances, of making an attempt to abort an inflammation; and yet it is equally well known that such an attempt, when made after the inflammation has progressed so far that to abort it has become impossible, must not only fail, but, equally certain, will be productive of positive harm. It is a common rule of treatment, and one that holds good in the great majority of instances, that an irritated, sore, or inflamed part is to be put as nearly as possible at rest, and that whatever increases the pain suffered is likely to be injurious. Why shall we make an exception to this rule in all cases of peritonitis by giving salines, which throw the bowels into a state of great activity, and increase the pain, at the same time denying the patient opium, which equally certainly relieves?

I have been, and am an advocate of the use of opium in all cases of peritonitis as seen by physicians, but at the same time I have never denied my patients the use of laxative medicine, and it is, I am sure, by the judicious administration, according to the special needs of each particular case, of the two seemingly diametrically opposed drugs that the best results will be attained. The reason, probably, that the use of opium in the disease is being decried is that it has been abused. It should not be given to the point of narcosis, nor should it be expected that in cases of severe peritonitis the pain will be abolished. Measurable relief only should be looked for, with alleviation of the terrible colicky pains so characteristic of the disease in its full development. I have never been a believer in the treatment by the use of anodynes exclusively, and think it absurd to talk—as I have heard—of purging the patient by the use of opium and belladonna. If we had six months in which to work, and could first establish the opium habit in the patient, we might, perhaps, encourage diarrhœa, or at least not interfere with it by the administration of opium. In a disease, however, which lasts usually but a few weeks at the very outside, such an expectation can end but in disappointment.

The treatment that will give the best results, according to my view, is the following: in all cases in which no physical obstruction can be diagnosticated, for which operation must be at once recommended, and this should include doubtful cases in which operation may subsequently become necessary, there should be prescribed liquid diet, small quantities every two hours, and every two hours a quarter of a grain of opium, and one-twelfth of a grain of extract of belladonna. To this may be added, if it should seem advisable on account of pain, the administration twice, or at the outside, four times in twenty-four hours, a one grain powdered opium suppository. At the same time injections of warm water, with or without soap, should be given once to three or four times daily. If flatus is passed, the case continues to be a very hopeful one. This course should be rigidly adhered to for from twenty-four hours to five days, or possibly longer, when the time will have arrived at which it becomes necessary to consider the propriety of using some sort of aperient.

Purgatives are given in peritonitis for two distinct purposes: first, to increase the peristalsis, and thus overcome obstruction; and, second, to induce large watery movements, for the purpose of directly depleting the abdominal, and especially the intestinal, bloodvessels. After operations, inflammation in greater or less degree is so common, and we are so well aware that it is liable to occur, as to be always prepared to meet it. This being the case, it may be met in its very incipiency, and if inflammation can ever be aborted, it is under such circumstances. The explanation of the success, therefore, of surgeons in treating peritonitis with large doses of saline purgatives would seem an easy one, for they deal with a stage of the disease which never comes under the management of physicians, as people in the early stages of the disease do not seek advice, and, besides, if they did, the differential diagnosis between idiopathic peritonitis in its earliest stage and enteritis or mere intestinal irritation would be an impossible one. No one, I think, should deny surgeons the credit their courage deserves for having instituted this revolutionary method of treatment, for, measured by our old standards, it is revolutionary; but at the same time we must not err upon the other side, and with undue haste conclude that the method is applicable to all cases. I have long

[1] Read before the Philadelphia County Medical Society, November 7, 1888.

been of the opinion that the old surgical practice of shutting up the bowels for a week, with opium, after an operation for hemorrhoids, was a bad method.

Having, then, quieted our patient somewhat during the first few days of attendance, with injections and liquid food, and belladonna and opium, and at the same time been very careful not to induce narcosis, or in the least to depress the respiratory forces, for, if we do, the remedy will be worse than the original disease: we must, as already said, consider the propriety of getting the bowels moved. The decision in regard to the precise moment at which this attempt is to be made is, in my opinion, one of the most delicate questions that can arise in therapeutics, and gives to each of us, when we meet it, an opportunity to show a real genius for the treatment of disease. The medicine, however, which shall be given is very easy to decide upon—here there is no inflammation in its early stage. and therefore there can be no question of aborting it. Salines could only act upon the bowels like other drugs, relieving tension, if you like, by abstracting water directly from the intestinal bloodvessels; but, so far as the mere moving of the bowels is concerned, they are by no means so effective, or, as the laity call it, "searching," in their action as some of the vegetable purgatives. Any one who has been called upon to treat cases of fecal accumulation (a paper upon this subject was published some years ago by the author, in the *Transactions of the College of Physicians of Philadelphia*) will have learned how useless and ineffective are salines if the bowels are very sluggish, while small and repeated doses of vegetable purgatives are perfectly satisfactory, and certain in their effects. In such cases salines, and even castor oil, will induce large watery stools, but no fecal matter is brought away, and it seems as though the fluid material had come from below the accumulated feces, or came by, and the patient is no better off than before, though probably he will have suffered much pain. No better combination can be given than a pill consisting of a twelfth of a grain of extract of belladonna, a quarter of a grain of extract of nux vomica, a quarter or an eighth of powdered aloes, and a half or one grain of rhubarb. This should be given at first once or twice in twenty-four hours, and; if violent pain be set up—which, however, seldom happens—it should be stopped, and the opium and belladonna every two hours used again for a day or two, when the attempt with the aperient may again be made. After a day or two the pill may often be given every four hours, and I have often seen the obstruction give way under this treatment, and the patient entirely recover.

It would be most unfortunate, it seems to me, for the science of medicine, and still more so for those who in the future are to suffer from peritonitis, if the treatment of the disease with sedatives should be entirely abandoned, as has been recently recommended. Let us look at the question reasonably, and without prejudice, and in the future assign to one class of patients operation by a competent surgeon, and saline purgatives afterward, if those skilled from a study of the subject in that particular direction judge that to be the proper course; and to the other, a reasonable use of anodynes and injections, with moderate doses of vegetable laxatives when the time comes for their administration. Because, in the past, the sedative method of treatment has been abused, and patients have been hurried out of the world by the unwise management of incompetent physicians who have narcotized them, is no reason why we should cast aside what is good in the method, any more than it would be wise for us now to assume that, because the administration of saline purges is advisable in the surgical treatment of some cases, it is, therefore, to be looked upon as a panacea in the disease, and the treatment to be recommended in all cases.

For my own part, I am a firm believer that the disease may arise idiopathically, and, when I say this, I mean from an attack of enteritis or violent indigestion, or from chilling of the body, just as I belive pleurisy may arise, and, in such cases, it is reasonable to suppose that the inflammation very soon becomes more or less generalized, though, of course, it must have had its origin at some point. Such cases as these, if it be conceded that they ever arise, are not amenable to surgical treatment, for there is no point of special obstruction, and operation could not effect any good, unless by merely cleansing.

In conclusion, I cannot perhaps, better emphasize the correctness of the statement that the treatment by sedatives should not be abandoned in all cases of peritonitis, than by calling attention to the fact that in many cases in the past, and the same thing is certain to occur again in the future, post-mortem examination has demonstrated that the disease was so extensive, or of such a nature as to be necessarily incurable. Under such circumstances, I think no one will dispute that the province of the physician is to do what he can to soothe pain, and to make the last days and hours of the patient as endurable as circumstances permit, and no other one drug will conduce so much toward this end as opium.

THE TREATMENT OF PERITONITIS.[1]

BY J. M. BALDY, M.D.,
OF PHILADELPHIA.

I PRESENT this brief paper to you to-night, not because I have anything particularly new to offer, either in the line of pathology or in that of treatment,

[1] Read before the Philadelphia County Medical Society, November 7, 1888.

but that a full discussion of this most interesting and important subject may perchance be drawn out. The points as I shall present them here are, I know, considered somewhat radical from a medical point of view; but they are views toward which surgeons are gradually drawing nearer and nearer, and of which actual experience is daily demonstrating the value.

Peritonitis arises, as you are well aware, from a vast variety of pathological conditions, and in dealing with it the origin of the inflammation must always be taken into consideration. The plan of immediately putting every case of this disease on the opium treatment is departed, and, nowadays, no one would think of pursuing such a course, in a peritonitis following rupture of an abscess, for instance, provided an abscess was known to have ruptured; nor in the case of a penetrating wound of any of the hollow viscera, with extravasation of its contents into the peritoneal cavity.

The first thing to be established when called to a patient suffering with peritonitis, is the cause of the trouble. This is not by any means an easy thing to do. A case may present all the symptoms of peritonitis, and on close examination an inguinal hernia be found. The temptation here is immediately to set this down as the cause, and proceed accordingly, especially if the hernial mass is tender, and presents other symptoms of excitation, where before it had been quiescent. In such a case one may readily be misled, as has happened to myself, and the real cause found to be something else.

Again, although the books lay down most beautiful rules for diagnosticating the different varieties of intestinal obstruction, it is often impossible to say more than that there is a probable mechanical obstruction of some kind or other, somewhere in the abdomen; but even then one cannot be sure that the obstruction is caused by the peritonitis, and not the peritonitis by the obstruction. I have seen peritonitis in cases in which, on examination, it was not at all certain that the pelvic contents were at fault, and yet an operation has developed the correctness of that hypothesis. One could go on indefinitely multiplying instances of mistakes of this kind, and mistakes which are perfectly justifiable in a majority of cases. It is simply impossible in a large number of instances to do more than guess at the real cause. But although we cannot always detect from a mere examination of a patient the cause of the trouble, it does not follow by any means that the disease has arisen idiopathically. The more I see of peritonitis, the closer and closer am I inclined to draw the line at the idea of an idiopathic origin. I am not yet quite ready to deny the existence of such an origin altogether, but as our knowledge of intra-abdominal troubles has grown, just so steadily has idiopathic peritonitis diminished in frequency.

On the other hand, cases of peritonitis are constantly falling into our hands in which the diagnosis is comparatively easy, and then I think the indications for treatment are plain; while the exact condition of affairs remains in doubt, the best of men may hesitate, and often their hesitation is responsible for the unfortunate ending. Once, however, given a correct diagnosis, there should be no hesitation as to the course to pursue.

To begin with, I must unhesitatingly condemn the use of opium in any of its forms. I think the use of this form of drug, in these diseases, tends rather to increase the trouble than to diminish it; at any rate, if it does not do damage *per se*, it certainly puts the parts in an excellent condition to continue on in the course in which they have started, and blinds us to the damage being done. In a paper read before the Obstetrical Society last November, on "The Use of Salines in Peritonitis after Laparotomy," I dealt with the use of this drug quite extensively, and my convictions then stated have been constantly confirmed and strengthened, not only in peritonitis following operation, but in peritonitis from all causes. I may quote the following from that paper:

"Heretofore I have treated cases of peritonitis on the opium plan. In one case I gradually increased the dose of the tincture of opium until the patient received in one day between sixty and seventy grains of the drug. I have never been satisfied with the results of this kind of treatment, nor have I been able to convince myself that it was even logical. We are taught that opium 'puts the bowels in splints,' and in this manner keeps the peritoneal surfaces from rubbing together and increasing the inflammation. But the bowels are already in splints, as it were, and any one trying to make them move will be quickly convinced of this fact; therefore, for this purpose opium is superfluous. The drug relieves the pain, it is true; but oftentimes it does not even do this, excepting in enormous doses. Relief of pain is practically all that opium can do for good, in peritonitis. It, however, does a world of harm; it helps to keep the bowels in splints and so favor the formation of those great masses of adherent intestine which we so often find the cause of subsequent intestinal obstruction; also, the formation of numerous bands of organized lymph which as often bring a patient to grief, in after years; still worse, it closes, by paralyzing all the excretory organs, all the avenues of escape for the poisonous products of inflammation formed in that great lymph-sac, and in this manner supplies material, the best possible, for keeping up and spreading the inflammation, much more surely than the rubbing together of the parietal and visceral peritoneum will."

It also almost invariably causes tympanites, with all the accompanying dangers of over-distention, and, as has happened, death from cardiac paralysis. And further, I may say that this drug lures us into a false sense of security, and benumbs all our desires to make any further effort in our patient's behalf.

The pain and tenderness being relieved, and the sufferer being made comparatively comfortable, we stand by and wait, our waiting as often leading us to the coffin as not, without our even suspecting that our patient is worse. After having stupefied and benumbed the patient, a consultant is perchance called in to the case, only to find his hands tied, by having all the symptoms masked, and with no possible way of knowing what progress the disease is making, but by a surgical procedure, and that, in view of the fact that the patient *seems* better, he dare not propose.

In great contrast to this picture stand the results of the use of salines. Here the bowels are put into active peristaltic action; this motion tends to prevent the formation of adhesions and bands; the peritoneal cavity is drained of the products of inflammation; the inflamed surfaces are relieved of all engorgement, by a thorough depletion of the vessels in the intestinal walls; the inflammation is most effectually stopped; the pulse and temperature almost immediately improve, and the pain is relieved as quickly as can be by the use of opium. This, theoretically, may seem strange, but nevertheless it is a clinical fact.

While writing this paper I was called to a woman sixty years of age. Her knees were drawn up; her abdomen was greatly swollen and tympanitic; the pain was excruciating, and she could not tolerate any manipulation whatever of the belly-wall; her temperature was elevated and her pulse quick; an anxious expression of the face and vomiting were present. The cause of the attack could not be detected, probably only because she could not be handled properly for an examination. Salines were administered, and in much less than fifteen hours the belly-walls were shrunken and flabby, permitting of free manipulation, with hardly any evidence of pain; vomiting had ceased; pulse and temperature were both in good condition, and, in fact, all the symptoms were rapidly disappearing. She passed a most comfortable night, sleeping almost the whole of it. In twenty-four hours more I had discharged the patient, simply with instructions to keep her in bed for a few days longer, and feed her well, in order that she might regain the strength she had lost. I may add that the case had appeared so bad when first seen, that I had notified my nurse to be ready for a possible operation the next day. This same result has followed this treatment so often, and so constantly in my hands that I have come to look for it with certainty as soon as the bowels can be made to act. Of course, should we suspect that a strangulated hernia was at the root of the trouble, or that there was pus in the peritoneal cavity, or that the intestines were obstructed by an organic lesion at any point, we would not think of resorting to purgation, but would immediately turn to our surgical resources.

The sources of a peritoneal inflammation are so numerous, it would be useless to attempt to enumerate them further; but the general rule might, I think, be safely laid down, that where it can be demonstrated that the disease is caused by an organic lesion, abdominal section is indicated, and that in addition those other cases which refuse speadily to yield to purgative treatment, should be immediately dealt with in the same manner. When a pus sac is known to be at the bottom of the trouble, or an appendicitis is in existence, it is folly to fool with drugs of any kind; and where drugs are used and relief does not quickly follow, whether the cause is known or not, it is equally unwise to delay longer. The source of the disease once removed, the peritonitis will rapidly disappear.

Cases reported in the journals are constantly demonstrating the worthlessness of all medical interference, and are steadily pointing to the fact that peritonitis is preëminently a surgical disease, and should not be intrusted in the hands of a purely medical man, but should be always and at once turned over to the surgeon. An article by Mr. Tait, in a recent number of the *Annals of Gynecology*, sets this forth in flaming colors The very first case reported by him was one of purulent peritonitis, which had been tinkered with, until even the operation he performed was too late to save the woman. An abdomen containing pus, either encysted or free in the cavity, whether produced by puerperal disease or any other, demands opening and removal of that pus from wherever found. If there is not active peritonitis present, the person afflicted is liable at any minute to be so attacked. This fact does not seem to be sufficiently understood, and physicians are constantly treating pelvic abscesses with local applications, electricity, etc., sometimes suspecting the true condition, at others, mistaking it for some other condition, such as tubal pregnancy, for instance, as has been done lately by one of the most prominent advocates of the electrical treatment for extra-uterine pregnancy, in this country.

Where an intestinal obstruction, an appendicitis, an inflamed tubal condition, a penetrating wound of any of the viscera, a tumor, or any of a dozen other troubles are found, they should be dealt with according to our present surgical light. In such cases as these peritonitis is not a disease, but merely a symptom, and when the original cause is removed the trouble subsides at once. Often the mere opening of the abdomen, together with irrigation and drainage, is sufficient. This seems especially to be true of those cases of tubercular peritonitis, so many of which have lately been springing up, and to which I called attention in my paper on "Exploratory Laparotomy" last spring. Then I was able to show that six deaths from various causes had taken place out of thirty-six, collected in Germany, and only

one death out of seventeen cases which I had collected in this country. This death was due, not to the operation itself, but to defects in the details of the operation. In all these cases irrigation or drainage, or both, followed the operation, and seemed all that was needed to effect a permanent cure. It is useless to take up your time by quoting cases—literature is teeming with them, and almost every journal picked up contains a lesson.

To sum up the conclusions of this brief paper, I should say that when called to attend a patient suffering with peritonitis, we should first determine the cause, and if it is found to be an organic one, the immediate use of the knife, followed by irrigation and drainage, is the only proper method of procedure.

Should the cause be found to be functional, the use of purgatives, followed, if necessary, by enemata, is indicated; and these failing to relieve quickly, surgical methods should soon follow.

If the case is of doubtful character, I would be inclined first to try the purgatives, and stand ready to interfere with the knife at a moment's notice.

Of course, it is impossible to lay down any absolute general rules for the treatment of every case, as each and every one must be a study of itself; and yet, as nearly as rules can be laid down, the above seem to me to be the proper ones.

EFFECT OF ANTIPYRIN ON THE SECRETION OF MILK.

By T. HAVEN ROSS, M.D.,
of Buffalo, N. Y.

The following case I think worth reporting, and I hope that further proof of the action of antipyrin in suppressing the flow of milk will be forthcoming from other members of the profession, as it is a simple and usually safe medicament.

The notes of this case as taken from my record are as follows:

"October 27, 1888, 9 A. M., was called to see Mrs. ——. She had taken her child (sixteen months of age) from the breast the previous evening, and at the time of my visit was experiencing much pain and discomfort from the distention of her breasts. Ordered breast-pump applied, which drew off eighteen fluid-ounces of milk; also ordered eight grains of antipyrin three times daily. (Had previous knowledge of this patient's tolerance of the drug.) At 3 P. M., eight fluid-ounces were drawn with the pump.

Oct. 28, 9 A. M., six fluid-ounces, and at 6 P. M. three fluid-ounces were drawn.

29th, 9 A. M., two fluid-ounces, and at 6 P. M. one fluid-ounce were drawn.

30th. No milk in breasts. Medicine discontinued. Pain and discomfort disappeared after first dose of antipyrin. No change was made in the previous rather generous diet. Appetite and digestion remained good."

Reference may be made to an article in the *Bull. gén. de Thérap.*, June 30, 1888, page 554, mentioned in the *American Journal of the Medical Sciences* for October, 1888, page 404.

MEDICAL PROGRESS.

The Local Treatment of Disorders of the Cerebral Membranes.—The local treatment of disorders of the cerebral membranes has always been recommended. For a number of years Mosler has adopted a derivative treatment in such conditions, with success even in severe cases. In a case of intense meningitis, following upon acute rheumatism, prompt results were attained by the application of a large fly-blister to the shaved head and two behind both ears, after other methods had been fruitlessly tried. The author has used this mode of treatment in various forms of meningeal disease and has demonstrated that extensive counter-irritation (by vesicants or ointment of tartar emetic) applied in the immediate neighborhood of a suffering organ, as directly upon or close to the scalp, is even efficacious in chronic affections of the cerebral membranes. Failure may be owing to the application not being extensive or protracted enough; aspiration, in case of chronic hydrocephalus, was not attended with permanently favorable results. Notwithstanding the compression made after the operation, the exudation reaccumulated. Repeated aspiration of hydrocephalic fluid, however, is well borne. Loebker has punctured the head in two cases of chronic hydrocephalus, evacuated the fluid and applied compression. The fluid returned in a few days. Both children died from the disease.—*Therapeutische Monatshefte*, October, 1888.

Therapeutic opinions upon Ichthyol and its Preparations.—Dr. Carl Pauli, of Cologne, writes that upon the merits of the above-named preparation, he finds opinions very much divided. While some hold that it is totally useless, others highly praise its merits. Among the latter is Unna, who lately has written a monograph upon this preparation, in which he states that he has used it in different affections, but especially in skin-eruptions.

Lorenz adds to this that he found in ichthyol an unsurpassable remedy for acute and chronic articular rheumatism, for gout, mastitis, and contusions, in which troubles the curative actions of this drug were surprisingly quick.

Klony is of the same opinion (*Therapeutische Notizen von Rabow, J. C.*, 1886, No. 9). He treated at sea a number of shin-bone affections with ammoniated ichthyol and oil of turpentine, with marked results. According to him, after the application of this drug to the painful surface, pain disappears, a blister taking its place.

The opinion of Klamann is not quite so favorable ("Treatment of Erysipelas with Ichthyol," *All. Med. Central Ztg.*, March 26, 1887). He states, "that although he has obtained some satisfactory results from its use in erysipelas, he found that in the more severe cases it was unable to retard the progress of the affection, and he was compelled to return to his old but surer remedy of terpentinphenol, in conjunction with the internal administra-

tion of salicylate of sodium and tincture of aconite." Klamann likewise states "that the drug in question showed no material action upon articular rheumatism, while upon synovitis its action is at times satisfactory, at times not. With some patients the pain from the burning was so intense that nothing could induce them to submit to a second application."

"My own experience," writes CARL PAULI, "has been that for contusions and distortions there is no drug from the outward application of which we derive greater benefit. The same might be said of its use in lymphangitis, if three cases which I treated with it are worth considering. It was my intention to try ichthyol in erysipelas, but Dr. Oppolzer's old advice to me, 'never throw away dirty water, till you are sure of the fresh,' made me abstain, and adhere instead to Schwimmer's and Gayza Faludi's treatment, which consists in applying the following:

R.—Carbolic acid	ʒss.
Olive oil	ʒj.
Precipitated chalk	q.s.—M.

Make a soft paste.

"I can say but little about its use in skin diseases, but suppose that its beneficial action here is largely due to the sulphur it contains. Thus Unna finds it of great use in urticaria, in which disease he says that it surpasses salicylate of sodium and atropine. As to the use of ichthyol in articular rheumatism, my observations concur with those of Klamann. I might state here that an old lady, a sufferer of more than twenty years from this malady, obtained no marked benefit from its use, but continued to rub it in the affected parts at night, as, according to her daughter's statement, she slept better after the application."—*Deutsche med. Wochenschrift*, October 25, 1888.

Treatment of Cancer with Intraparenchymatous Injections of Ozone-water.—DR. IGNAZ REICHERT, of Aschaffenburg, gives an account of a case of cancer treated according to the methods of Dr. Schmidt, which consists in the intraparenchymatous injections of ozone-water

The patient, a widow, born May 31, 1821, presented herself with an epithelial carcinoma of the left cheek, which she attributed to a wart which had formed there four years ago, and had become inflamed through repeated irritation. The carcinoma was of the size of a quarter of a dollar, its edges red and infiltrated. The needle of a Pravaz syringe permeated its substance as though it were butter; the neighboring lymphatics were not enlarged.

The patient was treated from May 15th to July 24th with intraparenchymatous injections of Lender's ozone-water, the strength of the injections being increased by degrees. Resolution took place rapidly; on July 7th the size of the cancer was reduced to that of a ten cent piece, its body and edges being studded with new granulations, its substance was firm, the syringe entering with great difficulty. From this on, the size of the affected part became smaller and smaller. On July 24th the writer made his last injection. Two days later union had taken place, palpation revealed slight infiltration; the skin of the cheek was of a uniform color.

In a foot-note the writer adds that he submitted Lender's ozone-water to a chemical analysis, and found that it contained a large amount of chlorine, and puts the question: "Is the success of this treatment due to the ozone or chlorine?"—*Münchener medicinische Wochenschrift*, September 4, 1888.

The Milk-curdling Ferment of the Stomach.—DR. E. G. JOHNSON has studied the action of the milk-curdling ferment of the stomach in the clinic of Professor Riegel, of Giessen, and subsequently in the Sabbatsberg Hospital, Stockholm. Researches were made in twenty-four cases on the presence of the ferment and the pathological conditions relative to it. Fourteen of these patients suffered from hyperacidity, accompanied in four of them by moderate dilatation of the stomach. In one of these latter there was also hypersecretion of the gastric juice. One case had considerable dilatation of the stomach, with hyperacidity and marked hypersecretion. In three cases the dilatation was insignificant, but there was hyperacidity, complicated in one case by slight, and in another by very great, hypersecretion; in the third case the hyperacidity was accompanied by chlorosis. Three other patients suffering from hyperacidity were also the subjects of gastric ulcer. Dr. Johnson also examined four cases of hyperacidity with neither dilatation nor hypersecretion, of whom three were chlorotic; a case of catarrhal jaundice, four cases of severe chronic dyspepsia, and five cases of carcinoma of the stomach. The contents of the stomach were removed while the patient was fasting, and also four or five hours after food had been given for the purpose of the observations.

Dr. Johnson sums up his researches as follows: 1. The milk-curdling ferment is a constant product of the glandular secretion of the stomach, and it is met with at all periods of digestion except in cases of cancer of the stomach, in which it is never found. 2. The ferment was also found in the hypersecretion of the gastric juice of a fasting patient after his stomach had been washed out the previous evening. 3. Gastric juice, which contains hydrochloric acid, and which when neutralized causes coagulation of milk, does not appear to be affected in its action by the greater or less amount of acid contained in it at first. 4. The milk-curdling ferment does not pass into the urine. 5. The ferment is easily destroyed by an excess of alkali, and it is probably on this account that it does not pass into the feces under normal conditions. 6. During fever the ferment appears to be absent from the stomach. 7. The ferment causes coagulation more slowly in boiled than in fresh milk. 8. During the coagulation of milk by the ferment the reaction remains neutral, and lactic acid is not met with after coagulation.—*Lancet*, November 17, 1888.

Hygienic Treatment of Dyspepsia.—DUJARDIN-BEAUMETZ affirms that, in order to regulate the diet of dyspeptics, we must distinguish three conditions: 1. One in which there is an over-secretion of the gastric juice; 2. One in which the secretion is deficient; 3. One due to sympathetic disturbances.

1. *Dyspepsia due to over-secretion of gastric juice.*—Diet to be purely vegetable, consisting of eggs, farinaceous preparations and fruit. *a.* The eggs to be soft-boiled, especially the yolk. *b.* Farinaceous foods to be taken in the form of soft soups, as potato, turnip, lentil, Indian wheat, chestnut, oatmeal, barley, and macaroni soups; all these, of course, to be rendered as thin as

possible. *c.* Vegetables to be thoroughly cooked and to be taken in the form of vegetable soups, or soup made of small peas, all salads to be well boiled; the same holds good for spinach and turnips. *d.* All fruits, with the exception of raisins, to be made in the form of jelly. *e.* The bread to be well baked, or toasted. *f. Drinks.* Wine mixed with water, light beer, or milk mixed with alkaline waters.

2. *Dyspepsia due to deficient secretion of the gastric juice.*—Peptonized substances, toasted bread, bouillon, mixtures of broths and milk, powdered meats, scraped meats, peptones, pepsin, lemonade with hydrochloric acid:

℞.—Acid hydrochloric . . . . . ʒij.
Aquæ . . . . . 1 pint.
One glass after each meal.

3. *Dyspepsia due to sympathetic troubles.*—Diet to be purely vegetable.—*Revue de Thérapeutique*, November 1, 1888.

Action of Antipyrin on the Teeth.—Dr. Galippe, a dentist, finds that antipyrin taken internally has the effect of blackening the teeth. Teeth which, previous to the administration of this drug, had lost their enamel, blackened sooner than otherwise healthy teeth. The discoloration is only temporary, as it can be removed by cleansing the teeth with water containing an abundance of oxygen.—*Deutsche medicinische Wochenschrift*, November, 1, 1888.

Tubercle of the Aorta.—Pittrich relates (*Zeitsch. f. Heilk.*, abstr. Weichselbaum, *Centralbl. f. Bacteriology*, iv. 20) a case of acute miliary tuberculosis in a boy, twelve years of age, in which the source of general infection appeared to be the rare (hitherto undescribed) condition of tuberculosis of the aorta; for to the posterior wall of the ascending aorta adhered some tuberculous lymphatic glands, from which the tubercle had spread into the coats of the vessel. Bacilli were found both in the glands and in the aortic wall, and it is assumed that they were disseminated through the blood stream by direct detachment from the intima of the vessel.—*Lancet*, November 17, 1888.

Inoculation of Erysipelas in Cancer of the Breast.—Dr. A Holst (*Centralblatt für Bakt.* and *Journ. des Cour. Méd.*, 1888, 39) reports the following: "Several months after the extirpation of one of her breasts for cancer, a woman noticed upon her skin a new cancerous formation, the entire right side of her chest resembling a budding field. Her general condition being good, she was advised to submit to an erysipelatous inoculation, to which she consented willingly.

"The first inoculation proved unsuccessful, but thirty-six hours after the second one, the patient was seized with rigors; the characteristic eruption of erpsipelas gradually spread over her right arm, and by degrees the disease was well developed, the redness extending to the left side of her chest and back. The fever abated on the seventh day.

"Four months and a half after inoculation, everything had returned to the initial stages; the perceptible improvement of the first few months had disappeared, cancerous nodules reappeared on the inner surface of the arm, and the malady continued its onward course.

"To sum up, Holst concludes, in accord with Nelsen, that under the influence of erysipelas the progress of cancer is at first arrested, but later on its fatal termination is hurried."—*L'Union Médicale*, November, 1888.

Treatment of Ozæna with Naphthol.—At the last medical congress of the French Laryngological Society, Dr. Ruault stated that in treating ozæna he irrigated the nasal passages three or four times daily with the following mixture:

To one pint of water add a large spoonful of the following powder,

℞.—Borate of soda.
Bicarb. of soda, āā equal parts.
And then a teaspoonful of the following:

℞.—Naphthol . . . . . 12 parts.
Alcohol (90°) . . . . . 84 "

In very obstinate cases after having performed irrigation with the above, insert into the passage, and allow to remain for fifteen minutes, a tampon saturated with the following:

℞.—Naphthol . . . . . 12 parts.
Tr. quillaiae . . . . . 88 "
Aquæ dest. . . . . 400 "

The advantages of this treatment are, first, a rapid disappearance of the bad odor; and second, marked diminution of the secretion. The only disadvantage in the use of naphthol is a slight burning sensation, perceived immediately after its application, which, however, soon disappears. It is *essential* that the irrigating mixture should be freshly prepared before each application.—*Deutsche med. Wochenschrift*, October 25, 1888.

Treatment of Hepatic Colic with Olive-oil.—Dr. Charles N. Valin, of Zeloeil, Que., reports that he has tried the "olive-oil" treatment for hepatic colic, as first advocated by Dr. Just Touatre, of New Orleans, with marked success. He had tried all the remedies recommended by the leading authorities, such as morphine, chloroform, ether, antipyrin, and various purgatives, without any decided benefit. In the present case he resolved, as a *dernier ressort*, to try olive-oil. His patient, a woman about forty, was getting rapidly worse. Her temperature was high and unvarying, with marked delirium; her digestive organs very irritable; tongue red, dry, and glazed. He was in doubt whether she would be able, while in such a condition, to take and retain such large doses of oil. Still he tried. Two large glasses of oil were administered, the second fifteen minutes apart from the first, and, to his surprise, both were retained. Two hours later, she passed a number of calculi, some large, some small; some hard, others soft. From this on the temperature subsided, the tongue became moist, food was retained, and his patient made a rapid recovery.—*L'Union Médicale du Canada*, November, 1888.

Treatment of Pneumonia.—Maragliano, of Genoa, at the first Congress of the Italian Society for Internal Medicine, recently held in Rome, states that he regarded the cardiac weakness in pneumonia as due to poisoning of the blood from the infecting microbes of this disease, and holds that venesection is indicated in pneumo-

nia under the same conditions that it would be indicated in uræmia. In his experience the internal administration of iodide of potassium and calomel, as well as parenchymatous injections, has proven to be of no avail. Cold baths he has found to do good. Of antipyretics he holds quinine to be the best. Alcohol is indispensable. Ipecac he finds injures the heart.

CARDARELLI thinks it would be difficult to assume from the mere spreading of the pneumonia infiltration whether venesection was indicated or not; it would likewise be difficult to state that venesection would rid the blood of its infectious elements. As for ipecac, it was certainly a heart poison, but its beneficial action upon the bronchia and lungs would certainly supplant its action upon the heart.—*Deutsche med. Wochenschrift*, November 1, 1888.

Action of Hydrofluoric Acid on the Tubercle Bacillus.—At a late meeting of the Academy of Medicine, DR. JACCOUD called attention to the fact that he had inoculated four guinea-pigs with the sputum of phthisical patients, and then six others with phthisical sputum which had been submitted to the action of hydrofluoric acid for forty-five minutes, with the following results:

Two of the first four died rapidly of septicæmia, the autopsy revealing no tuberculous lesion whatever. The two remaining presented a diffuse tuberculosis, the greater part of the granular deposit being found in the axilla, the neck, and the mediastinum; while in the lungs, the liver, and spleen the deposit was just in the state of formation.

The six guinea-pigs inoculated with the sputum which had been submitted to the vapor of hydrofluoric acid presented all, at the expiration of from five to eight weeks, a diffuse tuberculosis, identical with that of the first six guinea-pigs. The extent of the tuberculous deposit was even greater, reaching the mesenteric ganglion, and this too when the strength of the acid was at its maximum, being of equal parts of acid and water.

Hence he deduced the conclusion that hydrofluoric acid in solution does not modify in any way the virulence of the bacillus tuberculosis.

Similar experiments with pure hydrofluoric acid led Dr. Jaccoud to conclude that it would destroy the bacillus tuberculosis, but the establishing of this fact was of no practical value, since it would be impossible to introduce pure hydrofluoric acid into the human economy.

DR. HÉRARD, responding to Dr. Jaccoud, said that air charged with pure hydrofluoric acid could be inhaled for at least one hour at the rate of two pints a minute; the acid thus inhaled would contain from fifty to sixty per cent. of water, which could even be tolerated by children.

Dr. Hérard further spoke in commendation of the experiments of Dr. Trudeau, of New York, while he criticised severly those of Drs. Grancher and Chantard, these gentlemen having made use of intra-venous injections, while hydrofluoric acid should be simply inhaled. He also stated that a number of physicians have obtained great success from the acid inhalations; thus Drs. Moreau and Cochez treated sixty cases, in twenty-eight of which there was marked improvement; Dr. Goetz treated thirty cases with improvement in nineteen. He regretted that Dr. Jaccoud did not put his experiments to greater advantage. With pure acid, or with a solution of two-thirds or three-quarters pure acid, the remaining one-third or one-quarter being water, the results would differ largely. In his opinion Dr. Jaccoud had experimented with solutions too dilute to act with efficiency.—*L'abeille Médicale*, November 8, 1888, and *L'Union Médicale*, November 8, 1888.

Meco-narceine a New Hypnotic.—DR. LABORDE reports in the *Bull. de l'acad de Méd.*, 1889, No. 19, that in conjunction with Dr. Duquesnel he has obtained from opium a new alkaloid to which he has given the name of méconarceine. He claims for this preparation, that it produces a quiet sleep, only slight contraction of the pupils, slight anæsthesia, no headache, and no disturbance of the digestive tract.—*Centralbl. für klinische Medicin*, October, 1888.

To Prevent the Deposition of Fat in the Mammæ.—After speaking of the difficulty which women encounter in taking iodide of potassium to prevent the deposition of fat in their breasts, PROFESSOR KISCH gives the following treatment, which he praises highly:

At first the breasts must be covered with a salve of iodoform, the formula of which is as follows:

R.—Deodorized iodoform . . 1 part.
Vaseline (pure) . . . 15 parts.
Essence of peppermint . . 11 drops.—M.

The breasts are then enveloped in warm linen cloths which have previously been dipped in the following solution:

R.—Alum . . . . . 1 part.
Acetate of lead . . . 15 parts.
Distilled water . . . 100 " —M.

Over the towels place some waxed paper, the whole to be left in place for twelve hours. The inunctions and wrappings are repeated morning and evening. The treatment must be continued for several weeks. The breast should also be rubbed with an aromatic alcohol to harden the skin and prevent it from drying up. Finally, a bandage should be worn which will hold the breast well up.—*Gazette Gynécologie*, November 1, 1888.

Successful Treatment of Leprosy.—DR. DRECKMANN claims to have successfully treated a typical case of lepra tuberosa and anæsthetica by Unna's method, which consists in painting the entire body, hands and feet excepted, twice daily, with a ten to twenty-five per cent. salve of chrysarobin, while to the hands and feet is applied a five to twelve per cent. pyrogallic-acid salve. Internally, forty-five grains of ichthyol are taken daily, in divided doses.—*Wiener med. Presse*, Nov. 11, 1888.

Treatment of Whooping-cough.—DR. WIKSTRAND, of Stockholm, writes (*Wiener med. Blätter*, No. 17, 1888) that in Sweden alum is considered the best remedy for whooping-cough. It is administered in a two per cent. solution, of which a small teaspoonful is taken from four to six times daily. Under its influence the severity as well as the frequency of the cough abates, the vomiting ceases, and the appetite is reëstablished.—*Centralbl. für klinische Med.*, Nov. 17, 1888.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, DECEMBER 8, 1888.

DEATH BY DECAPITATION AND BY ELECTRICITY.

THERE has recently been considerable discussion among the learned societies and by the press, in France, upon the subject of capital punishment by decapitation, as practised in that country. There are those who oppose the mode of execution by decapitation, because, as they suppose, feeling and consciousness survive, for a time, the severance of the head from the body; others, who regard the application of capital punishment as a great social crime, which has never prevented any other crime, and are opposed absolutely to the death penalty in any form whatsoever.

M. PAUL LOYE, who has made a careful study of the subject of death by decapitation, with the object of determining, by the aid of scientific experimentation, whether consciousness survives decapitation, has sought the present opportunity for publishing the results of his investigations. He has left out of the question everything that relates to sentimentality and the right society exercises of depriving a human being of life, and has devoted himself strictly to the scientific aspects of the question. He has not shrunk from being present at the execution of criminals, and of noting carefully the appearances after decapitation; and being instructed on this point, he has sought in the laboratory the explanation of the facts which he has observed, and has endeavored to determine their physiological value. The conclusion arrived at which most interests society is that, if the penalty of death is to remain in the penal code, decapitation is the mode of punishment which abolishes most completely the sufferings which result from the application of the penalty.

Investigations have shown that if, by means of anæsthesia, an animal is plunged into profound unconsciousness, the contractions of the face, the distortions which appear to indicate violence of suffering, produce themselves with their usual regularity and physiognomy. They are not then conscious phenomena, indicative of sensations received, but unconscious automatic acts.

While society has the right to demand that the criminal who has merited the penalty of death shall not be subjected to horrible torture, it is not ready to assume the position of the "elegant sentimentalists, sometimes maudlin and semi-poetic," who would abolish capital punishment absolutely. The mutilation of the body by the guillotine is repulsive, though unattended by suffering, and furnishes a specious argument to the opponents of capital punishment for pursuing their opposition. The suffering often caused by hanging through maladroitness of the executioner, suggests a change to a mode which would meet the requirements of the law without the possibility of inflicting torture. It is upon this ground that New York has recently prescribed the mode of execution by electricity in the place of hanging. No execution has yet taken place by this mode.

In THE NEWS of May 14th last, the subject of death by electricity was discussed, and reference was made to the recent studies of Arsonval upon this mode of death, which show that the action of electricity is direct and disruptive, causing instantaneous and immediate death, by disintegrating effects upon the nervous, vascular, and muscular tissues, which lose instantaneously their physiological properties. Fell, of the Niagara University, Buffalo, by a series of experiments on animals, has found that a sufficiently powerful electric current produced instantaneous death, and that resuscitation after the passage of such a current is impossible.

As it has been proved that both the mode by electricity and that by decapitation are unattended by suffering, it would seem to be a matter of indifference, from a humanitarian standpoint, whether the one or the other be the established form of capital

punishment, but the latter cannot be relieved of the picture of horror. Time will determine whether the country is prepared to follow the precedent established by the State of New York.

THE FLORIDA EPIDEMIC ABATES.

At Jacksonville, November 27th was the first in 112 days in which a "clear bill" was declared by the Board of Health; that is, no new cases of yellow fever and no deaths from that cause were registered on that day. Twenty cases only then remained in the city, and these were all convalescent and past the danger-point. The total cases during the epidemic will approximate very closely to 5000; and the ratio of mortality, according to the latest official data, is not quite nine per cent. of the reported cases. The fair presumption is that the epidemic of 1888 is about to pass quietly into history, to be grouped with the numberless other pestilences that have destroyed human life.

But just what will be the condition of Florida when Jacksonville has wholly recovered? It becomes highly important, during the coming winter, to settle the sanitary questions which so deeply interest the southern tier of our States; they are questions which relate to the dangers, believed by many to be permanent at several points below the frost-line in Florida; and also to the remedies and the future prevention of a similar destruction of life and values. A grave responsibility rests with the Legislature of the afflicted State as to what steps are taken this winter toward the formation of a strong State Board of Health. No false economy should be allowed to come between the welfare of the State and country and the full and efficient policing of the Tampa Bay district.

We would strongly urge the medical press to join in pointing out the prime importance of establishing a vigorous and liberally equipped State Board of Health. The profession should unite in holding up the hands of our Southern brethren, who must otherwise struggle yearly with an entrenched enemy. Those who travel in Florida should also be cautioned that the lower part of its peninsula may be infected all the winter through. It is reported on good authority that there were cases of fever in Jacksonville as early as last February, the infection having been brought northward from Key West and Tampa in midwinter along the line of the railway from the latter town.

We rejoice with Jacksonville that the terrible visitation of 1888 is apparently drawing to a close, but we must not overlook the dangerous possibilities which must continue if this winter's preventive work be not done wisely and well. To imitate a form of expression used by Pasteur, in his recent address, the law of humanity places the duty, upon those in authority, to guard well the "frontiers of life."

The resignations of Prof. D. Hayes Agnew from the Chair of Surgery and of Prof. William Osler from that of Clinical Medicine were presented to the Trustees of the University of Pennsylvania last Tuesday, to take effect at the end of the winter's course. They were accepted with expressions of regret and high appreciation of the value of the services which they had rendered to the University.

The Commissioner of Agriculture has appointed a commission, consisting of Professor William H. Welch, of Johns Hopkins University; Dr. E. O. Shakespeare, of Philadelphia; and Professor T. J. Burrill, of the University of Illinois, to investigate the subject of swine diseases in the United States, and the methods of their treatment and prevention.

A protest to the Council of the British Medical Association, signed by a large number of the most influential members of the profession in Great Britain, calls attention "to the publication in the 1450th number of the *Journal* of the Association of the facsimile of a 'script' by the late Emperor Frederick of Germany, referring to his treatment by one of his medical attendants. The publication of this document the signers regard as a violation of professional confidence, and its appearance in the *British Medical Journal* as discreditable to the medical profession of this country. They accordingly request the President and Council to take such immediate action as may be required to clear the Association and profession from the discredit now attaching to them in respect to this matter."

The *British Medical Journal* of November 24th (just received) "feels it necessary to say that the protest appears to us, editorially, to be based on incomplete information, and that an answer which we consider adequate will be laid before the Council." A press cablegram from London, on November 28th, however, states that at a Council meeting of the British Medical Association a resolution was passed deprecating the publication of the details of the late Emperor Frederick's illness as a violation of professional confidence; and that the Council

accepted the regrets of the Editor of the *Journal*, concerning the publication of them.

In this connection it may be further stated that Sir William Jenner has resigned from the British Medical Association on the grounds, it is alleged, that as Court Physician he could not countenance the publication, in the *British Medical Journal*, of the late Emperor Frederick's notes to Sir Morell Mackenzie; and Sir Morell Mackenzie has resigned his membership in the Royal College of Physicians for reasons which are not stated.

Recent elections in England and Wales have placed medical men at the head of the municipal government in the towns of Hull, Bath, Marlborough, Wolverhampton, Liskeard, Morpeth, Godalming, Congleton, Calne, New Romney, and Yeovil.

At the University of Vienna a considerable number of American students registered at the opening of this year's session of the medical school. The *Lancet*, November 17th, states that there were seventy English-speaking medical students, "most of them American," and that some of the courses are given in English. The *Vienna Weekly News*, the only paper published in English in that city, has a column devoted to the interests of the medical students.

SOCIETY PROCEEDINGS.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, November 7, 1888.

The President, J. Solis-Cohen, M.D., in the Chair.

Dr. A. V. Meigs read a paper on the

TREATMENT OF PERITONITIS.

(See page 641.)

Dr. J. M. Baldy then read a paper on the same subject.

(See page 642.)

Dr. J. H. Musser said that he had but little, if anything, to add to the able papers of Drs. Baldy and Meigs, unless it be his own personal experience. While interested, and in a measure agreeing with the remarks of Dr. Baldy, yet, as a medical man, he must largely agree with the conservative views of Dr. Meigs. In one respect, however, he begged leave to differ, and he believed that cases of idiopathic or so-called functional (?) peritonitis must be very rare, for in the course of a tolerably large experience he had not met with any; but, on the other hand, had had frequent cases that originated from some local cause. Indeed, it is his belief that in every instance almost, some disease, acute or chronic, in the intestinal tract, or diseases of the organs covered by the peritoneum, is the cause of inflammation of that membrane, apart from septic or microbic causes.

A successful treatment of all cases, therefore, must depend, in the first place, upon the recognition of the many antecedent pathological conditions that may be considered as causal. A large majority of the cases that he has seen got well without resorting to surgical measures. In these instances a similar plan of treatment to that suggested by Dr. Meigs was, to a certain extent, carried out, notwithstanding the fact that a local or a focal origin, if you please, of peritonitis could always be determined, and the general and local medical treatment will often either prevent, or at least counteract, the deleterious effects of a general inflammation, as before intimated.

The plan of treatment which he has carried out in most of the cases has been rather simple, beginning in the first place with local depletory measures either by blisters or by local depletion with leeches, not fearing the depressing effects of local depletion, but rather encouraging further bleeding than otherwise, following the depletion by poultices, and possibly by general stimulating applications, such as turpentine. At the same time he endeavors to open the bowels as early as possible, and while, on the one hand, vegetable cathartics are of service, yet, on account generally of the excessive vomiting, some mercurial has usually been preferred. He uses principally, if vomiting is present or not, calomel in doses of one-twelfth, one-eighth, or one-fourth of a grain every hour or half hour, until the desired effect is produced; and, in addition to the purgative effect, he is, indeed, not disturbed if he can get a constitutional effect of the drug also, for, as is well known, its antiphlogistic effects in peritonitis are undoubted.

With regard to opium, he uses it simply to relieve pain, and, hence, in the smallest doses possible. He prefers the hypodermatic injection of morphia, and it is surprising frequently what small doses are sufficient to give comfort. Sometimes an eighth or a sixteenth of a grain, twice daily, will suffice. In addition to the anodyne effects of the drug, its stimulating effect is, of course, of service, and after the mercurial has acted on the bowels, he combines the extract of opium with the drug, giving the opium more frequently, and the mercury less. Usually he uses atropia with the morphia, and in this way counteracts the depressing effects of the opiate.

Stimulants are worthy of mention. He begins their use early, and, indeed, from the first twenty-four hours in some cases permits it as the only kind of food administered until all danger is past. He gives it early, in order to avert or to mitigate the stage of collapse which is likely to ensue. With this general plan of treatment, bleeding, moderate purgation, opium to relieve pain, and the use of stimulants, his patients have usually recovered. He may very often endeavor to give in some way quinine, preferably by suppositories.

Patients die of peritonitis generally, not because its management is not understood, but because it is not recognized sufficiently early. Hasty examinations without due regard to the local origin of the symptoms of the disease—and of these pain is usually the earliest—cause one frequently to overlook the actual condition of the case. Two cases he has seen lately, one in consultation, another at the autopsy, illustrate this. They were both cases of peri-cæcal abscess. In the one instance the

patient was ill for four or five days prior to my visit. Prior to the last twenty-four hours he visited the physician's office, simply complaining of recurring attacks of sharp abdominal pain, which were attended with a moderate amount of diarrhœa. The physician looked upon it as a case of cholera morbus, and treated it accordingly. The day of his death the patient did not leave his bed, but was visited by the physician, who was horrified to find him in collapse. Unable to recognize the cause of collapse, not even suspecting that death was imminent, he asked me to see the patient. The thready pulse, the persistent watery vomiting or regurgitation of fluid, the cold sweat and the cold extremities, the tympany, and the rigid abdominal muscles, told the tale more plainly than his words, and an area of dulness in the right iliac fossa, with faint local swelling and tenderness, pointed to the appendix as the probable source of the inflammation. Death ensued a short time afterward, and at the autopsy a most extensive peritonitis, secondary to rupture of the vermiform appendix and peri-cæcal abscess, was found.

In the other instance the patient, a lad sixteen years old, was seen by the physician at six in the evening. In the hurry of his work he neglected the minute examination which he usually bestows upon them, and prescribed for what he thought was a colic induced by indigestion, which colicky pains had been going on for two or three days, the patient, however, being out most of the time. He saw him later in the evening, much improved, apparently, from the effects of opium, so often misleading because it masks symptoms, and was shocked to hear the next morning that at six o'clock his patient had died in collapse. In this case foreign bodies in the appendix had caused the usual rupture, with peritonitis and death. So, too, peritonitis arises, as we know, after inflammation of the tubes or ovaries, after disease of the biliary passages, and after other instances of local disease.

The most difficult question for the physician to decide, and the one that has always been the most serious in his mind, next to the grave question of when to open the bowels, is when to ask the surgeon's help. Given a case with a palpable tumor, with local œdema, the fever, the vomiting, and the general tenderness indicating a general inflammation, and the question is an easy one to decide. On the other hand, the tumor being obscure, possibly only an area of dulness outlines it, the symptoms, however, becoming threatening: shall we then ask for help? He always does, of course, when in doubt; but he is fixed in his mind to have surgical aid and instructs the family to that effect when persistent vomiting continues, when the night-sweats become marked, and when tympany and bowel obstruction are decided. Indeed, after the second night-sweat, even if there is no general peritonitis, but physical signs or clinical phenomena of local disease, he is much disturbed. Then, too, the increased frequency of pulse, or perhaps the signs of approaching collapse, which thus far, in his cases he has not waited for, would induce him at once to ask for a surgeon.

A word in regard to salines, of which he has mentioned nothing before. He has never been impressed with their value in peritonitis, although he has seen some of his colleagues administer them. In but one instance were they of any service, and this was after an abdominal section. But in all probability persons with a larger experience than he has had may see benefit. He did not wish to mislead any to think all his cases got well by medical treatment. Drs. Keen, Price, and Kelly could testify that he has sought the benefit of their skill several times.

A word in regard to a variety of peritonitis which he has neglected to mention, and that is, the so-called cases of recurring peritonitis. In a large majority of instances they are secondary to tubal disease or disease of the appendix; and if a second attack occurs he advises at once operative interference, either before the attack has terminated or after the attack has subsided.

In corroboration of his remarks as to the value of the medical treatment of peritonitis, he quoted the experience of Dr. Girvin, which has been large, and who is a most careful, astute physician. He told him recently that he had never lost a case of peritonitis, and that his plan of treatment is the use of some remedies to open the bowels, along with the use of remedies to allay the pain. To open the bowels he usually gives a pill containing a quarter or a half a grain of calomel, half a grain of extract of rhubarb, half a grain of aloes, with one-eighth or quarter of a grain of the extract of opium. Giving the pill early, he very soon secures a purgative effect, and when that is induced feels much more comfortable in regard to the welfare of his patient. He uses morphia by subcutaneous injection, and only in sufficient doses to keep the patient comfortable throughout the illness.

(Dr. Musser was compelled to leave the room before the discussion closed, but has learned that Dr. Baldy asked why he should endeavor to open the bowels early in a case of peritonitis. In reply he begs to add this, which is the only explanation which has satisfied himself, and which he gives, of course, with reserve, as he does not believe it has been previously mentioned. Take, for instance, a case of appendicitis with rupture. We know that the inflammation is always due to obstruction in the canal. If such obstruction breeds deleterious effects in this canal, a similar obstruction would produce the same bad effects in the larger canal, the intestine; and, in addition to an inflammation of the serous coat, a retention inflammation is set up, and an enteritis complicates the case. Moreover, great danger in peritonitis arises from the tympany, no doubt, and to prevent it the lumen of the canal must be opened early, for if not, the bowel paresis which ensues in peritonitis, and which contributes to the tympany, will prevent clearing the canal.)

DR. JOHN B. ROBERTS said that on general principles he objects to opium after operative procedures. The question to-night seemed to be dogmatically settled by gentlemen of large experience. He was brought up on the opium treatment and has employed it. He believes now that it was a mistake in many cases.

DR. M. PRICE did not believe that peritonitis is ever idiopathic. Call it by what name we please, it resolves itself into some irritation or lesion. Carbolic acid, almost pure, and phenol sodique, in its full strength, he has known to be poured undiluted into an abdomen after an operation. There will always be peritonitis after operations until so-called antiseptic surgery of the peritoneum is abolished. Mr. Tait is correct in saying that the opium treatment has its place only when you have given

up all hope of curing the patient and want to make him comfortable. We make him perpetually comfortable. We not only put the bowels in splints but the whole body in a fracture-box. Prof. George B. Wood, thirty years ago, advocated after bleeding, calomel and purging with Epsom salts and senna, and perhaps somebody suggested it before him. But in recent times the credit of the saline treatment belongs to Mr. Tait. Something was said of five days' treatment. The case should be in the surgeon's hands before that. There is already pus.

The tympany is of several kinds. The distention is often the cause of death. He has opened the belly and found a diverticulum adherent to the omentum, with the intestine through it; the intestine was returned without difficulty; the distention was the cause of death. Many cases of recovery are of such character. If we knew it, purging would be out of place. In operations when there are sharp pain and indications of inflammation, then we do not wait. We open the belly and supply moisture. We pour in hot water—gallons of it—and give turpentine enemata and Epsom salts.

The bowels are already in splints. He has given six ounces of Epsom salts where ordinarily half an ounce would answer. As soon as free movement occurs the patient recovers.

DR. C. B. NANCREDE said that he was the first surgeon in this city to open the belly for shot-wound, and as he never hesitated to operate on abdominal cases when necessary, he cannot be accused of timidity. But is it not time to draw the line when we are told that all cases of peritonitis which do not at once improve should be treated with the knife? He is a living specimen of recovery without section after an appendicitis.

No one has here advocated the use of a drug valuable in the sudden collapse incident to the onset or in the later stages of some cases of peritonitis, when opium means death. That drug is atropine, hypodermatically, in large doses. If it is true that the vast majority of, if not all, cases of peritonitis are secondary—or, in other words, infectious—there are many experiments besides those quoted to-night, shedding a flood of light upon the subject, which show that the peritoneum can take care not only of fluids or foreign bodies, but even of pathogenic organisms and feces, provided that the quantity introduced during a given time does not exceed a certain limit. If all the material can be absorbed in an hour or two, the animal is safe. If that limit is exceeded, we have general suppurative peritonitis. Here the eliminative treatment finds its explanation in preventing a general peritonitis, as the peritoneum is only an enormous lymph sac.

If opium is only to be given to relieve pain, this is not what was formerly understood by the opium treatment. It will not splint the bowel in mere anodyne doses, which was Alonzo Clark's original idea, and that of all his followers since.

He disagreed with the medical gentlemen who would send for the surgeon to lock the stable-door after the horse had escaped; in other words, wait, as is too often the case, until an operation is what is termed a "last resort," which amounts really to there being no reasonable chance for a success which an earlier resort to the knife would have very probably insured. The surgeon should be permitted to see the case *early*, and share in the decision as to when the operation should be done, when it should be postponed, and when declined; it is only by the chance afforded by a study of the *medical course* pursued by the case that the surgeon can operate intelligently and successfully.

He is using less opium as he grows older in all surgical work. He has tried the saline treatment of peritonitis in several cases after section, and he has had no cause to regret it.

DR. JOSEPH PRICE had learned something new, to-night—that abdominal distention impedes the locomotion of germs. He was glad to be enlightened on this point, it will be of very great value to the class of operators that fear them so much. Experienced operators in abdominal surgery fully recognize the deleterious effects, and the great danger of distention. The mere presence of an excess of fluid or gas in the intestine is, in itself, an efficient cause of obstruction. He was not prepared to accept such counsel. He would much rather incise the bowel, and thus favor the evacuation of gas and drainage of intestinal contents. Dr. Meigs counselled delay. On the contrary, the earlier and simpler the operation the greater is the chance of recovery. He could not, therefore, conceive any advice more unfortunate, more unjustifiable for patients dying of peritonitis. In fact, the whole tendency of modern surgery is to anticipate exhaustion, shock, and collapse. The paper of Dr. Baldy referred to peritonitis, and not to pain and tenderness, and his remarks were devoted to peritonitis due to a recognized lesion, and not to pain and tenderness.

The treatment of peritonitis resulting from external or infectious origin would be entirely irrational were drainage discarded. Once decide that the best method of clearing up a peritonitis is by operation, then drainage must follow that operation as naturally as sutures are used to close an incision.

If a peritonitis is septic in its origin, such as is seen frequently after criminal abortion, carlessness after miscarriage, and after gonorrhœal tubal disease, drainage is the third statement of the argument of operation:

1. Operation is required.
2. Douching and flooding the abdomen are necessary.
3. Drainage is the bulwark of the whole procedure.

That cases of infectious peritonitis recover without drainage, is no more an argument against it than that some patients recover from smallpox, never having been vaccinated. If he used all the antisepsis possible before and during an operation, and at its close overlooked the fact that he was leaving a possible infection behind, his antisepsis was only a parade, and misleading. If Listerism is the foundation of modern surgery, drainage is the keystone of its application in such cases of abdominal surgery.

DR. LONGAKER said that from the remarks of the previous speakers it appeared that the opinion held of the value of opium in peritonitis depends upon the question, Is it ever an idiopathic disease? His own views are that it is not, he had never seen a case in which it was. In general he agreed with Dr. Baldy.

In the *Transactions of the Pennsylvania State Medical Society* for 1888, vol. xix. p. 103, there is reported a case in which abdominal section was done for puerperal peritonitis. It was one of the first cases operated on in this city. In June, of the present year, he operated on a second case, whose history is very interesting. Female, aged twenty-six years, married fourteen months. About two years

before, she "caught cold" during her menses. Her periods became painful, and a physician was consulted. Weekly intrauterine applications were made, but as there was no improvement, and as the treatment was extremely painful for hours, other advice was sought. Two months before his visit she fell into the hands of the gentleman with whom he saw her. He found the uterus fixed by a mass in Douglas's cul-de-sac; sound entered two inches, At her next period the doctor was called up in the middle of the night because of great suffering. She passed from bad to worse, and on the day preceding his visit developed unmistakable signs of general peritonitis. She failed to get any relief in spite of grs. ij ext. of opium by suppository. Magnesium sulphate, ʒj dissolved in hot water, was ordered to be given every hour. It relieved the obstinate constipation, and gave her far more relief than the opium. Twenty-four hours later abdominal section was made. Pus was found in the abdominal cavity. Irrigation and drainage were used. All her symptoms improved, but on the fourth day she began to fail, and died on the fifth. Autopsy revealed obstruction of the bowels. It also showed a ruptured pelvic abscess situated in the appendages of the left side. The peritoneal cavity contained no fluid, and the operation had arrested the course of the disease. A knuckle of ileum had become adherent to the pelvic viscera, causing obstruction and death. The case is a warning to those who are in the habit of treating the endometrium promiscuously.

DR. J. TYSON confessed that when he heard Dr. Meigs portray his typical case of peritonitis he felt that the treatment he advocated would be the one he should always prefer to follow. Yet he did not think the parallel he drew between the state of the peritoneum in peritonitis and that of a "sore" is altogether justified. The inflamed peritoneum is rather to be compared to the earlier stages of inflammation in which we resort to leeching and depletion, and he had, by what has been said since, been strongly impressed by the rational character of the saline aperient treatment. It has the further advantage in quickly cutting short those doubtful cases in which a fecal accumulation is producing pain, the first symptom of inflammation, which disappears at once with its cause —the fecal mass.

He desired to call attention to a fact not mentioned, that rheumatism of the abdominal muscles sometimes simulates peritonitis so closely as totally to mislead. He has himself had this experience, and seen the symptoms yield with magical promptness to salicylate of sodium.

DR. MEIGS could not see why any one should doubt the possibility of the occurrence of idiopathic peritonitis any more than idiopathic pleurisy. There is no reason, in the nature of things, why it should not occur, and that some physicians have not met with it is no proof that others who say they have are mistaken. Pleurisy, by extension of the inflammation, may be the cause of pericarditis, and in cases of diaphragmatic pleurisy peritonitis to some extent is a common secondary result. If there be diarrhœa, with inflammation of the mucous coat of the bowel, why should it not give rise to peritonitis? It seemed to him that in the discussion the difference between peritonitis, as seen by those who are not surgeons and the disease as a sequel of operations, has not been sufficiently kept in mind.

DR. BALDY said that Dr. Meigs and Dr. Musser believe in the opium treatment, and yet after giving opium for a few days they give purgatives. He should like to ask them what object they have in view when they give the purgatives, and what they expect to accomplish with them? Theoretically it is perfectly possible to have idiopathic peritonitis. Practically, however, he had never seen it. Some of the gentlemen in discussing this subject seem to draw a line between the cases of peritonitis seen by the physician and those seen by the surgeon. Peritonitis is peritonitis the world over. It makes no difference whether it is set up by the surgeon himself or comes on idiopathically (so called): the result is always the same—inflammation of the peritoneum; the cause cannot alter the principles of treatment. His paper discussed peritonitis and not simply pain and distention; as for an inflammation throwing out a bland fluid, he did not believe it. The products of inflammation are always irritating. Opium has been advocated in small doses and to relieve pain. In his experience small doses will not relieve pain. The dose must be comparatively enormous. Purgatives will relieve the pain as quickly as opium, and when once relieved it remains relieved, which it does not do with opium. If he were aiming at the relief of pain solely, he should most decidedly turn to his salines.

The objection has been made that salines give watery stools and do not carry away much feces. Of course, it is desirable that the fecal matter should come away, and so it does in great part. But large, watery stools are exactly what we desire to obtain. The whole principle of this treatment lies in its depleting powers. For this purpose the salines are given in large and *concentrated* solutions: they are peculiarly adapted to the early and highly inflammatory stages of inflammation. If purgatives are going to relieve, they will do so quickly, and we have no need of waiting for four or five days to know what to do next. Often, unless we use the knife, our patient is dead in five days. Recurring peritonitis always demands surgical interference.

Together with Dr. M. Price, he had but one use for opium in this disease—if everything else has failed, it is a good thing to give *ad libitum*, to ease the last hours of the patient.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, November 6, 1888.

THE PRESIDENT, GEORGE W. JACOBY, M.D., IN THE CHAIR.

DR. W. H. THOMSEN read a paper entitled

PARENCHYMATOUS NEURITIS,

including the histories of a number of cases.

Case I. was that of a man of fifty-six years, formerly engaged in the lumber business and obliged to stand in water containing floating ice for hours at a time. This patient's symptoms had first pointed to central spinal trouble, but later had been those of a multiple neuritis. They had, however, been gradual in their onset, and there had been no evidences of pressure. There had been no shooting nor lancinating pains. The actual cautery had been applied over the spine and the hot glass rod over the sensitive nerve trunks. Nitro-glycerine had given the greatest relief from pain in this case.

Case II. was that of a man of thirty-five years, convalescing from diphtheria. There was no pain, but the laryngeal and pharyngeal paralysis was so profound that the general health suffered.

Case III. was that of a boy convalescing from typhoid fever. There were pains in the legs and feet with dropping of the feet.

Case IV. was that of a woman confined to her bed for three months in the course of phthisis. There were pains in this case in the feet extending to the knees, and in the hands with dropping of the ankles and the wrists, which progressed steadily till death, when extensive nerve degeneration was found without any evidences of inflammatory action. The case was presented as a typical example of a widespread inflammatory degeneration of the nerves. It was a parenchymatous neuritis analogous to that which could be produced by a ligature. The origin and history differed from those of an inflammatory neuritis, however much it might resemble this condition in its ultimate results. In the cases of typhoid fever and phthisis the degeneration may have been due to a mechanical cause—pressure from the loss of the surrounding fat. The fact that the vagus was implicated in the latter disease did not disprove the theory, as no statement had been advanced in regard to the condition of the bronchial glands.

The theory of a non-inflammatory parenchymatous nerve degeneration was important, as the treatment of such cases would differ from that of cases of inflammatory origin. In the latter antiphlogistic and soothing treatment was indicated, while in the former stimulating applications were required. It was questionable whether the term neuritis could be correctly applied to this type of the disease.

Dr. L. C. Gray had not heard the commencement of the paper, and did not understand why Dr. Thomsen objected to the term neuritis. He thought that the symptoms could be scarcely classed under any other name. There had been, as he understood, downright pain in the course of the nerves and eventually paralysis and atrophy. These were the clinical symptoms of neuritis and measured the severity of the neurotic lesion. The treatment of neuritis was, he believed, excepting traumatic neuritis, still *sub judice*. Since attention has been called to the disease, all had probably met with cases in which no local measures seemed to do any good. Quinine, the salicylates, and iron had been most beneficial in his own cases. Change of air was to be recommended. Even in the paralytic stage it was his custom to move the patient to another part of the city or even from a lower floor to a higher floor in the house. Change of location was especially indicated in the cases arising in our somewhat malarial suburbs.

Dr. M. A. Starr applied powdered menthol diluted with starch under a flannel bandage for the relief of the pains of neuritis.

Dr. Jacoby did not find the diagnosis of neuritis so easy as Dr. Thomsen had represented it, especially in typhoid fever. Myositis was a more probable lesion in typhoid fever. Zenker had even stated that neuritis was never found in this disease. As to the distinction made between the inflammatory and degenerative processes, both might be found in the same case. Which process was primary, and which secondary was still a question.

Dr. Thomsen had intended to call attention to only a single point, and necessarily had neglected many others touched upon by the gentlemen in the discussion. He had intended to call attention simply to the impropriety of the term neuritis, as applied to the process in the cases which he had described. There was no reason to suppose that the process in the case of phthisis had been inflammatory. The inflammatory process had certain definite characteristics, there were vasomotor disturbance, infiltration with serum and leucocytes, or living matter. In the neuritis of alcoholism, both in private and in hospital practice, he had observed circulatory and nutritive changes; there had been the same tendency as in the inflammatory process in other parts of the body. There was evidently inflammation of the sheath of Schwann and constriction of the nerve. These conditions contrasted with those in the cases which he had described. In the treatment of true neuritis he had used an application of equal parts of the oil of peppermint and olive oil, a preparation similar in action to that which Dr. Starr had recommended.

Dr. Gray inquired whether Dr. Thomsen recognized no inflammatory process within the sheath of Schwann.

Dr. Thomsen replied that he knew of no changes within the sheath of Schwann which could be called inflammatory.

NEWS ITEMS.

Disinfection of Clothing.—The Lord Mayor of Dublin made his formal inspection on Saturday last of the newly organized establishment for the disinfection of clothing, which has been opened by the Public Health Committee. The system is worthy of notice, not only as a guide to other sanitary authorities in organizing similar establishments, but for the purpose of satisfying the public that they may with confidence avail themselves of the facilities thus afforded to purify articles of clothing which may have been in contact with infection.

Much that has been done in the name of disinfection heretofore has been worse than useless. A common system in workhouses and other places where the matter is not understood, has been to fetch the bedding and clothing from infected houses in a van, that which is only suspected of infection being mixed with that which is reeking with miasm. The mass is then placed in what, for euphony, is called a disinfecting chamber; a pauper nurse or other unreliable official is supposed to raise the temperature to at least 240 degrees, which, unless he is watched, he may not do. The clothing is afterward removed and replaced in the cart which conveyed it to the place, and distributed to the owners, bringing back with it, possibly, not only its own original infection, but a share of that which the other clothes contained.

The arrangement which has been established in Dublin, under Sir Charles Cameron's advice, has none of the vices of this method. The clothes are collected by a van kept specially for the purpose, brought by the front gate to the receiving-room, and, having been ticketed, introduced into the disinfecting chamber (one of Dr. Scort's invention), where, under proper inspection, they are heated and kept up to the needful temperature for a specified time. They are then taken out by the opposite door into the laundry, where they are made up in the usual way, at the usual laundry charges, and sent off in a separate van by the back gate, never

having come into contact with infection from first to last. The process is carried out without charge, except for the laundry work, which is not essential to the disinfection, but is provided in order to induce the public to use the establishment without sending the infected clothing to ordinary laundries.

The entire establishment costs the citizens about £500 a year, which, if a total loss, would be money well expended, but it is expected that the receipts from hospitals and the public will recoup to the taxpayer a considerable part, if not the whole of this expenditure. The effective disinfection of clothing is one of the most important items in the improvement of the public health of any town, and it may be taken for granted that a penny expended in this way will probably save many shillings, so that the outlay of the Public Health Committee in this direction will be found to be true economy, and will redound to their credit and to that of Sir Charles Cameron, their very efficient officer.—*Medical Press*, November 7, 1888.

The Employer Responsible for the Medical Fees of his Servant.—According to the *Bulletin Médical*, the Justice of the Peace at Châlons-sur-Marne has rendered a decision by which he compelled an employer to pay the physisician whom he had called in to attend his servant; the judge in this case naming the amount of the fee himself. From this the *Bulletin* draws the conclusion that an employer calling upon a physician to treat his employé, the former is responsible for the fee of the latter; especially would this be the case when the employé who is being treated is unknown to the physician, and who while being treated is discharged by his employer, the latter failing to notify the physician to stop treatment; but in this case the employer will not have to pay any more than the person benefited by the treatment could have afforded to pay.—*L'Union Médicale*, November 6, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM NOVEMBER 27 TO DECEMBER 3, 1888.

By direction of the Secretary of War, leave of absence for two months is granted HENRY M. CRONKHITE, *Major and Surgeon*, to take effect upon his being relieved from court-martial duty at Little Rock Barracks, Arkansas.—Par. 7, *S. O. 276, A. G. O., Washington*, November 26, 1888.

By direction of the Secretary of War, the leave of absence granted EDWARD B. MOSELEY, *Captain and Assistant Surgeon*, in Special Orders No. 67, November 12, 1888, Division of the Pacific, is extended three months.—Par. 13, *S. O. 275, A. G. O.*, November 24, 1888.

CARTER, WILLIAM F., *Captain and Assistant Surgeon* (U. S. Army).—Is granted leave of absence for one month.—Par. 4, *S. O. 116, Headquarters Department of Texas, San Antonio*, November 12, 1888.

CLENDENIN, PAUL, *First Lieutenant and Assistant Surgeon* (U. S. Army).—Is granted leave of absence for fifteen days, to take effect December 4, 1888.—Par. 3, *S. O. 116, Headquarters Department of Texas, San Antonio*, November 12, 1888.

BENHAM, ROBERT B., *Captain and Assistant Surgeon* (U. S. Army, Fort Laramie, Wyoming).—Is hereby granted leave of absence for one month.—Par. 1, *S. O 111, Headquarters Department of the Platte*, November 24, 1888.

By direction of the Secretary of War, the leave of absence granted ROBERT R. BALL, *First Lieutenant and Assistant Surgeon*, in Special Orders No. 129, October 18, 1888, Department of the Missouri, is extended one month.—Par. 11, *S. O. 279, A. G. O., Washington*, November 30, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING DECEMBER 1, 1888.

GAINES, J. H., *Surgeon*.—Detached from the "Dolphin," and ordered home.

ANDERSON, FRANK, *Passed Assistant Surgeon*.—Detached from the "Pensacola," and ordered to the "Dolphin."

JONES, WILLIAM H., *Surgeon*.—Detached from the "Richmond," and ordered to the "Pensacola."

RUSSELL, A. C. H., *Passed Assistant Surgeon*.—Detached from the Naval Academy, and ordered to the "Wabash."

DRAKE, N. H., *Passed Assistant Surgeon*.—Detached from the "St. Mary's," and ordered to the Coast Survey.

WHITAKER, H. W., *Passed Assistant Surgeon*.—Ordered to the Nautical School-ship "St. Mary's."

LEWIS, D. O., *Passed Assistant Surgeon*.—Detached from the Coast Survey, and ordered to the Naval Academy.

WENTWORTH, A. R., *Assistant Surgeon*.—Ordered for examination preliminary to promotion.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE FIVE WEEKS ENDING NOVEMBER 24, 1888.

WYMAN, WALTER, *Surgeon*.—Detached from New York, N. Y., and ordered to Washington, D. C., November 16, 1888.

LONG, W. H., *Surgeon*.—Detached from Detroit, Mich., and ordered to Cincinnati, Ohio, November 16, 1888.

FESSENDEN, C. S. D., Detached from Norfolk, Va., and ordered to Louisville, Ky., November 16, 1888.

PURVIANCE, GEORGE, *Surgeon*.—Detached from Cincinnati, Ohio, and ordered to Baltimore, Md., November 16, 1888

AUSTIN, H. W., *Surgeon*.—Detached from Chicago, Ill., and ordered to Milwaukee, Wis., November 17, 1888.

GODFREY, JOHN, *Surgeon*.—Detached from Louisville, Ky., and ordered to Milwaukee, Wis., November 14, 1888.

GODFREY, JOHN, *Surgeon*.—Detached from Louisville, Ky., and ordered to New York, N. Y., November 16, 1888.

MEAD, F. W. *Passed Assistant Surgeon*.—Detached from Baltimore, Md., and ordered to Norfolk, Va., November 16, 1888.

GUITÉRAS, JOHN, *Passed Assistant Surgeon*.—Detached from Camp Perry, Fla., and ordered to Charleston, S. C., November 15, 1888.

DEVAN, S. C., *Passed Assistant Surgeon*.—Detached from Savannah, Ga., and ordered to Washington, D. C., November 15, 1888.

URQUHART, F. M., *Passed Assistant Surgeon*.—Detached from Live Oak, Fla., and ordered to Dupont, Ga., November 3, 1888.

BROOKS, S. D., *Passed Assistant Surgeon*.—Detached from Wilmington, N. C., and ordered to Savannah, Ga., November 15, 1888

STONER, J. B., *Assistant Surgeon*.—Detached from Charleston, S. C., and ordered to Wilmington, N. C., November 15, 1888.

BAILHACHE, P. H., *Surgeon*.—Granted leave of abence for twenty days, November 24, 1888.

LONG, W. H., *Surgeon*.—Granted leave of absence for sixteen days, November 21, 1888.

MCINTOSH, W. P., *Assistant Surgeon*.—Granted leave of absence for thirty days, October 24, 1888

MAGRUDER, G. M., *Assistant Surgeon*.—Granted leave of absence for thirty days, November 23, 1888.

COBB, J. O., *Assistant Surgeon*.—Granted leave of absence for twenty days, November 20, 1888.

ORIGINAL ARTICLES.

PRELIMINARY REPORT OF AN OPERATION FOR THE FORMATION OF AN ARTIFICIAL PUPIL THROUGH THE SCLEROTIC COAT OF THE EYEBALL.

BY GEORGE STRAWBRIDGE, M.D.,
OF PHILADELPHIA.

IF reference is made to v. Hippel's article on a "New Method for Corneal Transplantation" (Graefe's *Archiv*, vol. 34, Part I., p. 108), it will be found that the author admits that this operation is only adapted to partial corneal leukoma (a condition, in my judgment, not warranting the operation). In fact, I should consider it never indicated if an iridectomy could be substituted for it, but in those cases in which the cornea has become opaque in its entire diameter, with adherent iris, and in the staphylomatous corneæ, the operation is not advised. Now, it is in these cases, and in others in which the natural passage of light to the retina is prevented by the destruction of cornea, iris, lens, and ciliary changes, that some operative relief is so much needed, and as yet no treatment has been proposed.

The vast majority of the blind are so from diseased conditions affecting the anterior part of the eyeball, and many of these eyeballs show good light-perception, showing that the nerve part of the eye has some vitality. The question arises, Can anything be done to help such cases that are now considered hopeless? I have performed the v. Hippel operation on two such cases in the past few months.

The first case was a man, æt. forty-four. The right eye was an atrophied stump, without light-perception, entire front of eye destroyed. Left eye: moderate atrophy of eyeball, cornea entirely destroyed and replaced by inflammatory tissue; iris and lens destroyed, moderate light-perception and projection; in this condition for twenty years (cause, purulent conjunctivitis), a hopeless case by our present methods. With v. Hippel's trephine I removed a central button of tissue, and went as deep as possible, until the oozing of the fluids from the interior of the eyeball caused me to stop, although opaque tissue still showed itself in the canal. A graft from a rabbit's cornea was placed in this opening, not with the idea of a visual result—an impossibility, by reason of the fact that opaque tissue remained in the canal—but to ascertain if union could take place under the existing conditions, of a free oozing of the eyeball fluids. Rapid union of this graft resulted, but it soon became opaque, and so remains.

The man thinks his eyesight improved; but, if so, it is due to the fact that so much opaque tissue was removed by the trephine as more than to equalize the opaque corneal graft. Of course, it will be said that this was not a proper case for the v. Hippel operation; but, unless this operation covers more than the removal of a partial corneal opacity, it has no field at all.

The second case was a child, æt. four, with a large anterior staphyloma of both eyes, due to corneal ulceration and destruction following an attack of measles. Here, again, was a case of loss of cornea, iris, and lens, but good light-perception was present in the left eye. Through the left staphyloma a central opening was made by the v. Hippel trephine, and extended inward until a dark ground showed itself through the thick inflammatory tissue, and a rabbit's corneal graft inserted. This quickly became adherent, but, unfortunately, also opaque.

These two operations convinced me that it was an absolute necessity to trephine inwardly until a transparent media was reached, even if it was necessary to enter to a considerable depth.

The next indication to be met was, How to block up such an artificial opening with a transparent media, one which would not be washed off by the oozing eyeball fluids, and one which would remain transparent (a rabbit's corneal graft became an impossibility under such circumstances). The idea occurred to me that the conjunctiva close to the cornea, in a normal condition, is nearly transparent. Then why not use a conjunctival flap from that part of the eyeball? This would also have the great advantage of a broad base to support it in position and keep it alive, and this free end could be stretched across the new opening, and held in position by stitches.

As to the best position for the artificial opening? Through the anterior part of the eyeball (the natural seat of the cornea) would be found the products of the former inflammatory attacks, and this would increase the risk of closure of the new opening. The advantage would be central vision. But why not boldly *trephine through the sclerotic coat posterior to the ciliary bodies?* Here the tissues would be more normal, and the chance of a clear vitreous greater; but, of course, eccentric vision. My experiments were made on rabbits' eyeballs.

Summary of experiments.—The eyeballs were washed with a biniodide of mercury (Panas) solution, and a two per cent. solution of cocaine applied. In-

struments were washed with alcohol. *Six operations* for artificial pupil through the *sclera*, posterior to the ciliary bodies, were made, the conjunctiva first being dissected away and inverted, and the rectus muscle divided. A v. Hippel trephine 4.5 mm. in diameter was used to make the scleral opening in four of these operations, in one of which two-thirds of the opening was made through the ciliary bodies without any additional irritation. This was interesting, as in the human eye a ciliary traumatism is looked on as generally fatal to the integrity of the eyeball, and the query would be whether a clean cut through the ciliary bodies, as an operative procedure, would not show a different result from a lacerated wound. In two operations I used a Graefe cataract knife to make two incisions in a triangular opening, the third side being cut out with the scissors (the trephine not being in order). These two pupils were of about the same area as the other four.

In all, there was a moderate vitreous escape, and in two a slight hemorrhage in addition. The conjunctival flap was then stretched over the scleral opening and stitched to the conjunctiva at the corneal border; the effort being made to have the conjunctiva nearest to the cornea to come over the opening on account of its greater transparency. The animal was then allowed to run without further care. All healed equally well. The conjunctiva for a few days was moderately swollen, but the eyeballs remained without reaction. Week by week the conjunctiva covering the scleral opening has become more transparent, and at time of writing (an average of five weeks after operation) the scleral openings show themselves like dark pupils, covered by a three-fourths transparent conjunctiva through which light can be reflected; there is no tendency in these openings to close, and the improvement goes on steadily as regards increase of the transparency of the pupil and conjunctiva. If the conjunctiva becomes again as transparent as it was in the normal condition (and there is every indication that it will be so), surely a most serviceable amount of vision will be obtained through these scleral pupils. The fact also that the eyeballs remain healthy is a strong point as to the feasibility of this operation on the human eye.

It is, therefore, fair to say that these experiments (as far as rabbit's eyes are concerned) prove that a large scleral pupil can be maintained without the least tendency to contract, and that the conjunctival covering will attain again to the normal transparency, and through this opening light can be reflected; also, that the eyeballs are not damaged.

In one of these operations, at the end of the fourth week, when the scleral pupil showed itself as a dark opening, covered with a three-fourths transparent conjunctiva, I purposely dissected the new conjunctival flap away from the scleral pupil to determine the effect of depriving it of this covering. No vitreous escaped, but a lymph covering was in a short time spread across it and so greatly decreased its transparency. This would indicate that the conjunctival flap must be considered as a permanent covering.

Two operations for artificial pupil were made through the *entire thickness* of the centre of the *cornea*, with the same trephine. In one case the lens was injured and there was also an iris prolapse into the wound. This pupil was covered by a long narrow conjunctival flap taken from along the upper corneal border, and held in position by stitches through the cornea at the edge of the circular opening, giving the appearance of a narrow pterygium, stretching from above down to the centre of the cornea. The slight reaction was quickly over and the eye is now entirely free from irritation (six weeks after the operation) and in a normal condition, excepting a partial lens clouding and an iris prolapse, due to the operation. The conjunctival flap remains firmly attached to this corneal pupil, but is opaque, and will probably remain so, due to the fact that the conjunctival flap is not so well nourished.

The second corneal pupil operation was through the centre of the entire cornea also, and a similar long conjunctival flap was stitched over the opening, the stitches going through the edge of the cornea at the circular opening. This operation is following the course of the other, and will probably show the same result. In this case a more severe reaction was noted.

Summary of corneal pupil operations shows that a large corneal pupil can be made and covered by a permanent conjunctival flap, but this flap will probably remain

I now considered that I was justified in performing this operation on the human eye, particularly as I was attacking an eye utterly hopeless under our present methods. In trying the v. Hippel trephine on an enucleated human eyeball, I found that it had not sufficient power to penetrate the sclera and, therefore, had a spring of greater strength inserted. This also was insufficient, and I then tried as a motor power the dental engine with trephines of 4.5 mm. diameter adapted to it. This was found more delicate in its manipulation and in every way satisfactory, and was used in the two following operations:

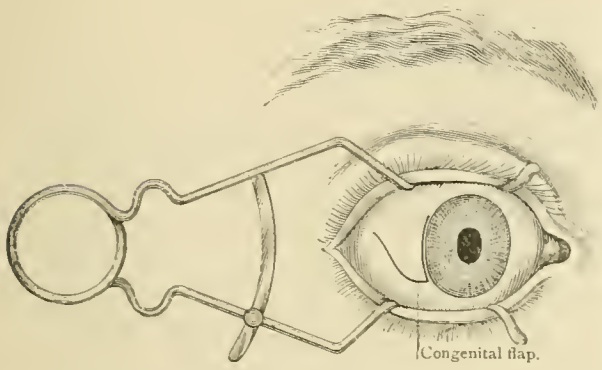
On December 4th I made two scleral pupils on the human eye.

Case I. was that of a man, æt. forty-six, who had lost his right eye in boyhood by an accident, and this had been removed four years ago as an irritable stump, producing sympathetic irritation. The left eye had been losing sight for the past ten years,

and for the past four years had only light-perception, due to the sympathetic irido-choroiditis with cataract formation. Four months ago I attempted the lens removal, and had a violent escape of fluid vitreous at the stage of iridectomy, at which point the operation was stopped. Inflammation followed, with complete pupillary closure later on. Iridectomy was attempted without result, and the eyeball slowly began to atrophy with a —2 tension at the present time of operation.

The man was placed under ether, and a conjunctival flap (vide Fig. 1) was made by grasping the

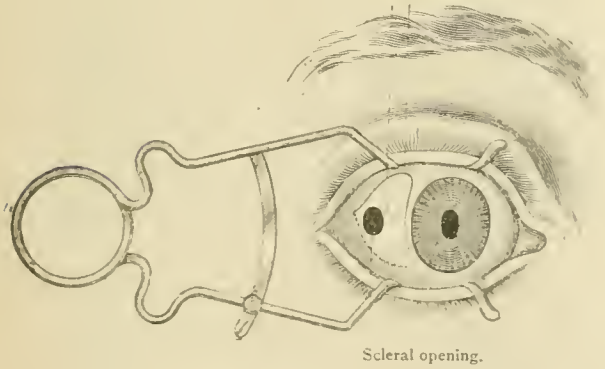
Fig. 1.



conjunctiva with forceps and making a horizontal cut close to the outer lower quarter of the cornea,

Fig. 2.

Insertion of tendon of rectus externus. Congenital flap inverted.



The dotted line represents the conjunctival flap sutured in position.

and then extending this upward along the outer corneal border; a third cut from this horizontal incision upward and outward, extending to the upper border of the tendon of the rectus externus, completed the flap. This was inverted and the rectus externus tendon severed; a forceps then firmld grasped the insertion of the rectus tendon any pulled the eyeball inward and held it steady. The trephine knife (having 4.5 mm. diameter and worked by a dental engine) was then placed on the sclera behind and close to the rectus externus tendon insertion, so as to avoid the ciliary bodies (vide Fig. 2), and a moderate rotation caused it to cut its way quickly into the vitreous. The button of the sclera was found clinging to the trephine on its withdrawal, and a quantity of straw-colored fluid escaped from the eyeball. The conjunctival flap was quickly placed over it and held by three stitches in its place; and a light bandage of cheese-cloth keeps the eyeball quiet, and thus far (six days) no reaction has followed whatever. Moderate swelling of the conjunctiva shows itself, but this already is rapidly passing away, and the dark scleral opening begins to appear.

Case II. was that of a child, æt. four and one-half years; has lost both corneæ from ulceration following measles, three years ago; quite sizeable staphyloma corneæ are present, and it is thought that light-perception exists in the right eye.

A similar scleral pupil was made in the right eye, the patient being under ether, and in this case healthy vitreous escaped in moderate quantity. At this time (six days after the operation) no reaction exists. The staphyloma has entirely flattened, and the dark scleral pupil is seen through the still thick conjunctiva.

It is to be noticed, in the rabbit experiments, that a lapse of at least two weeks was needed before the conjunctiva became sufficiently thin to discern the scleral opening through it, so that no immediate result is to be expected until sufficient time has been given to allow a partial return of the conjunctiva to its normal condition.

Scope of the scleral operation:

1. As a means of making an artificial pupil in eyeballs now considered hopeless: for the purpose of giving vision.

2. It will be probably an efficient means of reducing staphyloma anterior by making a permanent opening, through which omosis of the eyeball fluids may go on without injury, and in this way prevent intra-ocular pressure.

3. As a means of combating glaucoma in the chronic stages, by allowing free osmosis through the conjunctiva and scleral opening.

4. It may be useful in retinal attachments, by its ability to drain the retinal sac of its fluids through the scleral opening, and by keeping up osmotic action, lessen the risk of a re-separation.

In answer to the natural inquiry, How dangerous is this operation to the integrity of the eyeball? I will say that the rabbit experiments show that the risk is small, as no eye was damaged; and considering that the opening is made through a part of the eyeball posterior to the ciliary bodies, it is most probable that the operation will be attended with but little risk. But even taking the opposite view, it is always to be remembered that the eyeballs on which

the operation would be performed are, as a rule, such desperate cases that the element of operative risk will not give rise to anxiety.

In regard to what may be expected from the artificial pupil through the cornea—and by this is meant a pupil extending inward through all opaque tissue until clear vitreous is reached, at the present time I am inclined to believe that the conjunctival covering will, probably, not become transparent enough for any amount of vision through it, as it must necessarily be of sufficient length to reach to the corneal opening; and this means a larger dissection and a more narrow base to it: also, the risk of closure of the artificial opening is greater, as it passes through the seat of largest intensity of inflammation. But it may be found that actual experience on the human eye will give a different result.

I would have preferred to postpone this preliminary notice until I had a larger number of operations, with their results, to report; but the interest excited is so great, and I have been so beset by inquiry for information by members of the medical profession, that I take this method of giving my results as far as I have obtained them.

To my friend, Dr. Shaffner, who has kindly assisted me in my experiments on the rabbit's eyes, I make my acknowledgments.

FORCED RESPIRATION.

A Report of Six Cases, showing its Effects on Narcotized Human Subjects, and its Adaptability in Cases of Drowning and Shock.[1]

By GEORGE E. FELL, M.D., F.R.M.S.,
PROFESSOR OF PHYSIOLOGY AND MICROSCOPY, MEDICAL DEPARTMENT OF NIAGARA UNIVERSITY, BUFFALO, N. Y.

The term *forced respiration* may be unfamiliar to many physicians; the reasons for its introduction are given. The term *artificial respiration* has been applied to all artificial methods alike, as those of Marshall Hall, Sylvester, Howard, and others, which depend for their success upon the movements of the limbs or body of the patient, supplemented usually by pressure of the thorax on the part of the physician; those in which tubes and mouth-pieces are used, and the air supplied by bellows of different forms, and the methods used on various animals in the physiological laboratory, in which the trachea is opened to supply the air for respiration. To the latter method, which, in operation, requires the forcing of air into the lungs by mechanical appliances, I have heretofore suggested the term *forced respiration*, to distinguish it from the ordinary methods of *artificial respiration*. The necessity for a distinctive term and its appropriateness will be conceded, when it is noted that respiration has been successfully carried on in man by these forcible means for many hours after artificial respiration has proved futile. The operations are so different in application, that a distinctive term is absolutely required to prevent confusion.

For the history of forced respiration and description of original apparatus used by the author in the following cases, see forthcoming (1888) volume of *Proceedings of New York State Medical Association.*

Case I.—At 12.30 A.M., July 23, 1871, was called to attend Mr. B. Found the patient in a semi-conscious condition. His wife reported that he had been drinking heavily. His excesses induced him to try chloral to produce sleep, but finding this unsuccessful he added twenty grains of morphine with the following result: The drug was taken late the preceding afternoon, so that sufficient time had elapsed to permit complete absorption.

When first discovered, he was breathing stertorously, and was with difficulty aroused. Emetics, followed by cathartics, were administered, producing vomiting. To keep the patient awake, he was dressed and two attendants walked him around the block. At each round atropia was administered. On the fourth round his limbs gave out, stertorous breathing was renewed, and he was carried into the house and laid upon the floor, as I believed, to die.

3.30 A.M.: Respiration failing, artificial respiration (Sylvester) was employed, and kept up at intervals without apparent benefit to the patient. I notified the family that the patient could not live. The last rites of the church were performed, a bed was prepared in the front parlor, the patient laid upon it to die, the data for the death certificate were obtained, and after confirming my opinion that death was imminent and certain, I left for home at five o'clock in the morning, completely exhausted. The pulse ranged from 180 to 200; respirations at 4 A.M. five per minute, and at 5 A.M. intermittent, or with a long intermission, followed by a few spasmodic respiratory efforts, and then apparent inanition for a time.

After a sound sleep at home, I was awakened about 8 o'clock A.M., by a call from Mrs. B. Dr. F. R. Campbell, who, through illness, was unable to respond to an early summons from Mrs. B., called at 8 o'clock, and finding Mr. B. still alive, sent for me.

On reaching the house, I found the patient with respirations not more than one per minute, and the pulse at the wrist difficult of detection. The extremities were cold, face cyanotic, pupils still contracted. My associate suggested more atropia hypodermatically, to which I assented. Together we repaired to a drug store near by, and had some

[1] Portion of a paper read before the New York State Medical Association, New York City, October 9, 1888.

powders prepared, but on our return found the pupils *widely dilated;* it is needless to say *no more* atropia was administered. The sudden dilatation of the pupils is a frequent occurrence in the *last stages* of opium poisoning, and is indicative of general muscular paralysis; it is, also, known as the "dilatation of asphyxia."

Dr. Campbell remarked: "We can do nothing more now." I agreed with him; but recalling the case of Mr. Dyke, and my views then entertained, I mentioned to the doctor my conviction that Mr. B.'s life might be saved by opening the trachea, placing a tube in it, and keeping up the respirations with suitable apparatus, until the poison could be eliminated. I informed him that I had the apparatus used on dogs in the laboratory of the college at my residence near by. He offered to assist, if I would make the experiment. I quickly obtained the apparatus, and on the way asked Dr. George H. McMichael to assist in the operation. The hemorrhage was considerable, but was controlled before incising the trachea. Difficulty was experienced in passing a ligature about the trachea and tube to prevent the air from passing up the throat; when accomplished, we were ready to begin the forced respiration. The blood coming from the incision was a dark coffee color, indicating an extreme venous condition. No respiration had been made for some time, and the dark blue tinge of the face had materially increased.

We began the forced respirations, which resulted in producing some remarkable physiological changes, which are recounted in that portion of this article relating to the effects of forced respiration on narcotized human subjects. After the first inflation of the lungs not the slightest expiratory effort was made, indicating not only the paralyzation of the respiratory centres, but the loss of elasticity in the lung tissue, a most important, if not the most important, factor in expiration. These facts are fully explained in that portion of the article just referred to. In the course of time the patient revived and began to move uneasily about, starting hemorrhage through the loosening of the tube in the trachea. Three soldiers boarding in the house were quickly summoned, and performed efficient service in restraining the patient.

At twelve o'clock, mid-day, after the forced respirations had been under way *two and one-half hours,* an ordinary tracheotomy tube was substituted for the tube of the apparatus, and the patient allowed to breathe for himself.[1]

The *second* case occurred September 20, 1887, and was cited in the *Lancet* of October 15, 1887. Dr. Länger, of the Vienna Hospital, took an overdose of morphine. An incision was made in the trachea, and the patient's life was saved by *forced respiration.* The operation was made after the reports of my first case (read before a section of the Medical Congress at Washington) had appeared in the medical journals.[1]

CASE III.—Mr. J. A. V., aged forty-three, took two ounces of laudanum and some chloral about 9 or 10 P. M., Saturday, December 10, 1887. At midnight, his wife heard him breathing heavily; she tried unsuccessfully to arouse him, and sent for a physician.

Dr. Lawrence G. Hanley was the first to respond, and was shortly followed by Dr. Jacob Goldberg.[2] The condition of the patient at this time, 1.15 A. M., indicated that a large dose of some powerful narcotic had been taken. Breathing stertorous; pulse 128; respirations 6, and pupils contracted. At 1.40 A. M., Saturday morning, I was called and found the physicians employing Sylvester's method of *artificial respiration,* and at their request assumed entire charge of the case.

2.20 A. M.: Natural respirations ceased, or would last but a short time without *artificial respiration.* Pulse 72 to 84, indicating satisfactory oxygenation of the blood; however, the notes[3] taken at the time show that the natural respiratory efforts were irregular, deficient, and difficult to count.

Their inefficient character, even when supplemented with the *artificial respirations of Sylvester,* was indicated by gradually marked increase of cyanosis. Previous to this, when noticing the good results of the *artificial respiration,* I informed the physicians that this would be a good time to answer effectually those who believed that *artificial respiration* would accomplish what forced respiration would in cases of deep narcosis from poisons which act upon the respiratory centres. I informed those present that if the life of the patient could be saved by *artificial respiration,* or any other *known* means, my apparatus *should* not be used.

From 2.30 to 2.45 A. M.: Natural respirations ranged from 7 to 15 per minute, but were "shallow," so that little good was effected by them. Pulse 120.

3.25 A. M.: Respirations failed. Owing to evident signs of heart failure, it was considered by all the physicians present that the life of the patient demanded the application of *forced respiration.* Time was given to demonstrate the uselessness of *artificial respiration,* and it was feared the patient might succumb before the *forced respiration* could be applied.

3.40 A. M.: Tracheotomy made; blood venous; Dr. Hanley remarked that it was "ebony-colored."

4.05 A. M.: *Forced respirations* begun. In a short time, the pulse became stronger, and was reduced to 78 per minute.

5.30 A. M.: Pulse 102.

5.45 A. M: Pulse 64.

6.25 A. M.: The patient, *previously insensible,* opened his eyes, stared in a half-dazed manner,

[1] The analysis of the urine first drawn from Mr. B. gave clear evidences of morphia. A quantitative analysis is now being made by Dr. John A. Miller, of Niagara University, Buffalo, as a matter of interest.

[1] November 12, 1888: Have just received from Prof. Böhm, of Allgemeines Krankenhaus, Vienna, a full report of this case.—G. E. F.

[2] Dr. Samuel Goldberg was present later in the case. Also a number of medical students.

[3] This case is reported from full notes taken during its progress by the different physicians present.

raised his head from the pillow, and recognized Dr. Goldberg by voice only.

6.45 A. M.: First noted that when *forced respiration* is discontinued not the slightest attempt at breathing is made by the patient, even when the cyanotic condition is extreme.[1]

In one or two instances the *forced respirations* were unintentionally kept up when the patient was swallowing water; the glottis being opened at this time, it entered the lungs and was subsequently coughed up and passed out of the opening of the valve of the apparatus.[2]

7 A. M.: Pulse 96.

8.15 A. M.: Pulse 108. It was found that the patient could breathe for himself, but only for a short time, and the *forced respirations* had to be continually kept up.

9 A. M.: The trachea tube not being secured tightly in the trachea, permitted quite an amount of blood to pass into the lungs, and the air to pass into the mouth, so that the lungs were not thoroughly inflated at each respiration. This blood gurgled ominously at each inspiration. With a curved needle another ligature was passed and tightened about the trachea and tube. The *forced inspirations* following, markedly improved the action of the heart.

As the poison became more completely incorporated with the blood, through absorption, the effect of even a short stoppage of the *forced respirations* was indicated in a weaker action of the heart. At one time, the rubber tube connecting the respiratory valve with the trachea tube became almost completely clogged with clotted blood. It was removed and cleaned, as was also the inner tube of the tracheotomy tube a number of times. Digitalis was given, also atropia, one-eighth grain at one time, and smaller doses also. No dilatation of the pupils took place at this time.

The question of keeping up the *forced respiration* when there seemed to be no prospect of ultimate recovery of the patient, was *seriously* discussed. I was urged to discontinue the respirations on account of the case being considered hopeless. At one time, I stopped them for a longer period than usual, thoroughly discouraged and tired. The man was not dead, and we *had to keep it up*.

11.30 A. M.: Patient drank some brandy and water; vomited. Case was hopeless.

12 M.: Pulse 117. Grain $\frac{1}{75}$ atropia administered hypodermatically.

12.10 P. M.: Face cyanosed; efforts to breathe made; twitching of toes; respirations not supplying enough air.

12.40 P. M.: Owing to a solution of atropia being placed on or in the eyes, the pupils gradually dilated.[3] Pulse 126.

12.55 P. M.: The patient, who had become unconscious for a short time, regained consciousness, and drank some water. Pulse, after drinking, 168, weak and flickering. After this, more air was administered, and three movements of the bellows used for the inspirations instead of two, as formerly.

3.20 P. M.: Temperature 100.5° Fah.

6 P. M.: Pulse 120.

6.15 P. M: Respiration natural, 14 per minute. Patient began breathing for himself. This lasted fifty-five minutes, when the respirations lowering to 8 per minute, *at the request of the patient* the *forced respirations* were again proceeded with.

9.15 P. M.: Pulse 120: respirations 14, natural; becoming shallow, they were supplemented with the *forced respirations*.

11.30 P. M.: Pulse 100.

December 11, 1887, 12 Midnight.: It is now twenty hours since the forced respiration were begun.

1.05 A. M.: Pulse 128, strong. The patient has been breathing for himself for the last four hours, but has *now requested* that the *forced respirations* be used for a time. Since then, he has breathed for himself. For over fourteen hours he could not be left to breathe for himself even for a half-minute, without evident discomfort and danger, viz., between 4 A. M., 10th inst., and 6.30 P. M., 10th inst., and for nearly seven hours thereafter the *natural* had to be supplemented by the *forced respirations*.

4 A. M.: Pulse 117. Although olei tiglii gtt. v have been administered, no movement of the bowels has taken place. Nutritive drinks and enemata of water, soap and water with oil and stimulants, given also.

Every six or eight hours catheter used. Up to 12.30 A. M., 11th inst., nearly twenty-four hours after the patient was first discovered, and some twenty-seven hours after two ounces of laudanum had been taken, not more than six ounces of urine had been drawn from the patient. This large amount of poison (two ounces) had been undergoing the round of the circulation, producing its maximum effect on the whole system. The left arm was partially paralyzed, the brain congested.

Between 3 and 4 A. M., 11th inst., the bowels moved for the first time. At 7 A. M. the patient left the table, without assistance, to use stool. At 9 A. M., the tracheotomy tube was removed, wound plugged antiseptically, and patient put to bed.

Although very seriously ill for three or four days following, no serious lung difficulty set in; the patient has fully recovered.

CASE IV.—Julius B., of Lockport, N. Y., aged forty-five years, nervous temperament, of a naturally lively disposition, was subject, through ill-health and mental suffering, to spells of melancholy, which were aggravated by several serious reverses in business. He was of medium height, weighed about one hundred and thirty-five pounds, and was in poor condition to withstand a terrible physical ordeal. January 24, 1888, he left home for Buffalo, having previously obtained a two ounce vial of laudanum. On his arrival at Buffalo he put up at the Continental Hotel, complained of not feeling well, ate very little supper and retired to his room. This was the

[1] See effects of forced respiration on narcotized subjects further on.

[2] This indicates, in part, the value of the application of the apparatus in cases of drowning, and also that it would be objectionable to pass a tube into the larynx by way of the buccal cavity when the elimination of poison is important, as liquid, in swallowing, would be apt to enter the lungs.

[3] This may not have been judicious, but was done under the belief of all the physicians present that the patient could not recover.

last time he was seen, until he was found next day at 3 P. M., to all appearances dead (so reported).

The first physician to arrive at the hotel was Dr. Luther Phillips, who, on examination, gave up the patient. The physicians from the Fitch Emergency Hospital, Dr. George E. Penrose in charge, next appeared and administered brandy and ether subcutaneously. Drs. William A. Hoddick, Carlton R. Jewett, Herman Mickle, John D. Flagg, and several others subsequently were present during the progress of the case. They, without exception, gave up the case as hopeless. Coroner Kenny was summoned, and before leaving his office telephoned to undertaker Rodney to go to the hotel with a coffin, which he did.

The two ounce vial of laudanum was found empty; the throat of the patient was cut, severing the trachea and anterior jugular vein; it was found also that the left arm had been incised with a razor so as to expose clearly, without opening, the basilic vein. At this time the patient was making a faint gasp once in about ten seconds and breathing through the hole he had made in the trachea.

I was called about 5 P. M. On arrival found the corridor and bed-room filled with physicians and laymen, the patient lying on the right side of the bed. To indicate the extent of hemorrhage, it may be mentioned that the right side of the over- and under-shirt, the shirt sleeves to wrist, right end of the pillow, and side of the mattress were literally soaked with coagulated blood. A tall slop-jar at head of bed was half-full of blood and water. The pupils were contracted; face pallid; an occasional gasp indicated that life existed. No pulse at wrist, and fluttering movements of heart on auscultation; skin cold; patient unconscious, had an exsanguinated cadaverous appearance. The physicians had ceased their efforts at resuscitation.[1]

My first marked interest was in noting that the incision in the trachea was just suited to my tracheotomy tube, which I immediately inserted, causing a reflex inspiratory spasm. Within one minute from the time I entered the room I was practising forced respiration upon the patient. Within a few minutes the cyanotic hue slowly passed from the face. In about three hours, 8 o'clock P. M., the pulse could be detected at the wrist and the patient showed signs of returning consciousness. Great quantities of stercoraceous matter passed frequently from the patient. At 9 P. M. patient became fully conscious of his condition and surroundings. Contraction of the pupils continued. When forced respiration was discontinued an occasional attempt at respiration was made; at no time, however, during the twenty and a half hours the instrument was in steady use, did he make more than two or three attempts at respiration without it.

As he gradually became weaker from continued movements of the bowels and frequent attacks of vomiting, attempts were made to nourish him. The most easily assimilable substances were rejected. Milk and lime-water, peptonized liquids, liquid and powdered peptonoids, iced champagne, brandy, etc., were used, but the stomach would not retain them. Vomiting continued; the patient approached the stage of collapse; brandy, hypodermatically, frequently given without marked benefit. The action of the heart was of a bounding, uncertain character, produced by deficiency of blood upon which to work. At one time stercoraceous vomiting set in; in fact, a most deplorable condition existed. It was decided to attempt the introduction into the circulation of a saline fluid by the transfusion method. I repaired to the Fitch accident hospital, secured the apparatus and assistance of Dr. Penrose, who, with Dr. Mickle, opened the conveniently exposed basilic vein of the left arm, introduced the transfusion canula and allowed about six ounces of the fluid to mingle slowly with the circulation.[1] No apparent change was noted in the condition of the patient from the injection; the forced respiration was continually kept up, and the life of the patient depended upon it, as all other means would have proved futile without it. At this time no pulse at the wrist could be detected for fifteen minutes at a time.

Continued the work through the night with the aid of my class of students from the college and a number of physicians; toward early morning the opinion prevailed that the case was hopeless.

I was urged to discontinue the work of resuscitation, on the plea shared by all, that it was only prolonging the misery of the patient, and the case was hopeless. I urged, as in my second case, that a physician was not justified in giving up until life was extinct, and kept the forced respiration under way. Attempts at nourishment by the stomach had been discontinued for a time after the stercoraceous vomiting. The nourishment of the patient, however, had become a matter for serious consideration, and at the suggestion of Dr. C. R. Jewett, half teaspoonful doses of Cibil's fluid extract of beef diluted with a little carbonic acid water were administered. This was the first substance to be retained; dose repeated, increased, and at last the patient showed signs of improvement.

Some twelve hours after we had been at work, the satisfactory result of forced respiration, as a means of breathing for a human being, was demonstrated in the easy, passive condition of the patient. During the forenoon the effect of the narcotic gradually passed away, the pupils dilating more and more. The condition of the patient was such, however, that he could not breathe for himself for any time without evident discomfort, and the forced respiration had to be kept up. Noon passed, and yet the patient could not be left to breathe for himself. At 1.30 P.M., however, nearly one full day (twenty and one-half hours) after forced respiration was begun, Mr. B. began to breathe for himself. In a few hours he became so fatigued that he begged to have the

[1] Dr. Wm. A. Hoddick reported the condition of the patient at the time of my arrival as follows: "Skin cold; cadaverous appearance; lips colorless; the pallor of death apparent; extremities cold; pulse almost imperceptible; only a slight fluttering of the heart could be discovered; eyes insensible to light, pupils completely contracted; but little blood in the body."

[1] The formula for this fluid was as follows: "℞.—Sodic carb., grs. j; sod chloride, grs. vj; ft. chart. aquæ, ℥ij, M. xxx. Misce Inject one to four ounces.

forced respiration resumed, and the little instrument was again called into action, quieting and easing the patient again. Several times was this done before he continuously breathed for himself, thus making the use of the instrument to cover more than a day before it was laid aside for good.

Toward evening the patient was transferred to a warmer and better room. Under careful treatment he rapidly improved, but complained of constant pain in his chest. It was feared that pneumonia would set in as the respirations were somewhat rapid. It did not, and there was nothing, as we will see, to indicate that the lungs were *unfavorably affected* by the long-continued forced respirations. Within five days after the operation the patient was transferred to the hospital of the Sisters of Charity, and his temperature was normal and pulse 96. The pain in the chest was caused by the *hypodermatic* injections given at a time when the circulation was so inactive in the surface capillaries that gangrene was produced by them. The poor fellow suffered for months after the operation from this cause. The greater portion of the left breast sloughed down to the ribs, and in the right thigh an abscess, produced from the same cause appeared, which, when opened on the 20th of February, gave out a pint of pus. There is, then, a possibility of overdoing the hypodermatic treatment where a large quantity of blood has been lost.

I do not hesitate to state as my belief that Mr. B. would have been in condition to leave the hospital within two weeks of the date of the operation had it not been for the results produced by the hypodermatic medication. At this time, following it, his throat was closed up and in good condition. He was able to walk about and do light work long before he left the hospital, and when he did so was in better physical condition than he had been for years.

Regarding my first three cases, there is no question as to the result had any other known means been tried to save them. Forced respiration alone is to be credited with the saving of these lives to future usefulness. To demonstrate beyond question the thoroughness of the work accomplished, at my request these patients, Messrs. Burns, Van Orden, and Baere, all in good health, appeared before the Western Division of this Society in Buffalo, May 8th of this year, where I gave a preliminary report upon the subject of this paper.

To the insurance companies this work was a boon, as it saved to them some $23,000 assurance.

With all associated in the cases, I stand equally surprised at the results.

The following series in many respects are not so interesting as the first three, but still presenting the influence of forced respiration in these serious cases in a most remarkable light.

CASE V. is taken from the records of the Emergency Hospital, where it occurred, and is reported by the house physician, Dr. J. F. Mulherin. Hospital case No. 1000. Peter C., aged eighty, United States, admitted May 18, 1888, 8.30 P. M. This man was brought in an ambulance from a house where he was found in a dazed condition. Patient had stated to friends at this place that he had taken laudanum, ℥j; empty bottle shown to ambulance attendant. On admission patient unconscious, pulse full and strong (84 per minute), respirations about 10 per minute, pupils contracted to pin points.

Emetics administered, atropia gr. $\frac{1}{100}$ hypodermatically, and catheterization at 8.35 P. M.; repetition of atropia gr. $\frac{1}{100}$ in ten minutes. Artificial respiration, Sylvester's method. At 9 P. M. heart failed and respirations about 3 or 4 per minute; respirations gradually became imperceptible, atropia gr. $\frac{1}{100}$, also brandy and digitalis given hypodermatically.

At 11 P. M. Dr. Fell called and tracheotomy with forced respiration determined upon. Present, Drs. Fell, Heath, Mickle, and Mulherin. Trachea opened and tube inserted by Dr. Heath. At 10.25 P. M. forced respiration commenced: patient seemed to revive; pulse became fuller, was irregular, color in face returned, and at 12.15 A. M. patient first opened his eyes. Stomach-tube introduced to wash out contents at 12.30. Injections of soapsuds per rectum at 1 A. M. These were found inefficient, and gtt. ij olei tiglii administered at 1.15; urine again drawn at 1.45. Signs of returning consciousness at 2.30. Patient opened his eyes and lifted his hand. Between 2 and 3 condition good, pulse full and regular; vigorous slapping of face, yelling in ears elicited no response. 3 A. M. pulse 90. 3.45 A. M. patient suddenly raised his arms and attempted to speak. At this time the forced respiration was discontinued, but patient refused to breathe. At no time since the operation was begun had the patient been cyanotic.

At 4.15 A. M. patient again threw his arms about, and, in answer to a question, said he was "awake." Hæmostatic forceps removed from the neck after the vessels were ligated; slight hemorrhage. Respiration continued. 5 A. M. patient opened his eyes, became somewhat convulsed, and again relapsed into a state of unconsciousness. Two drachms of nitre given by the mouth and stimulants through the air-heating section of the apparatus. At 5.15 A. M. bellows working at the rate of 108 movements per minute; patient by this means receiving 21 respirations to the minute; pulse good, and color of face normal. 5.20 air-heating apparatus again used. 5.40 heated air discontinued. At 5.50 ℥ij urine drawn. 7 A. M. face and hands more cyanotic; pulse 90, temperature 99½° F. 7.30 pulse growing weaker, patient somewhat cyanosed. 8.20 heart failing. 9 A. M. pulse 88. 9.10, heart very weak. 9.30 pulse varied, becoming alternately strong and weak. At no time during the operation has the patient been able to breathe of his own accord. At 10 A. M. pulse 60, temperature 98° F. Peptonized beef extract given per rectum. 12.45 P. M. patient made a few convulsive efforts to breathe, again relapsed into unconsciousness: pulse becoming very weak and feeble. Patient grew pale; skin cold. Complete cessation of pulse at 1.10. Patient dead. Forced respiration discontinued and instrument removed at 1.13 P. M.

In this case the patient was kept alive by the forced respiration for fourteen hours and ten minutes, and it is reasonable to infer that his life was prolonged at least twelve hours longer than it could have been by any other methods known.

Case VI.—May 26, 1888, I was called to the residence of H. C. F. Found his eighteen day old infant held by a nurse in a tub of warm water; body deeply cyanosed. An occasional gasp indicated that life still existed; pupils contracted, reflexes absent. Inquiry elicited the following history: Dr. "Blank," an old and respected homœopathic practitioner of Buffalo, had been called to prescribe for the child. He took out of his case a powder containing morphia sulph. gr. j. By mistake he gave it to the nurse, directed her to give it to the babe, at the same time thinking he had replaced it in his case and handed her a harmless powder in its stead. Some time after the physician had left the house the nurse called the child's mother's attention to the superscription on the powder, morph. sulph. gr. j, and with the belief that all medicine was harmless, thinking it was only a sleeping powder, the fatal drug was placed upon the tongue of the little one at 12.45 P. M. and all absorbed.

At 2.30 P. M. the child was discovered in convulsions, a physician, Dr. A. M. Curtis summoned, and the usual steps taken to resuscitate. When it is considered that the quantity of morphine taken was equivalent to about seventy doses for an infant of this age, it appeared a hopeless task. From 2.30 until about 4.30 P. M. artificial respiration was used with little benefit. It was nearly 5 P. M. before I arrived at the house, and with difficulty only to be appreciated by experience I made tracheotomy. Previous to the trachea being reached respirations would cease, by placing my mouth over the nose and mouth of the babe and forcibly blowing, the lungs were inflated, resulting in keeping up the action of the heart until the trachea could be irritated.

Irritation of the trachea followed by incision seemed to stimulate the respiratory centres for some time, but, as the case was approaching a crisis, at last a small-sized catheter, one-eighth of an inch external diameter, was used to make connection with the trachea, and by an increasing series of larger tubes this was connected with the tube from the air-valve of the forced respiration apparatus. About 6 P M. the forced respiration was begun, Dr. A. M. Curtis giving valued assistance in holding the small tube in the trachea. In fifteen to twenty minutes the cyanotic condition passed away; child steadily improved for an hour, when the cyanosis returned. Examination revealed that the tube had slipped out of the trachea. After replacing it, forced respiration was continued, and the natural hue of health returned. The pulse improved, ranging for a time up to 134 per minute. Drs. W. H. Heath and George W. T. Lewis were called in to assist. Natural movements of the limbs returned, reflexes were again established, the limbs moved, bowels acted freely, and eight or ten natural respirations were taken. Hopes for recovery were almost entertained from the remarkable changes produced by the forced respirations, but at 9.10 P.M. pulsations indicated heart failure, and at 9.30 P.M. the heart ceased beating.

In this case, no less than in those preceding, the result of forced respiration was remarkable. The infant only eighteen days old had for five and one-quarter hours been subjected to the influence of one grain of morphine, in an asphyxiated condition for at least four and one-half hours, thus weakening the muscular tissue of the body. Under forced respiration life was retained, with the result mentioned, for three and one-half hours. If forced respiration had been instituted within the first two hours, it is probable the result might have proved different.

EFFECTS OF FORCED RESPIRATION UPON NARCOTIZED HUMAN SUBJECTS.

Observations obtained from various sources and the practice of forced respiration upon animals have given us a comparatively full knowledge of the physiology of respiration. The result of the same operation in the cases reported will, I think, add much interest to the subject, emphasize some points, and confirm others obtained by observation on the lower animals.

I present the conditions observed beginning with my first case, Mr. B. It will be remembered he had taken morphia, grs. xx. When forced respiration was first applied the patient was cyanotic. The effect of the respiration was observed much sooner on the heart than on the lungs. The change from the venous to arterial state of the blood was first noticed; the pulse at the wrist became stronger and quite regular some time before the attempts at respiration were made by the patient. Forced respiration was under way some twenty minutes before any attempts at breathing were made by the patient. A long interval elapsed before additional attempts were made. The ruddy hue of health returned to the face, and the first attempts at natural respiration were indicated by two or three quick, hurried movements of the lungs. These subsided and without both forced inspiration and expiration the patient would have quickly succumbed.

Sensibility was returning as indicated by reflexes of the ocular muscles. The next feature was movement of the limbs followed by one of the arms. Shortly after the eyes opened, staring wildly. Consciousness returned, the patient eagerly drinking water proffered to him. After about two hours' work the natural respirations became longer and longer, until they appeared almost normal.

The opening in the side of the valve (one-eighth by one-half of an inch), which permitted air to pass in for the natural respirations, was not large enough to supply the lungs with their full requirement of air, so that natural breathing could only be carried

on for a short time before dyspnœa would ensue. This was evidenced on the part of the patient by gasps and uneasy movements. When this occurred, the natural were supplemented by the forced respirations with the effect of always quieting and easing the patient.

When the *forced respirations* were kept up for a short time, and the blood became surcharged with oxygen, it would be some time before attempts to breathe were made—this was frequently observed; advantage was taken of this, and this condition was produced when the change from the cumbersome tracheal tube of the respiratory apparatus was made for an ordinary tracheotomy tube, and the patient allowed to breathe for himself.

In the variation in the number of respirations we find one of the most interesting and instructive features of the whole case. When the operation was begun at nine o'clock, Saturday morning, the rate was *less* than *one* per minute; when completed, three hours later, some *eighteen* or *twenty* per minute, and remaining at the normal number during the rest of the day. During the following night, they were again modified by the delirium, and the next day, or about twenty-four hours after the operation, had lowered to the unpleasant rate of *only six per minute*. Here they remained for a short time, then gradually came up to eight, ten, twelve, and fifteen, and two days after the operation became normal in number and action. This remarkable variation can most easily be explained by assuming that the shock and paralysis to the system had been almost completely overcome by the forced respiration; that the effect of the residual poison in the blood did not exert its influence under the forced respirations, but that in the following twenty-four hours, under the ordinary conditions of the system, the poison *remaining* again produced its effects; and had not the eliminative organs steadily continued to rid the system of the poison, secondary poisoning might have taken place with serious, if not fatal, results, or forced respiration might have had again to be resorted to. In all these cases it is interesting to note the marked difference in favor of forced respiration over artificial respiration in effects produced on respiratory centres. Where the latter will not suffice, the former should always be substituted before a fatal prognosis is rendered.

In Case III. the paralysis of the respiratory centres was more complete than in Case I. Two ounces of laudanum were fully absorbed. The patient had been kept alive three hours by artificial respiration, when the forced respiration was carried on for two and one-half hours before consciousness fully returned. Fifteen minutes after this it was noted that the patient would not make the slightest attempt to breathe when the forced respiration was discontinued. This was not apnœa (taking that meaning of the term in which the respirations are discontinued by the surcharging of the blood with oxygen), but under the ordinary continuous operation of the apparatus. During the first six or eight hours of this case, the bellows were given two movements for inspiration, not furnishing sufficient air to supply the system with its full requirement of oxygen. The consequence was that cyanosis gradually increased until the face, neck, lips, eyelids, pinna of ears, and dorsum of neck gave marked evidence of it. In this condition, when it would seem that the tissues of the body would be demanding oxygen, not an effort would be made toward natural respiration when forced respiration was discontinued.

The most remarkable feature in this interesting case was that under this condition of marked paralysis of the respiratory centres and deep cyanosis the patient was *conscious*, and would respond to ordinary requests such as drinking when desired to; when asked to *take a long breath*, he would evidence the power of the will over the respiratory muscles or centres by responding with a good effort at inspiration. He would, however, immediately subside into his former lethargic state, and not make more than one voluntary effort at respiration. Cyanosis would increase and when the condition of asphyxia had been reached, extraordinary respiratory efforts were noted, but immediately subsided when the forced respiration was again substituted. Many persons besides the four physicians were present. This experiment was repeated a number of times in the presence of the physicians.

These facts, and those noted in connection with Case IV., give hopes that forced respiration may have a wider field than merely in cases of opium poisoning, and illustrate in a most interesting manner the marked difference in function between the medulla oblongata and cerebrum. In Case IV. the respiratory centres were not so completely paralyzed as in Case III. Owing to the great loss of blood the effects of the opium had almost passed away some twelve or fifteen hours after the forced respiration was instituted, but the vital energy remaining was not sufficient to enable the patient to breathe for himself until some twelve hours later. This is thoroughly attested. In this state the patient was as "quiet as a lamb" for long periods at a time, under the forced respiration, and after it had been discontinued requested the reapplication of it. It supplied a need in this case that artificial respiration, with its bodily movements, could not have done.

In the case of the old gentleman eighty years of age, who was reported to have taken tr. opii ℥j, the entire cerebral system seemed thoroughly paralyzed; the return of consciousness, compared with the other cases, was slow and lasted but a short time. Here old age had an influence, and the

tissues of the brain had, undoubtedly, lost their susceptibility to stimulation. In the case of the eighteen day old infant, the changes wrought by forced respiration were beyond comprehension; that a child in the state in which this was found could be made again to respond to the influence of any agent, so as to affect the entire system, after having been under the influence of so large amount of morphia seems almost incredible. I cannot ignore the grand results obtained by artificial respiration in many cases of opium poisoning, and could cite many remarkable cases; but feel from the short, although important, experience with forced respiration, that we have something more than a *dernier ressort* compared with artificial respiration, and all that is needed to demonstrate such to be the truth, is its application to suitable cases when presented. One fact which should be borne in mind is, that artificial respiration in extreme cases is always carried on at the expense of the patient's energy, and we might emphasize the fact that the physician expends *about all he has also;* whereas, in forced respiration, with an attendant to work the bellows, the patient is passive, and the physician has merely to press on a valve some eighteen times a minute. In a long-continued fight for life, this is a factor of no inconsiderable importance.

FORCED RESPIRATION IN DROWNING.

It is probable that forced respiration may come into application in all cases in which artificial respiration has been used and failed to keep up the action of the heart. In cases of drowning, we will find a favorable field for its use. All of the cases previously cited prove conclusively that the cephalic centres respond more readily to forced respiration than to artificial respiration. If I choose to make comparisons, I could show that the early return of consciousness in deeply narcotized subjects was greatly in favor of forced respiration. On this account, and the results I have already obtained, we must expect that in almost all cases of asphyxia, from whatever cause, forced respiration will be considered the most reliable agent we can apply. Where tracheotomy is always necessary, it may not be generally used. In drowning and many other cases tracheotomy need not be performed, forced respiration may be applied by intubation of the larynx or trachea.

I can best illustrate the method of applying it in drowning by presenting an imaginary case. A patient, removed from the water, lies still before us; slight fluttering of the heart indicates life; water may still remain in the lungs; with suitable forceps pull out the tongue, pass the flexible rubber tracheal tube, by aid of the trachea guide (a curved steel bar which hooks up the epiglottis and carries the tube back and presents it properly at the laryngeal opening, and by which it is easily passed a short distance into the trachea; withdraw the tracheal guide, secure tracheal tube with tape about the neck, connect forced respiration apparatus, and you are ready to breathe for your patient. Now force a minimum amount of air into the lungs; if water be present, a gurgling sound will disclose it.[1] To remove it, invert the patient, raise the hips and lower the head, and if water be present the air will rise above it and force it out of the air valve. After this, replace in the dorsal position, apply heated and medicated air, water per enema, hypodermatic stimulation, etc.; but nothing by the mouth, for fear it might pass into the lungs. We have in drowning no *poison* to eliminate, therefore, no special need of eliminative medication by the stomach. As soon as the patient may be depended upon to breathe for himself, remove the tracheal tube and give liquid food by the mouth.

FORCED RESPIRATION IN SHOCK.

In shock we have the combined afferent nervous impressions proceeding from the injured terminals, producing a greater or less degree of paralysis of the central nervous system, through, or by which the various important functions of the economy are carried on. We do not have the respiratory centres almost alone paralyzed, as in opium poisoning, but we may include all the functional centres of the economy. Did we not have frequent evidence of recovery from shock, I would not feel justified in suggesting the possibility of keeping up or saving human life in such cases by forced respiration. I offer the cases of Mr. Baere and Mr. Van Orden as instances from which it is reasonable to infer that forced respiration may be expected to give results in shock to be obtained by no other means.

72 Niagara St., Buffalo, N. Y.

TWO CASES OF STRICTURE OF THE RECTUM: EXTERNAL PROCTOTOMY.

By WALTER B. PLATT, F.R.C.S. (Eng.),
of Baltimore, Md.

Case I. *Syphilitic stricture of rectum; recto-vaginal fistula: external proctotomy; entire relief from difficulty of defecation.*—M. W., married, a small, thin, dark-complexioned woman, about thirty-five years of age. For three years patient had had difficulty and pain in defecation, with constipation; some blood passed at stool. She attributed her stricture to an operation for fistula in ano; no history of syphilis, or physical signs, except circular, pigmented spots on legs. The patient had, however, led an irregular life, and is now living with a negro. If no laxative was taken, bowels moved but once a week, and then with diarrhœa and pain. Apart from this she considered herself in fair health. Fluid fecal

[1] In Case III., the gurgling of blood in the lungs could be heard ten feet from the patient.

matter sometimes issued from vagina. She had a very lax anus, surrounded by a fringe of external piles, flat and bluish.

One and one-half inches up the rectum a great narrowing of the calibre of the bowel was felt, which barely admitted the tip of the forefinger. It appeared to be more in the superior part of the bowel. It was found, after the operation, to be three-fourths of an inch long, and somewhat longer on the inferior than on the upper surface. It was granular within, and very hard and inelastic to the touch. The stricture could be moved from side to side with the finger-tip.

After some weeks of anti-syphilitic and tonic treatment, the case was deemed eminently suitable for external proctotomy, which was accordingly done November 20, 1887. The patient being etherized, the skin and part of the adjacent tissues from the anus to the coccyx were divided with the thermo-cautery knife. Its use was so unsatisfactory that recourse was had to the knife to complete the operation. The skin, sphincter, lower rectum, and stricture being divided in the median line from above downward (the stricture by the introduction of a long stricture knife), the bowel above the stricture could be plainly felt—smooth, soft, elastic, and apparently not abnormally dilated. The hemorrhage was very free for a moment after the division of the rectum, and the blood was bright red in color. The flow was checked with little trouble by the free use of hot water and pressure with hot sponges. An oiled linen rag was introduced into the rectum, and filled with sponges, so as to exert pressure upon the rectal walls and the cut surfaces. One-fourth grain of morphia was given twice in the following twenty-four hours, and the sponges removed at the end of that time. There was considerable brownish discharge, and a little blood and pus escaped when the sponges and the oiled rag were removed. The wound was now thoroughly washed out twice daily with warm carbolized water, and iodoform dusted in as far as practicable; a pad of absorbent cotton applied over all.

December 9. Nineteen days after operation a Tiemann's soft-rubber conical rectal bougie (No. 6) was passed.

10th. No. 7 passed.

19th. Passed No. 10. I have five times passed No. 8 since last note. It gives the patient some pain to go about and uneasiness to sit down. Patient has a good stool every second or third day, after using licorice powder. She has control over flatus and feces, she looks well, and eats the same food as before the operation. Some time after this the patient was seen by my nurses going about the street. She said she was in good condition, and had one stool daily by smoking a cigarette. She did not consider a bougie any longer necessary, although she was advised to have it passed once a week.

Case II. *Syphilitic stricture of the rectum: recto-vaginal fistula; external proctotomy; entire relief form symptoms.*—F. W., a slender, small, pale woman, æt. twenty-five, married. There was a clear history of infection nine years ago, when she had a sore upon the vulva, followed by loss of hair, sore-throat, and a skin eruption. Soon after this a "wart" was removed from the perineum, and five months ago the writer removed abundant cauliflower-like growths from the labia-minora, perineum, and the circumference of the anus. Since last autumn, for about eight months, she had had difficulty in defecation, and fluid passages, two or three daily. Said she had rectal stricture and a fistula. She had palpable supratrochlear and inguinal glands. No evidence of skin eruption; remnants of the cauliflower-like eruption still visible on vulva. Rugæ in vagina greatly hypertrophied. A milky discharge from the vagina, and a small opening in the vaginal wall communicating with the rectum. Patient said that fluid feces sometimes exuded from the vagina in small quantity. Her husband had an abundant macular red eruption on his face.

About one and three-fourths inches up the rectum could be felt a very firm, slightly movable ring, barely admitting the tip of the finger. This was apparently one-half an inch in thickness. Operation June 18, 1888. The patient being etherized, a long probe-pointed bistoury was introduced into and through the stricture, the cutting-edge directed downward in the median plane. The stricture was now divided entirely through until the smooth, thin, soft, lower surface of the rectum above the stricture could be felt. The incision was then completed by dividing all the tissues of the rectum, sphincter, and skin down to the sacrum and coccyx. Hemorrhage was moderate and easily controlled by hot water irrigation. The knees were tied together, iodoform dusted over the region, and a pad of absorbent cotton firmly applied to the seat of operation by a "T" bandage.

Beyond a copious discharge of brownish, bloody fluid from the rectum for the first two days, convalescence was uninterrupted. The rectum was washed out with carbolized water twice daily, and after thoroughly drying the parts, a dusting powder applied. Very little pain was experienced after operation; patient complained merely of parts feeling very sore when irrigated. After three to four days, yellow discharge abundant. Passage of rectal bougie No. 6 begun on the eighth day; patient kept for a week on milk diet.

She was up and about the room in ten days. Went about as usual shortly after this. October 1, a No. 8 rectal bougie was passed twice for one week at the end of ten days, then once a week up to the present time. The patient was placed upon a treatment of biniodide of mercury before and after the operation, with moderate improvement. There was a return of syphilitic symptoms, enlarged sub-occipital and sub-lingual glands. These quickly disappeared after two weeks' use of twenty-five grains of potassium iodide three times a day, with hyd. cum creta and Dover's powder, one grain of each five times daily. A tonic treatment has been employed from time to time. Up to November 1st I introduced a No. 8 conical rubber elastic bougie, once a week with little difficulty. Some bronzing of skin about the anus from discharge and daily washing out with solution of carbolic acid. Patient has one comfortable stool daily. Perfect control of feces and

flatus as far as I can determine. Feels well and goes about as usual. With the exception of being pale she is in good physical condition. A pink, granulating slit, still open, extends from anus nearly to coccyx. This gives rise to no pain or discomfort. There is still a slight discharge.

REMARKS.—Both the above patients have expressed themselves as greatly relieved, and at the present time, one year and five months, respectively, from the time of operation, have excellent control of both flatus and feces, experience no discomfort, and almost no inconvenience. They are now going about and attend to their daily occupations. Like all known operations of any kind for strictures of flexible canals lined with mucous membrane, we look for palliation, not cure. A bougie must be passed once a week at least for the remainder of the patient's life.

With electrolysis I have had no experience. Whatever this procedure may do for soft and short strictures, the writer must confess himself sceptical regarding any benefit to be derived where the stricture is long and dense, as in the above cases.

External proctotomy was probably first advocated and extensively practised by Nélaton and Humphrey, who operated with the knife. It has since been practised principally by French surgeons; among them Verneuil, Fochier, Labba, Trelat, Panas; and by Kelsey and others in America. The operation was done at first by Nélaton with the knife; later surgeons have often used the thermo-cautery and écraseur, sometimes the galvano-cautery. The choice of an instrument may depend somewhat upon the cause of the stricture. If due to malignant disease, the thermo-cautery ought to be used to divide the stricture, if not anus as well. Or if for any reason hemorrhage is particularly expected, either the latter instrument, the galvano-cautery, or the écraseur. Otherwise I prefer the median downward incision with the long, straight, probe-pointed, strong bistoury.

The hemorrhage was not excessive in either of the two cases operated on by the writer, easily controlled by hot water, and in one case by an oiled rag packed inside with sponges. Previous to operation the rectum ought to be thoroughly emptied as far as possible, by giving a dose of castor oil the night before, and an enema on the day of the operation. After etherization the anus should be dilated by the thumbs of the operator, taking plenty of time to do it, dilating gradually but thoroughly. This adds both to the comfort of the patient and to the convenience of the surgeon. The after-treatment consists of rest in bed with the knees fastened together for the first twenty-four hours, a pad being interposed to prevent discomfort. Milk diet for ten days, and enough opium for forty-eight hours to insure quiet. The wound ought to be washed out twice daily with warm carbolized water, and after thoroughly drying the parts, apply iodoform to the wound, and some soothing dusting powder to the surrounding skin. To cut a rectum and anus for the lower two to three inches of its extent, down to the sacrum and coccyx, seems not only radical, but barbarous. We must not forget that we leave the patient with a granulating V-shaped slit for a long time after the operation, if not forever, instead of the previously circular and puckered anus; but any patient who has long suffered the miseries of rectal obstruction will thank the surgeon for the great relief he has afforded. Moreover, this operation will render that of artificial anus in the flank much less frequent, and is infinitely better in its results when it can be done in place of it.

The reason why we divide everything down to the bone and outward through the anus, is to solve the vital matter of drainage. Without this complete incision the lower rectum becomes a bowl of poison, which experience shows the system is likely to absorb with resulting septic intoxication and often death. With the incision, the operation is free, safe, and good in its results. The insertion of a drainage tube between the anus and coccyx, leaving the anus intact, would not solve the septic difficulty entirely, while it would leave a fistula to be operated on later by cutting through into the rectum.

I wish to acknowledge the kind assistance of Dr. S. T. Earle, who took charge of the second case after the first ten days.

859 PARK AVENUE, BALTIMORE,
November 19, 1888.

ON LESIONS OF THE CONUS MEDULLARIS AND CAUDA EQUINA, AND ON THE SITUATION OF THE ANO-VESICAL CENTRE IN MAN.[1]

BY WILLIAM OSLER, M.D.,
PROFESSOR OF CLINICAL MEDICINE IN THE UNIVERSITY OF PENNSYLVANIA.

THERE have been published recently several observations which add materially to our knowledge of injuries and lesions of the terminal section of the spinal cord and of its nerve roots, and which also throw considerable light on the exact situation of the ano-vesical centre.

In a suggestive and valuable communication "On the Segmental Distribution of Sensory Disorders," Ross[2] analyzes the distribution of the sensory branches of the lumbo-sacral plexus, and calls attention to the arrangement of the lower sacral and coccygeal nerves, which supply by the small sciatic, derived from the third and fourth sacral roots, the external aspect of the skin on the back of the thigh, and from these same roots, through the inferior hemorrhoidal, pudendal, and pudic nerves, the anus, perineum, scrotum, and penis.

[1] Read before the Philadelphia Neurological Society, October 22, 1888.

[2] Brain, January, 1888

Cases of injury have been reported in which a sensory paralysis of this distribution has been associated with paralysis of the rectum and bladder, and with little or no involvement of the parts supplied by the first and second sacral and the lumbar nerves. Such instances are, in fact, important and valuable experiments from the study of which much may be gathered. Thorburn[1] reports four cases of injury of the cauda equina in which, with paralytic symptoms of variable extent, there were incontinence of urine and of feces, and anæsthesia in the distribution of the branches of the lower sacral nerves. He quotes also a case of Olivier's of gunshot wound in the lumbar region, which nine years after the accident presented complete anæsthesia of the postero-internal and anterior parts of the thighs and of the penis and scrotum.

Bernhardt[2] records a case of injury, the result of a fall on the buttocks from a height, which was followed by retention of urine and incontinence of feces. There was no paralysis of the legs, but there was absolute anæsthesia of the anus, perineum, scrotum, penis, and the skin of the upper two-thirds of the thighs. There were erections and within a few weeks after the injury coitus was possible, but ejaculation was defective and the semen flowed slowly *post cohabitationem*. Although the scrotum was anæsthetic, the testes were sensitive to pressure, and the cremasteric reflex was present. These parts are supplied from the genito-crural nerve, a branch of the lumbar plexus, which is, as Thorburn points out, usually unaffected in these cases.

A still more instructive case is reported by Oppenheim in the last number of the *Archiv f. Psychiatrie*, Bd. xx. Heft 1. A workman fell from a height of nineteen feet upon his sacrum. There were numb feelings in the legs, paralysis of the bladder and rectum, and complete anæsthesia of anus, perineum, scrotum, penis, and of the skin on the postero-internal aspects of the thighs. No erections. The reflexes were retained. The movements of the legs were perfect and the numb feelings disappeared. The other symptoms persisted and death took place about three and a half months after the injury. The autopsy showed a fracture of the first lumbar vertebra, and a traumatic myelitis and hæmatomyelitis of the conus medullaris, and a degeneration of the posterior roots of the third and fourth sacral nerves coming from the conus at the seat of injury. We have here the very anatomical facts needed to complete the picture, and they moreover render it very probable that in these cases the terminal portion of the cord—the conus—is itself the seat of the lesion, although it is possible that involvement of the nerves alone would produce the symptoms.

[1] Brain, January, 1888.

[2] Bernhardt: Berliner klin. Wochenschrift, No. 32, 1888.

By no means the least interesting aspect of these cases is the light they throw on the situation of the ano-vesical centre in man. Kirchoff[1] had already concluded that it was situated in the conus medullaris in the region of exit of the third and fourth sacral nerves. In the case of a man who had fallen on the nates, and whose important symptom was paralysis of the bladder and rectum, the lesion was found in the conus three centimetres above the filum terminale. Oppenheim's case is a still more accurate demonstration.

The following case can be understood with the aid of the preceding remarks:

Joc. C. H., æt. sixty-three, applied at the Infirmary for Nervous Diseases March 7, 1888. Family history good. Has always been healthy and well, though as a young man he had syphilis. Served in the army and on June 8, 1862, sustained a fracture of the spine. In the battle of Cross Keys, as he was crossing a bridge, a bullet struck him on the cartridge-belt, and the shock knocked him off the bridge, and he fell on the rocks in a sitting posture. He was senseless, and on coming to found himself in the ambulance wagon. Was in the military hospitals three and a half years at Winchester and Fort McHenry, for three years of which time he was on a water-bed. The skin of the back was not broken by the fall. He was paralyzed in the legs and lost control of the bladder and rectum. After a time he could move the legs, but he did not walk until December, 1865. Since that time he has been able to be about, but he has never regained control over the bladder and rectum. Uses a catheter three or four times a day. Never knows when he is going to have a stool.

Present Condition.—Well-built, vigorous-looking man for his age; walks well, but favors the left side a little. When stripped, it is seen that the left leg is slightly smaller than the right. Measurements gave, right calf fifteen inches, left thirteen and a quarter inches; left thigh also somewhat smaller. He says the leg has been thin ever since the accident, but he is always able to get about quite well. The spine is straight, the lower dorsal vertebræ a little prominent, lumbar normal; no signs of abrasion or of any scars; no pain on pressure.

There is complete anæsthesia of the lower gluteal regions, posterior aspects of the thighs, perineum, scrotum, and penis as far as its root. In all other regions sensation is perfect. He does not feel the passage of a catheter. He is impotent. No information asked about seminal emissions.

Gluteal reflex well marked.

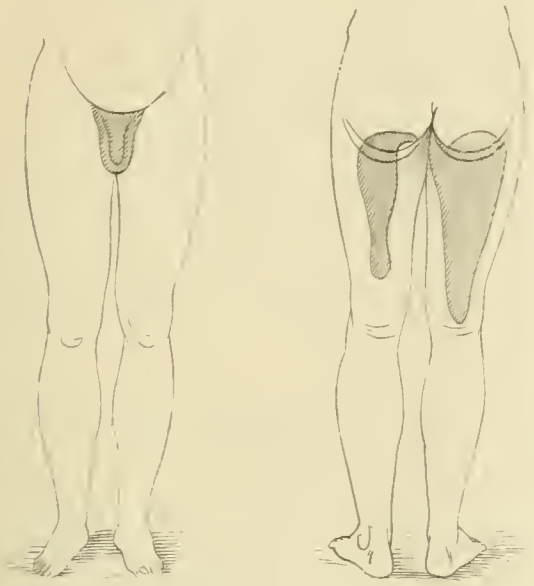
Cremasteric reflex present.

K.-J. + +. No ankle clonus.

We have to deal here with a residual paralysis of the bladder and rectum and of the skin supplied by the small sciatic, inferior hemorrhoidal, pudendal nerves arising from the third and fourth sacral roots. Whether the injury involved originally the cord or

[1] Archiv f. Psychiatrie, Bd. xv.

only the branches of the cauda equina does not seem possible to determine. The fact that slight wasting of one leg remains would indicate a neural rather than a central lesion.



Distribution of the anæsthesia.
Front view. Rear view.

These cases do not all result from injury. Rosenthal[1] reports the case of a woman, aged thirty, who, as the result of exposure to cold, had incontinence of urine and feces, associated with anæsthesia of anus, perineum, vulva, vagina, and lower gluteal regions. The legs were in all relations normal. From a consideration of these cases we may conclude:

1. That the ano-vesical centre in man is situated in the lowest segment of the spinal cord—the conus medullaris—at the region of exit of the third and fourth sacral nerves.

2. The association of paralysis of the rectum and bladder with anæsthesia in the distribution of the inferior hemorrhoidal and pudendal nerves points to a lesion of the lower sacral nerves or of the conus medullaris. It is not always possible to determine which is affected.

REPORT OF A CASE OF INTESTINAL OBSTRUCTION FROM EPITHELIOMA OF THE DESCENDING COLON.

Resection of Intestine; Subsequent Closure of Artificial Anus.

By CHARLES B. PENROSE, M.D., Ph.D.,
OF PHILADELPHIA.

B. P., aged fifty-three, had been suffering with obstinate constipation for twelve months. Defecation had gradually been becoming more difficult and painful. There had been no movement of the bowel for twenty-eight days before operation, though purgative medicines and rectal injections had been vigorously administered. Before the abdominal distention became too great, her attending physician, Dr. Bernardy, had observed a movable mass in the left iliac region, which he had diagnosticated to be cancer of the descending colon. There had been feculent vomiting for two days before the operation.

When seen by the writer, on February 1, 1888, the abdomen was greatly distended. There were constant abdominal pain and dyspnœa. Temperature 101°; pulse 130. Tongue dry and brown. There was no doubt about the diagnosis of intestinal obstruction—probably from cancer of the large intestine—and laparotomy was immediately performed. The incision extended from the umbilicus to four inches below. The intestines were congested, and there was a small quantity of bloody serum in the peritoneum.

As the distended intestines greatly impeded the search for the obstruction, a loop of bowel was incised, and the flatus and fluid feces allowed to escape. The opening was closed with a continued silk suture (Dupuytren's). A hard mass was felt lying deep in the abdomen, to the right of the vertebral column. This proved to be a dense, hard, annular constriction, about one inch in width, around the descending colon. The gentle traction used in bringing the constricted intestine to the abdominal opening was sufficient to break it transversely across—through the middle of the stricture. As, however, the growth involved the whole lumen of the bowel, each end remained closed, and no feces escaped.

The transverse section of the stricture presented the appearance of friable colloid material. The mesentery of the constricted portion of the intestine was thickened, indurated, and contracted. No indurated glands were discovered.

The stricture, with about ten inches of the contiguous thickened portion of intestine, and a triangular piece of mesentery, was excised. It was necessary to ligate many vessels in the divided mesentery. The upper end of the bowel was turned over the parietes, and a large quantity of flatus and a bucketful of green fluid feces escaped.

The two ends of the divided gut were stitched together for one-half their circumference, with a continuous strong silk suture, which penetrated all the intestinal coats. The ends were then stitched, at the lower angle of the abdominal incision, to the skin margin, by a similar continuous suture. The abdominal cavity was irrigated with warm distilled water, and the incision closed. No pus escaped into the peritoneum during the operation.

For thirty-six hours after the operation there was a continuous discharge of flatus and feces from the abdomen. The distention disappeared very rapidly, and in twenty-four hours the abdominal parietes were depressed below the costal margin. The relief to the patient was so immediate that she slept almost continuously for the first two days.

With the exception of an attack of pneumonia in the fourth week, the convalescence was uninterrupted. Examination of the excised bowel showed that the

[1] Ueber das centrum Ano-vesicale. Wiener med. Presse, Nos. 18, 19, and 20, 1888.

growth was epithelioma, involving the portion of the large intestine about ten inches from the anus.

The patient continued well, and had regular evacuations daily, about eight o'clock every morning, from the artificial anus. The opening contracted in size, so that three months after the operation it would admit but two fingers. The skin and mucous membrane at no time presented an abraded, ulcerated, or unhealthy appearance. There was at times a slight prolapse of the bowel through the opening.

On May 23, 1888, she was etherized, and Dupuytren's enterotome was placed on the septum between the two sections of gut. The enterotome came away at the end of seven days, and the bowels were moved by the natural anus. After this the bowels were moved daily, partly by the natural and partly by the artificial anus.

As a considerable spur still remained between the upper and lower segments of gut, and the feces had to pass over this to enter the rectum, Dupuytren's enterotome was again applied on June 24, 1888, and the spur was divided to the extent of about one and a half inches. The enterotome came away in seven days, and the bowels were moved for two weeks chiefly by the natural anus. Feces then began to come, in gradually increasing quantity, through the abdominal opening. A piece of heavy rubber catheter, six inches in length, was placed in the bowel, extending from the upper to the lower portions, in order to depress the remnant of the spur. This was used for six weeks. It was necessary to reintroduce it every two or three days, as it was frequently passed out by the natural anus. Its presence increased the relative amount of feces passed by the natural way, though about one-half the total quantity continued to escape by the abdominal opening.

On August 20, 1888, the patient was again etherized. The edges of the artificial anus were freshened by removing a circular strip of skin about a third of an inch in width, and a contiguous circular strip of mucous membrane about half an inch in width. An elliptical disk of rubber one-sixteenth of an inch in thickness, and with a long axis of one and a half inches, was armed with four silk ligatures placed symmetrically around its edges, and was introduced into the artificial anus on the plane of the parietal peritoneum—thus forming a floor for the abdominal opening, and protecting the intra-abdominal line of incision from feces and flatus. The four silk ligatures were passed through the parietes, in order to hold the rubber disk in place. The freshened edges of the artificial anus were united by sutures of silkworm-gut. A rectal tube was used continuously for the first two days. The bowels were moved by enema and sulphate of magnesia on the fourth day. The sutures were removed on the tenth day, and the silk ligatures attached to the rubber disk were cut. On the fifteenth day an abscess about the size of a pea ruptured at the lower angle of the abdominal wound, and for a few days a very small quantity of feculent material escaped. The rubber disk was discharged from the rectum about the sixteenth day.

When last seen, November 15, 1888, this woman was at work; her bowels were moved easily and naturally, and the abdominal line of incision was closed throughout, presenting the appearance of the incision of a simple laparotomy.

One of the chief points of surgical interest illustrated by this case is the advantage of making a temporary artificial anus after resection of the intestine, when there is a great collection of flatus and feces in the alimentary tract, rather than by uniting the gut by circular suture, and immediately restoring its continuity. The dangers incident to immediate suture are due to the following causes:

1. The sutures are introduced in an intestinal wall which has become weakened and attenuated by prolonged distention.

2. The line of suture is exposed to great tension, which in some cases of obstruction has been sufficient to rupture the intestine.

3. There is danger of sloughing and kinking at the suture line.

4. The relief to the patient is not so immediate, since the flatus and feces have to travel a longer road before escaping, and the danger of toxæmia, and of subsequent obstruction from kinking and intestinal paralysis, is increased.

Von Bergmann (*Deutsch. med. Wochenschrift*, No. 24, 1888) reports a case in which, after resection, the continuity of the intestinal tract was immediately restored by a circular intestinal suture, and on the second day it was necessary to reopen the abdomen, remove the intestinal sutures, and make an artificial anus.

Agnew (*Med. and Surg. Reporter*, September 15, 1888) reports a case of resection of the small intestine in which the continuity of the gut was immediately restored, and the subsequent autopsy showed that one of the stitches had been torn out, though there had been no escape of feces. And he adds:

"With the light daily accumulating in this department of surgery, it would have been better, instead of stitching together the ends of the intestine, to have brought them out of the external wound, and to have attached the half circumference of each to the parietes, preparatory to another and a later operation for reëstablishing the continuity of the intestinal tract."

A SUCCESSFUL LAPAROTOMY FOR STAB-WOUND OF THE INTESTINE.[1]

By J. C. SEXTON, M.D.,
of Rushville, Indiana.

In presenting this report, the writer does not feel that he is called upon to do more than direct attention to certain points in connection with the operation and subsequent treatment. "Rule of action" has already been formulated for the treatment of such cases to such an extent that further comment thereon is uncalled for, unless something distinctive is done or observed during the course of an individual case.

[1] Read before the Union District Medical Association.

While I will not use valuable time in reviewing the literature of the subject, I will make the statement that the number of cases successfully operated upon is now so large as to warrant interference in every one of these necessarily fatal cases. A large quantity of intestinal contents poured out into the abdominal cavity, and an external opening of only half an inch whereby it could escape, is quite as surely, though not so quickly, fatal as a stab in the heart itself.

If called to such a case, no surgeon should hesitate to operate even in the face of shock of quite considerable degree, provided he can surround himself with antiseptic advantages, and prepare his operating-room so that he can properly protect the exposed viscera.

The following case is offered in support of this position :

M. L., aged twenty-nine, received a stab-wound of the abdomen and immediately presented himself at the office of Dr. J. W. Rayburn, of Andersonville, Indiana. He was in great pain and very weak. Dr. Rayburn found a half inch opening in the right iliac region through which a knuckle of intestine was protruding. After cleansing the gut in a warm alcoholic solution he was able to return, after gentle manipulation, what appeared to be an uninjured intestine to the abdominal cavity, when, to his surprise, intestinal contents began welling up from the bottom of the wound. He applied a dressing of borated cotton, gave a grain of opium, and had the patient conveyed a short distance to the house of a relative.

I was called to his aid and arrived at the house at midnight, July 14th, three hours after the injury. The patient was a man of perfect physique, absolutely temperate, and up to the moment of injury in perfect health. He was very restless, and suffered from intense thirst and severe pain.

An examination, made under careful antiseptic precaution, disclosed an opening in the abdomen half an inch long, located two inches inward from the right superior iliac spine and half an inch below the level of that process, through which intestinal contents were oozing.

Diagnosis.—Stab-wound of the intestine. The patient decided to take the chance of an operation, and we began our preparations. We waited until daylight, and also availed ourselves of the valuable assistance of Dr. C. H. Parsons, of Rushville.

Nine hours after the injury the patient was placed on the operating-table in fair condition. All antiseptic precautions that were possible had been taken. The room had been cleaned. All the water to be used in the operation had been boiled. The dressings, instruments, sponges, etc., had been thoroughly disinfected. Patient was in front of an east window through which the sun was reflected quite hot. He was covered with clean warm blankets, and hot applications made to feet, thighs, and armpits.

The original wound was enlarged to five inches, and twelve inches of intestine turned out. This was emptied of its contents through two large perforations, and enveloped in napkins wrung out of hot 1 : 20,000 bichloride solution. The abdominal cavity was then emptied of more than a teacupful of intestinal contents. No other intestinal injury was detected and the perforations were closed with a single line of interrupted Lembert sutures of sublimated silk. The larger perforation was squarely transverse and divided the intestinal wall from the mesenteric attachment to the periphery. The smaller was about three-fourths of an inch long, somewhat diagonal, situated quite two inches from the other, and both on the same wall of intestine. The abdominal cavity was then flushed. Pitcherful after pitcherful of hot 1 : 20,000 sublimate solution was poured in until the water returned perfectly clear. The cavity was then mopped dry and the intestine returned. A rubber drainage tube was carried to the bottom of the pelvis. The peritoneum was closed with catgut and the abdominal wall with an alternate layer of deep and superficial sutures. The external dressing was of carbolized gauze, iodoform, and borated cotton.

He had a rise of temperature soon after the operation, but this subsided as soon as he became quiet. He was given a half a grain of morphia, with $\frac{1}{90}$ gr. atropia, forty minutes after the operation, but the drug was not again used. Tympanites, tenderness, and nausea came on promptly, so that we began the use of seidlitz powders in *fifteen hours* after the operation, giving from a third to half a powder every three hours.

July 16. Twenty-four hours after the operation: temperature $97\frac{4}{5}$; respiration 22 : pulse 92. Tympanites and tenderness much less. Nausea persistent.

17th Fifty hours after the operation: pulse 92; respiration 22; temperature normal. No pain, slight tympanites, tenderness nil. Nausea distressing, some vomiting. Wound looking well. He was given a quarter of a grain of calomel every two hours. This treatment stopped the vomiting. Nausea unrelieved.

18th. Pulse and temperature normal. Nausea unrelenting, can take no nourishment on account of it. Seidlitz powders, one-third part every three hours, and enema to obtain motion of bowels.

19th. General condition good. Takes a little milk.

20th. Three actions of bowel remove the swelling, tenderness, and nausea. Appetite returns. Patient calls attention to the fact that borborygmus does not hurt him, but makes him feel better for a time. Drainage tube removed. Stitches showing signs of cutting. Removed all of them and allowed the wound to open. Peritoneum united. Wound dusted with iodoform and packed from the bottom with borated cotton. Edges drawn up with plasters.

No further interest attaches to this now established convalescence. During the second week, however, his bowels were not moved for four days, when the tympanites and nausea came back, he lost his appetite, became depressed, had a rise of temperature, and pain in the bowels. These symptoms all disappeared at once, after free evacuation of the bowel was obtained.

The abdominal wound united by granulation. He went on to a perfect recovery, and was discharged at the end of the third week. The after-treatment of this case was wholly in the care of my colleague, Dr. Rayburn, and to his skill and personal attention I am greatly indebted.

An unlooked-for complication attaches still further interest to this case. On the eighty-eighth day (October 10, 1888) after the operation described above, this man was again injured by the bursting of a cannon which he was firing. He had so far recovered that he was able to do ordinary work, and, although cautioned by his medical attendants that the cicatrix was yet young and soft, he made no effort to protect himself against a ventral hernia.

He was holding the touch-rod, and fired the gun, when he was knocked down by a flying fragment. He was injured about the breast; sustained a fracture of the radius. He had several cuts and bruises about the body and face, and was struck in the right groin with sufficient force to open the old wound.

I arrived at the house five hours after the accident. Patient unconscious, very restless, badly shocked, and bleeding quite freely from some lacerations of the omentum. A large loop of intestine, with a portion of omentum, had escaped, and became strangulated to such an extent that Dr. Rayburn had been unable to reduce it by manipulation.

After stimulating the patient with atropia, brandy, and hot water, and flushing the abdominal cavity with hot 1 : 20,000 bichloride solution, he rallied sufficiently to be placed under an anæsthetic.

I enlarged the wound, amputated the lacerated omentum, and returned the bowel, after a hasty but fruitless search for the intestinal suture of the first operation. The abdomen was carefully sponged out, and a rubber drain carried into the cavity. The peritoneum was then closed with carbolized catgut. The old cicatrix was then dissected out, and the edges of the wound brought accurately together with heavy silk. This adjustment was reinforced by spreading over the abdomen and hip on either side of the wound a broad piece of heavy rubber plaster. The edges of this were placed one and a half inches apart, then by fastening hooks and eyes on its edges, it could be laced up so that all strain was taken off the stitches, and at the same time there was no interference with the absorbent and antiseptic dressing.

The patient rallied promptly. Under Dr. Rayburn's excellent management he escaped a second time the dreaded peritonitis, and made an uninterrupted recovery. Union by first intention took place, and no pus formed. He was able to walk to the polls and cast his vote on the twenty-seventh day after his second injury.

Concerning the intestinal suture, the fact pointed out by Halstead (*The American Journal of the Medical Sciences*, 1887), that the submucosa is the strongest part of the intestinal wall, is most valuable. The operator readily detects this point of greatest resistance, and feels that a suture passed into it will be secure. Many prefer a continuous suture in adjusting a rent of the intestine, because it is more rapid. With the interrupted sutures, however, the adjustment is more accurate, and, if the silk is fine enough, the knot will not retard the union, but can slough off into the lumen of the bowel more rapidly than the unbroken thread.

Flushing the abdominal cavity for cleansing purposes, or where peritonitis has already begun, has been spoken of so frequently that I need not mention it further in this connection. Flushing with hot solutions or simple water, for the purpose of overcoming shock, has not received the attention its utility deserves. Only one writer, so far as I am aware, has called attention to it up to this time. It is rapidly and easily done, and in our case had a prompt effect both times it was tried. The pulse became firmer, fuller, stronger, while the respirations and the color of the skin at once improved.

I find no record of a case in which the solicitation of peristalsis was begun so early after operation for intestinal perforation. The prompt relief afforded by this measure is very satisfactory. To see tympanites that threatens to tear out the sutures, that is giving pain, causing restlessness, nausea, and general distress, disappear in a few hours, and the patient become both calm and cheerful, will at once convince the most sceptical of the utility of this treatment.

The older method of locking up the bowel is just exactly what ought not to be done in such a case. One does not want adhesions, he wants to prevent them. Here is a proposition that I hold almost self-evident, viz., vermicular motion of the intestine is vastly less straining upon the intestinal sutures, than distention by accumulated flatus.

It may not be presumption in me to repeat the injunction so strongly insisted upon by others, that the administration of opiates is wrong in such a condition, when other means will not only relieve pain but overcome the cause of it.

This case adds but little to what as already been presented to the profession. Yet, coming, as it does, from a point far remote rom the centres of surgical triumphs and advancement, it does tend to prove that *any one* possessed of ordinary skill, who will surround himself with proper antiseptic care and preparation, may reasonably expect success to crown his work.

MEDICAL PROGRESS.

Treatment of Spinal Atrophy in Germany.—Therapeutic intervention in spinal atrophy, according to DR. GRAUPNER (*Der Fortschritt*, July 20, 1888), will favor remission in the progress, but will not cure the disease.

As a rule, he begins treatment with inunctions of mercury, starting with one drachm of the blue ointment, the dose of which is increased daily till it reaches two

and a half drachms. At this point the mercurial inunctions cease, and treatment is continued with the daily administration of seventy-five grains of iodide of potassium in three divided doses. Dr. Graupner gives the following formula for a solution of iodide of potassium, to which he adds some belladonna as an antidote to the iodide.

R.—Iodide of potassium . . 75 grains.
Ext. of belladonna . . 7½ "
Distilled water . . . 1½ pints.

The iodide of potassium can be replaced by the iodide of sodium, even if the tabes be not of syphilitic origin.

The treatment with nitrate of silver has in Germany, as elsewhere, its adherents and opponents; it consists in taking three times daily one of the following pills:

R.—Nitrate of silver . . 4¼ grains.
Terra alba . . . q. s.—M.
Make into thirty pills

Dr. Graupner also prescribes antipyrin in thirty grain doses three times daily, in preference to antifebrin, which is given in seven grain doses, or else he uses intracutaneous injections of the first.

To overcome the motor-incoördinations Dr. Ewald uses injections of physostigma.

R.—Salicylate of physostigma . ¼ grain.
Water . . . . . 2½ drachm.

One-half of the contents of a Pravaz syringe would be the ordinary dose for an injection, but it has a drawback, which is, that it at times provokes vertigo and vomiting.

In treating the torpid forms, recourse is had to hydrotherapeutics. Salt, sulphur, and bran baths are used; to the latter are added from one to three ounces of sulphate of potassium or sulphate of sodium, with one ounce of vinegar. With this are combined vertebral inunctions of balsam of musk, camphoretted alcohol, or some other exciting stimulant. Further, the continuous and interrupted currents are used. Add to this a strict diet, with moderate physical exercise, and the treatment is complete.—*Revue gén. de Clinique et de thérapeutique*, November 8, 1888.

Novel Curative and Prophylactic Treatment of Asiatic Cholera.—Under the above title, Dr. A. Tras sums up his views as follows:

1. In order that the treatment of Asiatic cholera should be complete and rational, it must be divided into (*a*) curative treatment, and (*b*) prophylactic treatment; the curative treatment comprising the treatment of the symptoms and the pathological conditions.

2. The symptomatic treatment, which comprises the treatment of symptoms, he does not consider in this article.

3. The pathological treatment, which really is the principal factor of this treatment, refers to the cause of the affection itself. The treatment must consist, theoretically speaking, in the administration of a microbe-destroying agent powerful enough to destroy pathological microbes situated in the most remote parts of the human economy.

4. From a practical as well as a clinical standpoint the bichloride of mercury, dissolved in the form of a liquor, similar to that prepared by Dr. Van Swietan, would seem to answer all requirements.

5. Further, still, if this chemical agent is taken inwardly, before the comma bacillus has been absorbed, it will act as a prophylactic against cholera, in preventing all possible growth of the cholera bacillus within the human body.

6. Bichloride of mercury can thus be justly called the "chemical vaccine of cholera."

7. During an epidemic one can obtain immunity from cholera by using hypodermatic injections of powdered calomel, or the yellow oxide of mercury, which being slowly transformed into the bichloride, would guard the body against infection for a considerable length of time. —*Gazette Hebdomadaire de méd. et de Chirurgie*, November 16, 1888.

Operation for a New Bladder.—Professor Tizzoni and Dr. Poggi, of Bologna, have devised and carried out an extremely ingenious operation for the purpose of "restoring" the bladder in cases in which it is partially destroyed by disease. The object of the operative procedure is to replace the bladder by means of a substitute, that substitute being a portion of intestine. The operation (on an animal) was performed in two stages, an interval of about a month elapsing between them. The first part of the operation consisted in the cutting out of a portion of the intestine, the two ends from which it was taken being immediately sutured; the mesentery was left attached to the excised portion. The ends of this portion were then closed so as to form a sac; one end was then brought down and fixed to the neck of the bladder. The second portion of the operation consisted in separating the ureters from the bladder, excising the latter organ, suturing the intestinal sac in the position of the bladder, and grafting the ureters on to its posterior wall. For a few days there was incontinence of urine, but after a fortnight the sphincter regained its power, and the animal recovered completely. In consequence, however, of the small size of the new bladder, micturition was necessarily very frequent. Professor Tizzoni and Dr. Poggi propose to repeat this operation on another animal, taking care to excise a larger portion of intestine, so as to imitate more nearly the normal capacity of the bladder.—*Lancet*, November 10, 1888

Action of Alcohol upon Pepsin.—Dr. Bardot (*Les nouvelles remèdes*, June 8, 1888), having made several experiments to determine the solvency of pepsin in the presence of alcohol, arrives at the following conclusions:

1. A moderate quantity of alcohol does not alter the fermentative nor the digestive power of pepsin.

2. Should the amount of alcohol exceed fifty per cent., the digestive power of pepsin is at first slowed, then gradually destroyed.

3. Wines containing large quantities of tannin are detrimental to the action of pepsin; small quantities of tannin have no action whatsoever.

The Influence of Moderate Exercise upon Digestion.—Dr. Cohn (*Archiv für klin. medicin*), in order to decide the question: "Is rest or exercise necessary to favor digestion?" made the following experiments in the laboratory of Professor Rossback:

He gave to a number of dogs scraped meat and water; after the lapse of a certain time the contents of the stomach

were removed, the dogs having been submitted to exercise as well as to rest.

With the dogs which had rested, digestion was at its highest one hour after the meal; the juices of the stomach were rich in hydrochloric acid and pepsin, and poor in lactic acid; at the end of two hours digestion was still further advanced; the quantity of hydrochloric acid and peptones considerable; of lactic acid only traces being found. At the end of six hours digestion was complete.

In the dogs which had been submitted to two hours' active exercise after their meal, traces only of hydrochloric acid and peptones were found, but large quantities of lactic acid. It was only after the lapse of five hours (the animals having rested for three hours) that digestion rebegan, marked by the presence of large quantities of hydrochloric acid and peptones At the end of six hours digestion was not yet completed.

Ewald and Boas made the same experiments with the same results. Hydrochloric acid is a product of secretion; lactic acid one of fermentation; the slower the flow of the first, the slower digestion and *vice versa*. The writer concludes that exercise after a meal retards digestion.—*L'Abeille Médicale*, Nov. 19, 1888.

Painless Injections of Antipyrin.—Dr. Hamon de Fougeray gives, in the *Gazette des Hôpitaux*, his method of rendering the hypodermatic injections of antipyrin painless, which is as follows:

Fill the hypodermatic syringe with the following solution:

R.—Antipyrin	5½ grs.
Sol. cocaine 10 per cent. . .	10 drops.

Insert the syringe deep into the soft tissue, inject and no pain will be felt.—*Gazette Hebdomadaire des Sciences Médicales*, November 3, 1888.

Lipanin a Substitute for Cod-liver Oil.—Dr. O. Hauser reports, *Zeitschr. f. klin. Med.*, the results obtained with lipanius at the clinic of Prof. Kohts, at Strassbourg. The preparation was administered to thirty-eight children, ranging in age from fifteen months to thirteen and a half years. In every instance it proved itself to be equal, if not, superior to the ordinary yellow cod-liver oil. Amongst the different affections in which it was tried were rachitis, anæmia, scrofulosis, tuberculosis, and convalescence from severe illness. In every instance the little patients took the preparation with great relish; digestive disturbances, which are observed when giving cod-liver oil, were absent. Even during summer lipanin was well borne. In all cases in which an increase in body-weight was expected, the same was fully realized. Lipanin is given in the same doses as cod-liver oil, and can be mixed with other drugs, such as creasote, menthol, phosphorus, etc.—*Wiener med. Presse*, November 4, 1888.

Treatment of Affections of the Respiratory Organs with Rectal Injections of Carbonic Acid.—Dr. Lecomte having tried rectal injections of carbonic acid gas upon patients suffering with pulmonary tuberculosis, asthma, emphysema, and chronic bronchitis, states that he obtained satisfactory results, such as marked diminution of cough and expectoration, and alleviation of the dyspnœa, especially in asthma.

The mixture of carbonic acid and sulphuretted hydrogen seemed to him to produce the best results. The use of eucalyptol and sulpho-carbonated water was followed by irritation, and a return of all the bad symptoms. After a certain period, the improvement at first obtained through the injections of carbonic acid ceases, even though the amount of this gas be increased.—*Gazette Méd. de Paris*, November 10, 1888.

Treatment of Diphtheria by Eucalyptus.—Dr. Marray Gibbes, a physician of New Zealand, reports a series of remarkable successes obtained with eucalyptus in the treatment of diphtheria. The results noted from this treatment were:

1st. A prevention of the multiplication of the microorganisms. The oil of eucalyptus (oleum eucalyptus globulus) introduced into the economy, through the medium of air, vapor, or food, reappeared in the secreting glands of the pharynx. Through its internal action it prevents the subsequent formation of false membranes. In none of the cases treated with this remedy was any paralysis observed.

2d. Prevention of putrefaction of the destroyed tissue, before its separation from the healthy tissue below. While under the influence of this remedy, the false membrane was always of a healthy color, and the breath remained sweet throughout the entire treatment.

3d. The external application of a moist and warm cataplasm aids the separation of the membranes. The vapors of the oil of eucalyptus will destroy microörganisms floating in the air. To obtain the best results, place some leaves of the eucalyptus tree (which contain the oil) in a dish of boiling water, near the patient, who should be covered with a tent.—*Revue de Thérapeutique*, Nov. 15, 1888.

Pomade for Eczema.—

Resorcin	15 to 30 grs.
Yellow vaseline	1 oz.

This pomade to be used in eczema of the hands; it calms the itch and hastens the infiltration of the skin.—*L'Union Médicale*, Nov. 13, 1888.

Subcutaneous Injections of Solution of Chloride of Sodium in Cholera Infantum.—At a meeting of the Berlin Medical Society of Nov. 7, Prof. Henoch stated that he had obtained excellent results by treating cases of cholera infantum with subcutaneous injections of solutions of common cooking salt. The little patients were brought to his clinic in a state of collapse, with cold extremities, imperceptible pulse, and sunken eyes; the chloride of sodium injections were repeated from six to ten times at one sitting, as many as forty injections being administered during twenty-four hours. The result was surprisingly good, and without doubt in many cases saved the patient's life; those in a state of collapse recovering rapidly without any other treatment.—*Wiener med. Presse*, No, 47, Nov. 1888.

Treatment of Diphtheria.—Dr. Lichterman (*Bull. thérap.*) gives an account of more than 300 cases of diphtheria treated by him at Bérézowka, in the government of Cherson (a country frequently visited by epidemics of diphtheria), by the following treatment:

Called to a patient, he selects the largest room in the dwelling and disinfects the same with chlorine gas.

After the lapse of one hour, the room having been ventilated, the patient is placed therein. Actual treatment begins with a mustard foot-bath of fifteen minutes duration, after which the patient is wrapped in woollen blankets and allowed to perspire for two or three hours. This bath is repeated every evening.

Local Treatment.—1st. Painting the interior of the throat four times daily, with a solution of salicylate of sodium and glycerin (salicylate of sodium 15 grains, glycerin ʒj). 2d. Gargling every half hour with an aqueous solution of chlorate of potassium (chlorate of potash ʒjss, water ℥vj).

Internal Treatment.—Two mixtures—one white, the other red. The first is composed of: chlorate of potassium, 45 grains, water 6 ounces, simple syrup 1 ounce. The second of: hydrochloric acid 2 scruples, water 6 ounces, and raspberry syrup 1 ounce.

The patient takes every hour one tablespoonful of the white, and immediately afterward one tablespoonful of the red mixture. Children under one year take only a teaspoonful, and below that age only half a teaspoonful.

Expectoration is made into a dish containing a 5 per cent. solution of phenic acid. At the end of twenty-four hours the temperature becomes normal, and at the end of forty-eight hours the entire disappearance of the false membrane will be noticed.

The results which the writer obtained through this treatment are as follows: Up to the month of April, 1885, he treated his cases of diphtheria by the method then in general use, with a mortality of forty-two per cent. From April, 1886, to October, 1887, he treated 237 cases, sixty-eight of which were of the gangrenous variety. In these 237 cases he tried the treatment given above, with but four deaths, or seventeen per cent.

When called upon in October by the government to combat an epidemic then raging in the neighborhood of Bérézowka, he treated 47 cases, 8 of which died—forty per cent; these 8 cases having fallen ill five days previous to his arrival.

Dr. Lichterman gives the following theory for his treatment:

1. Under the influence of perspiration the patient's blood loses water and becomes richer in salts, which, according to Dr. Wachsmuth, leaves a poor medium for the development of diphtheritic microbes.

2. The administration of chlorate of potassium aids considerably in this concentration of the blood.

3. Under the simultaneous administration of hydrochloric acid and chlorate of potassium, an acid of chlorine is formed, which last acts very energetically as an oxidizer and microbe-destroyer.—*L'Abeille Médicale*, Nov. 19, 1888.

For the Constipation of Children.—

℞.—Podophyllin . . . . . ¾ gr.
Alcohol . . . . . ʒjss.
Syrup of marshmallow . . . ʒjv.—M.

One teaspoonful once daily.—*L'Union Médicale*, Nov. 20, 1888.

Cyanide of Zinc in Cardiac Affections.—Dr. Lashkewitsch states that cyanide of zinc (zincum hydrocyanicum sine ferro) acts favorably in palpitation, in pain in the cardiac region, and in an irregular pulse due to valvular insufficiency or a neurosis; its action being best marked in the last-named affection. This remedy will be found to be of special service when digitalis, convallaria, and other cardiac remedies seem to irritate the digestive organs. The dose is from $\frac{1}{13}$ to $\frac{1}{11}$ grain, taken once during twenty-four hours.—*Journal de Méd. de Paris*, Nov. 18, 1888.

Therapeutic Uses of Strophanthus.—At the meeting of the Académie de Médecine, Nov. 13, 1888, Dr. Germain See read a paper, by himself and Dr. Gley, upon the therapeutic uses of strophanthus. He states that the drug was used in all cardiac affections, in doses varying from $\frac{1}{13}$ to $\frac{8}{13}$ grain, with but little variation in the results.

1st. In mitral lesions, particularly in stenosis of the mitral orifice, less so in aortic insufficiency, the results were very favorable—that is, the cardiac action was greatly increased, as proved by the sphygmograph; from the start the pulse, which was at first depressed, small, and feeble, gradually gained in strength, the line of ascent at first nearly horizontal, becoming rapidly vertical, and that of descent, which at first was nearly effaced, being now only interrupted at a few points. The irregularities of the pulse disappeared. These phenomena were observed even when the heart had lost its force, no compensation remaining, and even when pulmonary and renal stasis with peripheral œdema existed. But in none of these cases was there any relief in the dyspnœa, nor increase of diuresis or diminution of the œdema.

2d. In all dilatations and fibroid hypertrophies dependent upon a general sclerosis of the arteries, the same results were obtained, namely: an increase in the strength of the pulse and a return to the former general strength. No distinction was noticed between the maladies with *hyper-* or *hypo-*tension.

3d. In the painful affections of the heart and cardiac neuralgias, the administration of strophanthus proved harmful, by increasing the severity of the lesions.

4th. No disturbing action upon the stomach or brain was noticed; but at times slight vertigo was complained of.

Dr. Dujardin-Beaumetz was of the opinion that in prescribing strophanthus it was essential to indicate what preparation was desired, as there were no less than six different tinctures in the market, all of which were of varying strength. These are Hardy's, Gallois's, Armand's, Traver's, Catillou's, and the one made in the laboratory of M. Chevreul.—*L'Abeille Médicale*, Nov. 19, 1888.

Ointment for Furuncles.—

℞.—Red precipitate . . . . 1½ grs.
Lanoline or vaseline . . . ʒss.—M.

If a stye is to be treated, apply the ointment over the affected part and rub gently. In persons in whom the skin is soft and irritable, the amount of red precipitate can be reduced to ¾ or ½ a grain. A single application of three or four minutes' duration will suffice to arrest the progress of small furuncles; and even where the furuncles are large, several applications made the same day will effect a cure. This ointment is also recommended for acne.—*L'Union Médicale*, November 3, 1888.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, DECEMBER 15, 1888.

THE DIMINISHED MORTALITY OF THE PORRO-CÆSAREAN OPERATION.

A MOST extravagant claim for the Porro operation, rating its mortality at 13⅓ per cent. for the two years 1886 and 1887, and giving for the same period a table of forty-five operations, appeared in the *Journal of Obstetrics and Gynecology*, of St. Petersburg, for December, 1887, from the pen of DR. C. J. CHAZIN. Had this statement remained in its original language, it would have been capable of only a local misleading, but it reappeared as a translation by Dr. Neugebauer, of Warsaw, in the *Nouvelles Archives d' Obstetrique et de Gynécologie*, of August 25, 1888, and this rendering into French will give the record a much wider publicity. We, therefore, feel called upon to point out the important errors contained in this record of the work of the two years in question.

Dr. Chazin finds fault with Professor Credé for comparing in his statement of the results of the "conservative Cæsarean operation," the work of the last five years under this method, with the general record of the last ten years under the Porro-Cæsarean operation, and proposes to make a fair comparison of the two by confining his attention to the better work under the latter, accomplished in the two named years. As the result of his research he produced a table of 45 Porro operations, with but 6 deaths, or 13⅓ per cent., which he brought into competition with the Sänger mortality, which he rated at 28 per cent.

The original table purports to present cases of the two named years, but, in fact, collects them from ten; no dates are given, but the references settle the question of the year when each operation took place. Having carefully examined the whole table and the references given, we are prepared to state: 1. That he has credited the operators with two cases too many, which reduces their number to forty-three. 2. That he has given twenty-five operations which were performed prior to January 1, 1886, viz., two in 1878, two in 1881, two in 1882, six in 1884, and thirteen in 1885. This reduction leaves him eighteen operations, with only two deaths, a very remarkable result, if there were no other cases in the two years. The published cases thus far recorded for the two years amount to thirty-one, of which twenty, with four deaths, belong to 1886, and eleven, with three deaths, to 1887. This will give a mortality of $22\frac{18}{31}$ per cent. for the two years. But this does not tell the whole truth, as cases are still to be reported, and these at present can only be obtained by correspondence.

We have only, after four years, completed the record of 1884, and to do this three statistical collectors were engaged in making private researches and combining their work. The year gives 28 Porro operations, with 15 deaths, a mortality of $53\frac{4}{7}$ per cent. The record of 1885 is as yet incomplete, but gives 22 cases with 6 deaths, a mortality of $27\frac{3}{11}$ per cent. Probably not more than half of the operations of 1887 have been published, and thus far the mortality is also $27\frac{3}{11}$ per cent.

The Sänger-Cæsarean record for the whole world has been completed for 1887, and laboriously perfected by correspondence conducted by three statistical workers. The cases collected come from eleven countries, and number, in all, 47, with 10 deaths, a mortality of $21\frac{18}{47}$ per cent. This record thus fairly obtained, would appear to represent the "conservative Cæsarean operation" as it is now being performed in all countries collectively. The whole Sänger record, as far as obtained, reaches 149 cases, with 41 deaths, a mortality of 27½ per cent.; that of this country being 22 cases, with 13 deaths—a very damaging record to the general result, which, exclusive of the United States, shows a loss of less than 23 per cent. Contrasted with this, the Porro-Cæsarean record, which is not nearly so fully searched out, shows 232 cases, with 111 deaths.

The Porro operation has only recently commenced to show its true capability for saving life, and this

change for the better would appear to have begun with the year 1885. A very marked feature in recent records is the low death-rate in the children, which, in all Cæsarean work, has an intimate connection with a corresponding saving of the mothers. Four years ago we computed the maternal deaths under the Porro operation at 60 per cent., counting all the cases; but recent successes have probably brought down the general average to 50 per cent., and possibly a little lower. The Porro operation in Germany was very fatal in its early period to both mothers and children. Down to the close of 1884 there had been 28 operations, with 18 women and 10 children lost. Since the close of 1884 we have collected 11 cases to the credit of Germany, with only 2 deaths, one of which was by suicide; and nearly all of the children were saved. The Sänger operations of Germany, by their marvellous successes (only 12 deaths out of 80), have taught a lesson in careful management which has been of decided benefit to the cases in which it was thought advisable to prefer the Porro method, and hence the lower death-rate in both mothers and children. The conservative Cæsarean operations of Germany for 1887 numbered 26 and the deaths 2, each of mothers and children. Dr. Chazin attributes the successes of Germany to the work of a few very skilful men, which we answer by the fact that the operations (80) were under 38 operators and in 18 cities and towns.

Austria developed much earlier than Germany the possibilities of the Porro method for saving life, and her record stands in remarkable contrast to that of the latter—30 women and 35 children having been saved under 44 operations, a mortality for the women of $31\frac{9}{11}$ per cent., which should have been lower, but for the fatal experiments of dropping in the cervical stump, as devised by Gustav Veit, of Bonn, in 1880.

It is an error to encourage any rivalry between the Porro and Sänger methods, and we are glad to find that a choice is being made at times between them by the best operators, according to the special requirements of each individual case. Such noted men as Professor Leopold, of Dresden; Professor Chiara, of Florence; Professor Breisky, of Vienna; Professor Schauta, of Prague; Professor Schultze, of Jena; Professor Krassovsky, of St. Petersburg; and Professors Karl and Gustav Braun, of Vienna, do not hesitate to perform either operation, if they think it preferable at the time; and these operators have been marvellously successful in saving life under each method. Mr. Tait, of Birmingham, is prejudiced in favor of the Porro operation, because he has had four successes and no failures, and, besides, is in favor of rendering the women sterile. His cases, with one exception, have not been reported in detail. The seven successes, in order, of Professor Breisky have not wedded him to the Porro operation; neither did his three failures, in order, prejudice him against the Sänger method, as is shown by his fourth trial in October, 1887, the success of which introduced the method into the Krankenhaus of Vienna, where there have since been five more cases and no deaths.

There are those who object very decidedly to the Porro method, because it unsexes the woman; and these also oppose ligating the Fallopian tubes, or exsecting the ovaries, after the Sänger operation. They contend that this method, to be "conservative," must not only preserve the life of the woman and fœtus, but maintain her reproductive organs in their integrity. It is only occasionally that a Cæsarean woman bears a second child, and much more rarely a third; but they contend that she ought to be left capable of doing so if nature does not interfere. A second operation may be avoided in a large proportion of cases by the induction of premature labor, and the child may be reared, as long as required, in an incubator.

The Porro operation is certainly more fatal than the Sänger, although but a fraction more so in the hands of the best Sänger operators. The convalescence is more prolonged and the subsequent inconveniences greater. It should be preferred in cases of malacosteon, because the unsexing occasionally cures the disease. It should also be preferred, where practicable, in cases of obstruction by fibroids, but ought not to be resorted to where the pelvis is normal and the fœtus impacted in a transverse position. It should be preferably employed where the fœtus is dead and putrid; but such cases are apt to prove fatal, because of preëxisting sepsis. There is less objection to its performance in the cases of the unmarried than married, and where the induction of premature labor is unavailable by reason of a very short conjugate in the pelvis. To secure success, the patient should have a favorable pulse, temperature, and respiration, and her fœtus should be vigorously alive. A supra-vaginal amputation of the uterus after rupture is not a Porro-Cæsarean section, as it is not *completive of the Cæsarean operation*, as designed by Professor Porro, and does not contemplate the

saving of two lives. There is one such case in the table of Dr. Chazin. The extra-peritoneal supravaginal amputation of the uterus is older than its Porro application, or that of Prevôt, of Moscow.

A DECISION IMPORTANT TO PHYSICIANS.

The attention of our readers is called to the case narrated by Dr. Hunt in the present issue of The News, and to the importance of the principle involved. The judicial decision establishes the point that a consultant called in by the attending physician to a patient separated from his family and mentally disabled, is entitled to just compensation.

In the case in question the consultant, who was also the ordinary medical attendant, was absent from town, and his advice was given by letter. Against the claim for compensation, it was objected that the consultant could not show contract with the patient, who did not personally summon him, nor was he called by a relative acting for the patient. The Orphans' Court, however, affirmed the contract on the ground of public policy, and awarded the claim; and further affirmed the right of the attending physician, under the circumstances, to summon counsel, if he deemed it desirable.

This establishment of one of the rights of physicians in relation to their patients is a matter of considerable importance. On the part of the medical man, the contract existing with his patient is scrupulously recognized. His best efforts, most careful study, mature knowledge and experience are faithfully given; but, in return, adequate compensation is often questioned, and occasionally refused. A suspicion of failure on the physician's part to meet fully his obligation is even, not infrequently, made the excuse for a suit for malpractice; and so commonly are medical services rendered gratuitously to public charities, that the claim that a contract exists into which compensation to the physician enters, is often regarded with surprise or even ignored. We knew of an experienced surgeon who, hence, never treated a fracture without previously obtaining his patient's signature to a paper limiting his responsibility in the case to that commonly recognized by the courts —average knowledge, skill, and faithful service; and we also recall the experience of a surgeon who presented a very small bill to a millionaire, and was met by a request to please itemize his account.

While the sense of justice common to men ordinarily recognizes the physician's faithful performance of his part of the contract, it is well that the courts should establish clearly the fact that services rendered to a patient at his own request or at that of his relatives or friends or attendant, equally are given under contract and entitled to just compensation.

We congratulate the eminent surgeon who has had the courage to push this point until, finally, justice was obtained, upon the successful issue, and the profession are deeply indebted to him for establishing the important point of the right to compensation of a consultant under the not uncommon circumstances related.

The new Hoagland Laboratory, situated at the corner of Henry and Pacific Streets, Brooklyn, will be opened this Saturday evening by an address to be delivered, at eight o'clock, by Prof. H. Newell Martin, M.D., of the Johns Hopkins University, after which the Laboratory will be inspected by the guests present.

In the *College and Clinical Record* for December, just received, we notice a paper published as an *original* article, which is taken from our own columns of last September, and without any credit to the source of original publication. We are always happy to have the valuable papers which appear in The News noticed in abstract by our contemporaries, but a sense of propriety should prevent a contemporary from abstracting a paper *en masse*, and in infringement of the law of copyright.

Dr. William Robert Smith, at a meeting of the Royal Medical and Chirurgical Society, held week before last, reported the results of his investigations carried on in the Brown Institution, on the etiology of puerperal fever. By the cultivation on gelatine of the blood of patients who had puerperal fever, he obtained, in two or three days, numerous colonies of a micrococcus, and from his experiments he drew these conclusions: 1. That this organism occurred in the blood of persons affected with puerperal septicæmia in considerable numbers in the form of streptococci. 2. That, culturally, differences of a marked character distinguished it from other streptococci. 3. That its action upon mice and rabbits was distinct and definite. 4. That it could be distinctly distinguished from the erysipelas streptococcus of Fehleisen and from the streptococcus pyogenes of Rosenbach.

We regret to learn of the death of Dr. E. Headlam Greenhow, which occurred suddenly, from

syncope, in a London railway station. His name is well known in this country in connection with his valuable researches on diphtheria, chronic bronchitis, Addison's disease, and the pulmonary diseases of operatives. He retired from active consulting practice in 1881. He was in the seventy-fourth year of his age at the time of his death.

REVIEWS.

The Surgeon's Pocket-book: an Essay on the Best Treatment of the Wounded in War; Especially Adapted to the Public Medical Services. By Surgeon-Major J. H. Porter, late 97th Regiment; late Assistant Professor of Military Surgery, Army Medical School, Netley. Third Edition. Revised and Edited by Brigade-Surgeon C. H. Y. Godwin, Medical Staff; Assistant Professor of Military Surgery, Army Medical School, Netley; Late Medical Officer of the Royal Arsenal, Woolwich. 12mo. pp. 257. Philadelphia: P. Blakiston, Son & Co., 1887.

This capital little book has deservedly reached its third edition, this final one being under the clever editorship of Mr. Godwin, who has made such alterations and additions to the well-known work of Porter as to bring the book in almost all respects thoroughly up to the present times. Especially have the editor's efforts to remodel the work according to the principles of antisepsis and asepsis been fortuitous.

Although written more especially for the use of army surgeons, yet as a conspectus of surgery it will be found of great value also to students, hospital residents, ambulance surgeons, and, in fact, to any one; for besides being crowded with mention and illustration of all kinds of surgical resources and improvisions, the principles of surgical treatment, etc., are discussed in a thorough manner and conclusions of recognized and acknowledged soundness are therefrom drawn. To these are added many pages devoted to the formation, location, and transportation of field hospitals, their administration before, during and after engagement, the duties of the various officers of an army, and the general and special care of the wounded and sick under a great variety of circumstances. An appendix contains condensed information regarding food, water, ventilation and the general sanitation of troops and military hospitals. The illustrations are in the main good and sufficiently numerous.

Whilst our commendation is general, yet a few discordant assertions have arrested our attention in looking over the volume. Thus, we cannot agree with Mr. Porter in thinking a chisel and mallet and Hey's saw always preferable to the trephine, nor do we think his list of cases suitable for trephining sufficiently comprehensive. The statement, also, that ether is unsuited to military practice because of the cumbersome apparatus necessary for its administration is incorrect, although we do not deny that chloroform, even considering its greater dangers, may be the more practical anæsthetic for such purposes on account of the much less bulk of it which need be carried and its property of non-combustion.

Our only great disappointment has been to find the sections upon treatment of intra-peritoneal traumata so grossly deficient and absolutely at variance with modern, and more especially American methods. This portion of the book, as well as that upon the treatment of peritonitis, we trust to find entirely re-written in another edition. We are glad to notice the editor's condemnation of the use of poultices upon any kind of wound, and his significant advice that "any dressing had better be omitted rather than have it applied with dirty fingers or dirty water" even in heat of action. It is a source of satisfaction to know that in time of need such a thoroughly good, comprehensive, yet very portable book would be available; for its small size admits of carrying it in the breast-pocket, and we are inclined to think that it would prove a very efficient protection to the war surgeon, and especially to the vital region of his heart were it carried in the left breast-pocket.

CORRESPONDENCE.

THE RIGHTS OF A CONSULTANT TO COMPENSATION.

To the Editor of The Medical News,

Sir: I am happy to be the medium of giving to the profession the following very important decision of the Orphans' Court of Philadelphia County.

The circumstances of the case were these: In the summer of 1886, a business gentleman of large means, a patient of mine for many years, consulted me about some vague head symptoms. I advised him to give up business altogether for a time and to take a vacation with me. This he declined, as his business was too pressing.

Nothing occurred of any moment until after I had left the city to take my summer vacation. While at Bar Harbor I received a letter from Dr. Albert Fricke, whom the patient consulted in my absence, asking for information and advice. I answered at once. The case took a very serious turn, and within three weeks the patient was dead. During all the time of the sickness, however, a constant consulting correspondence was kept up with me.

One of our large trust companies was the executor of the decedent's estate, and to it I sent my bill.

The residuary legatee of the estate was in Europe at the time of the sickness and death, and of her own knowledge knew nothing whatever of the facts. She came home, and one day the Trust Officer of the Company said to me: "Doctor, I wish you would get the endorsement of Mrs. —— on this bill as correct, and we will pay you." I assented, and called at the house, expecting, if I expected anything, to be received with some expression of thanks for the care which was taken of her brother in his loneliness and extremity, for during his sickness he was living in the house with servants only.

Instead of this, I and the doctors who attended her brother were roundly denounced in unsparing terms, and she positively refused to endorse my bill. I have met with some strange experiences in a doctor's history during my professional life, but never with anything quite equal to this. I understood Judge Ashman to say that a case precisely like this has not been adjudicated before. The reason probably is that the opportunity rarely occurs. The common sense of justice in mankind mostly settles such questions, but here was one of the exceptions. There was nothing for me to do but to bow

myself out of the house, and to wait for the adjudication of the case before the Orphans' Court.

At this adjudication, the counsel for the accountant took the ground that Dr. Fricke acted on his own motion in consulting with me; that the patient was well enough when the doctor (Fricke) first saw him to ask, or to insist on his consulting with me if he wished him to do so. To my surprise, the auditing judge decided that as I had shown no contract with the patient I could not recover my bill, and that the attending physician had no authority to employ me. An appeal was immediately taken with the subjoined result, with which I must state the judge first hearing the case was, on review, fully in accord, and the judgment of the bench was unanimous.

The result, I am sure, most people will think is in accordance with public policy, with justice, and with humanity. WILLIAM HUNT.

PHILADELPHIA, Dec. 5, 1888.

"Sur Exceptions to Adjudication.

"Opinion by ASHMAN, J. December 1, 1888.

"Two principles, so commonly accepted, that they do not require to be vouched by individual authorities, seem to establish the right of the exceptant to recover. One is, that a principal will be bound by those acts of his accredited agent, which are reasonably incident to the full performance of the contract of service; and the other, that he will be bound by the acts of a self-constituted agent where his own neglect or the act of God, has rendered those acts necessary for his self-preservation, or for the well-being of society. The first was an ingredient in every contract of agency, under the civil law, and the second is largely due to modern ideas of humanity, but each has an equal and just claim upon our common sense. The cases of Fenn *v.* Harrison, 3 T. R. 757, Nelson *v.* R. R. Co., 48 N. Y. 498, and Richard *v.* Cartwright, 1 C. & Kir. 328, are strongly illustrative of the first of these rules. One of them decided that a broker, entrusted with a note for discount, may endorse it in the name of his principal; another that a carter employed to deliver a mirror to a common carrier, may sign a release for the shipper and owner, against liability for breakage; and the third, that a foreman, without special authority, may bind his employer, by contracting to deliver certain goods at a designated time.

"The spirit in which this rule is to be expounded should be in unison with the character and relations which the parties have themselves established with each other, and should be liberal just in proportion as those relations become more intimate and involve delicate questions of duty and responsibility. To say that the discretion to act promptly in an emergency, which a patient necessarily gives to his physician, is larger than that which a merchant gives to his drayman, is simply to say that a man will resign more of his own authority to the will of the person who is to save his life, than to that of the person who is to take care of his trunks. The trust, which includes the power for its exercise with which the patient vests his physician, is often practically unlimited, because it may require to be executed at a time when disease has taken away all ability to restrict it. The patient is not to be left to die, on the plea that during such an interval, no act of his adviser can be valid, for want of his direct approval. Or, the doctor may suspect the presence of an obscure disease, which, if it exists, demands heroic treatment. To communicate the suspicion to the sick man will probably finish him on the spot; may he not solve the doubt by consulting a specialist?

"But the case in hand is not even so problematical as the case which has just been supposed. The decedent, when he first consulted the claimant, was affected with a brain disorder, which culminated in paralysis, and killed him in three weeks. His powers of thought and speech were so far impaired that it was impossible to communicate intelligently with him as to his past symptoms or as to measures for the future. His sole next of kin was a sister, who was travelling in Europe, and his only attendants were servants. His family physician was in New England. The doctor who was called in by the business partner of the decedent, knew nothing of his patient's medical history; and he wrote for information upon that point and for professional advice, to the claimant, who had attended the patient for years, and who at once responded. If the right, in the consulting physician, to compensation for his services, is without legal merit, then the law is a reproach to conscience. That it has not been passed upon hitherto, means nothing; or rather, it means that it has never been questioned, any more than the right of the physician to charge his patient with the drugs he has purchased, or the nurse he has hired for him, when drugs and nursing were indispensable to his recovery.

"The doctrine, however, upon which the claim is now to be adjudicated, has been repeatedly enforced. It is the doctrine of public policy. In its application the courts have held that a parent who leaves his child in the care of a servant, will be liable to the surgeon who dresses a wound received by the child, although the surgeon was called in by the servant, and although the injury was caused by the servant's neglect: Cooper *v.* Phillips, 4 Car. & P. 581. They have also held, that a husband who abandons his wife, or leaves her even with her own consent, is liable for the necessaries which a third party may furnish for her support: Reed *v.* Moore, 5 Car. & P. 200; Harris *v.* Morris, 4 Esp. 41; that the estate of a decedent is liable for the expenses of a funeral provided by a stranger: Rogers *v.* Price, 3 Y. & Jer. 28; and the estate of a lunatic for services rendered in protecting his person or estate, Williams *v.* Wentworth, 5 Beav. 325, Bagster *v.* Earl of Portsmouth, 2 Car. & P. 178, or in supporting his family, Elwyn's Appeal, 17 P. F. Sm. 367. It is not necessary, for the purposes of this argument, that the decedent should answer to the legal definition of a lunatic. If he was so far mentally disabled as to be unfitted for the proper conduct of his affairs, it was sufficient to justify the action of the claimant: Young *v.* Stevens, 48 N. H. 135; Dennett *v.* Dennett, 48 Id. 531. We do not mean to displace the rule of liability from its footing of strict necessity. The burden of proof that in the absence of an express contract, an implied contract has arisen from the exigencies of the case, must always rest upon the claimant. But that burden was fully met in this instance; and we think that the claim should have been allowed.

"The exceptions are therefore sustained."

THE TREATMENT OF VALVULAR DISEASES OF THE HEART.

To the Editor of THE MEDICAL NEWS,

SIR: In reading Prof. J. M. Da Costa's valuable article on the "Treatment of Valvular Diseases of the Heart,"

in the November issue of *The American Journal of the Medical Sciences*, I notice, on page 444, the following sentences: "Now, we must remember that the very remedy we use most in cardiac disease, digitalis, contracts the arteries and arterioles, and the indications are often to get with increased cardiac power a free flow in the vessels without resistance from them. No remedy does this, and a certain remedy of the kind is greatly needed."

Now, during the past fifteen years, I have been using in such cases a tincture of Cactus grandiflorus with the happiest results. I think, if we have a heart tonic, pure and simple, it is Cactus grand. By its continued use the nutrition of the heart is improved, and the organ is permanently strengthened. I have not found it disagree with the stomach, even after using it for months at a time.

In valvular disease, where the dilatation has outstripped the compensatory hypertrophy, I have found this remedy more satisfactory than digitalis. In that form of cardiac disease called by Dr. Da Costa "functional valvular disease," cactus is now the only "heart" remedy I use. When there is a fault in the cardiac innervation, the heart's action being tumultuous, irregular, intermittent, feeble, the patient nervous, restless, and dreading some impending danger, the continued use of cactus will almost invariably give permanent relief.

I use a tincture made from the fresh plant, giving from one to five drops every two, four, or six hours.

Respectfully yours, C. L. GREGORY, M.D.

YREKA, CAL., Nov 22, 1888

NEWS ITEMS.

Scarlet Fever in Relation to a Glasgow Milk Service.—Dr. J. B. Russell reports the occurrence of another outbreak of scarlet fever associated with the use of milk from a special dairy. The occurrence was practically limited to a well-to-do part of the city; and, after local investigation into the distribution of the milk from two separate shops, and by means of vans and carriers, it appears that of three hundred and thirty-six families thus supplied twenty-nine were infected, and forty-three cases resulted. It is also noteworthy that of a total of fifty-six cases of scarlet fever heard of between Sept. 25th and Oct. 31st last, as many as forty occurred with unwonted suddenness in the three days Oct. 18th to 20th.

The story told by Dr. Russell is a complicated one, but the salient points may be summarized as follows: At one of the two milk shops lived a family, some members of which had suffered from scarlet fever whilst away from home, between Aug. 17th and Sep. 18th, when they returned to the shop, to remain there until the 26th. During this time it is impossible to conceive that they could have been free from infection, for even as late as Oct. 22d one child was found to be still desquamating on his feet, and another is stated to have been pulling bits of skin off his hands on Sept. 22d. Notwithstanding this, and although there was free communication between the residential part of the house and the dairy, no material (if indeed any) mischief appears to have accrued to the milk supply. But it is held that there are strong grounds for believing that during what must be regarded as an exceptionally dangerous period the infection became communicated to the second dairy shop, where sore throats and ill-defined ailments are admitted to have existed; and that it was essentially through the agency of these sufferers that the milk supply became infective. Incidentally, several points of interest are noted. In the first place, examination of the cows elicited no information as to disease. In the next place, there was a greater incidence of the scarlet fever in that branch of the business which carried milk to the largest houses, and Dr. Russell expresses his conviction that, whilst all users of the milk risked infection, the risk rose and fell with the quantity used.

The great lesson which the reporter desires to enforce is the folly of mixing up the milk business with family life. In this case the fortunes of two families were so interlaced with a milk distribution as to have insured risk on any chance occurrence of infectious disease. It is also noteworthy that the most trifling ailments, whether of man or beast, must not be thought beneath attention where milk supplies are in question. Recent research into the relation of diseases in the cow to the consumption by man of milk has abundantly shown this as regards the lower animals, and Dr. Russell's story enforces it again as to those minor throat ailments in the human subject which appear to be so trivial, but which are often singularly potent in their infectiveness.

The occurrence recorded is regarded as having been brought about by some ill-defined throat affections, and the result of consuming the milk was not only that of inducing the series of well-marked scarlet fever attacks to which we have referred, for there also followed in the line of the milk distribution a "cloud" of undefined but plainly specific illnesses of the nature of sore throat, vomiting, diarrhœa, etc.—*Lancet*, Dec. 1, 1888.

A Sextuple Birth.—A woman in Navarro County, Texas, is stated to have lately given birth to six living children, four boys and two girls, one of the latter being slightly deformed.

Quinine Depreciation. — Eight years ago the manufacturer's price for sulphate of quinine was ten and twelve shillings per ounce, while to-day it is worth about two shillings per ounce. This is perhaps one of the most remarkable instances of depreciation in the commercial value of a drug on record. This fall of price is, we are informed, due to the great extension of cinchona cultivation in Ceylon, which has of recent years been brought about. This go-ahead colony, on finding its coffee trade falling into decay, took to planting cinchona and tea trees, and in a few years this has proved very successful. It is estimated that, of a total demand of twenty-two million pounds of cinchona bark a year, fifteen millions now come from Ceylon. Moreover, the yield of the alkaloids from the Ceylon bark is much greater than that of any other country; the South American product being, we believe, the next competitor.—*Medical Press*, November 28, 1888.

Bacteria in Glaciers. — DR. SCHMELCK, of Christiana (*Centralblatt f. Bacteriologie*), has found immense numbers of bacteria on the Jerstedalsbræ, the largest glacier in Europe, as well as in the waters of rivers which receive water from the melting glaciers and snow. During their growth these bacteria formed a substance of a fluorescent color.

Under the microscope they appeared to be of the forms of small moving sticks, and resembled during their growth the fluorescent liquefacient bacillus. The writer finds a connection between the presence of these bacteria in the glacial regions and the greenish tints of the waters coming from these regions. During the melting of the ice, these bacteria grow with great rapidity. —*L'Union Médicale*, Nov. 22, 1888.

A Novel Precedent.—It is stated in *The Medical Press*, Nov. 28, 1888, that Mr. Bruce Clarke, of St. Bartholomew's Hospital, has recently been called into requisition by Sir Frederick Johnstone, in the treatment of his valuable horse "Friar's Balsam." Shortly before the last Derby "Friar's Balsam," which was the favorite, developed an abscess in connection with its lower jaw, the results of which incapacitated the horse from taking part in any engagements up to the present moment. A piece of loose necrosed bone having recently been detected, the operation of sequestrotomy became necessary, and it was for the purpose of carrying out this procedure in conjunction with the illustrious equine patient's ordinary veterinary attendants that the services of Mr. Clarke were secured. The operation was successfully performed recently, and presented no difficulty; the most noticeable feature in connection with it being the large amount of new bone which had formed round the sequestrum. It had been decided to administer chloroform in the event of the patient proving to be refractory, but the somewhat trying ordeal was patiently submitted to, without necessitating the use of the drug, and was completed in the course of about half an hour.

We presume that the operation of sequestrotomy would scarcely differ in detail to that which is performed by surgeons upon human patients, whether it happened to be required for the alleviation of the sufferings of a horse, a cow, or other animal. But the case probably would be different, if for instance a nephrotomy, or nephrectomy upon, say, a valuable mare, was ever deemed to be essential; undoubtedly, the great experience of this and other operations which some surgeons have gained would be of the utmost assistance, if not absolutely essential. But probably there would be difficulty about the horse's anatomy, and this would conceivably have to be taken into consideration. If, however, the precedent which Sir Frederick Johnstone has established comes to be followed largely in the future, operating surgeons, who have identified themselves with any particular procedure, might find it to their advantage to read, mark, and learn the various points of anatomical detail in connection therewith in the lower animals. There is surely no reason why animals of great value to their owners should not benefit by the experience of human surgery, in the same manner as man has become indebted to animals through the knowledge which has been evolved from them by experimental inquiry.

According to the *Med. chirurg. Rundschau*, Nov. 15, 1888, the Queen of Sweden has been ordered by her physicians to rise early, make her own bed, clean and dust her own room, then to take a brisk walk in her garden, return for breakfast, and subsequently to pass the greater part of the day out of doors. Her Highness follows these instructions to the letter, and finds that her nervousness is fast becoming a thing of the past.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM DECEMBER 4 TO DECEMBER 10, 1888.

Williams, John W., *Major and Surgeon* (U. S. Army).—Is hereby relieved from further duty with the battalion of the Second Artillery, at Fort Wadsworth, New York Harbor, and will proceed to join his permanent station, Jackson Barracks, La.—Par. 3, *S. O. 256, Headquarters Division of the Atlantic, Governor's Island, New York City*, December 5, 1888.

Town, Francis L., *Major and Surgeon.*—Is relieved from duty at the post of San Antonio, Texas, and will report in person to the commanding officer Presidio of San Francisco, California, for duty at that station, relieving Major and Surgeon Henry B. Tilton, and by letter to the commanding general Department of California.—Par. 19, *S. O. 286, A. G. O., Washington, D. C.*, December 8, 1888.

Tilton, Henry R., *Major and Surgeon.*—Upon being relieved by Major Town, will proceed to West Point, New York, and report in person to the Superintendent of the U. S. Military Academy, for duty at that station, relieving Major and Surgeon Charles F. Heizmann.—Par. 19, *S. O. 286, A. G. O., Washington*, December 8, 1888.

Heizmann, Charles F., *Major and Surgeon.*—Upon being relieved by Major Tilton, will proceed to San Antonio, Texas, and report in person to the commanding officer of that post for duty, and by letter to the commanding general Department of Texas.—Par. 19, *S. O. 286, A. G.O., Washington*, December 8, 1888.

Finley, James A., *Captain and Assistant Surgeon.*—Is relieved from duty at Fort Buford, Dakota Territory, to take effect upon the expiration of his present sick leave of absence, and will report in person to the commanding officer at Fort Assinniboine, Montana, for duty at that post.—Par. 19, *S. O. 286, A. G. O., Washington*, December 8, 1888.

Johnson, Richard W., *Captain and Assistant Surgeon.*—Is relieved from duty at Fort Adams, Rhode Island, and will report in person to the Superintendent of the U. S. Military Academy, West Point, New York, for temporary duty at that station.—Par. 19, *S. O. 286, A. G. O., Washington*, December 8, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING DECEMBER 8, 1888.

Bransford, J. F., *Surgeon.*—Detached from the Smithsonian Institution, and granted six months' leave, with permission to go abroad.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE TWO WEEKS ENDING DECEMBER 8, 1888.

Stoner, G. W., *Surgeon.*—When relieved, to proceed to Detroit, Mich., and assume charge of the Service, November 26, 1888. Granted leave of absence for thirty days, November 28, 1888.

Carmichael, D. A., *Passed Assistant Surgeon.*—Granted leave of absence for thirty days, November 27, 1888. Relieved from duty at Washington, D. C., and ordered to Marine Hospital, Wilmington, N. C., December 3, 1888.

Devan, S. C., *Passed Assistant Surgeon.*—Detailed as Attending Surgeon and acting Chief Clerk Marine-Hospital Bureau, December 3, 1888. Granted leave of absence for eight days, December 8, 1888.

Urquhart, F. M., *Passed Assistant Surgeon.*—To proceed to Evansville, Ind., for temporary duty, November 30, 1888.

Brooks, S. D., *Passed Assistant Surgeon.*—Granted leave of absence for thirty days, December 8, 1888.

Seaton, Norman, *Assistant Surgeon.*—Ordered to examination for promotion, November 27, 1888. Granted leave of absence for twenty-five days, December 8, 1888.

Fattic, J. B., *Assistant Surgeon.*—Ordered to examination for promotion, December 7, 1888.

Magruder, G. M., *Assistant Surgeon.*—Relieved from special duty at Way Cross, Ga., December 8, 1888.

Kinyoun, J. J., *Assistant Surgeon.*—Granted leave of absence for ten days, December 8, 1888.

Vaughan, G. T., *Assistant Surgeon.*—Granted leave of absence for twenty-three days, December 8, 1888.

Guiteras, G. M., *Assistant Surgeon.*—To proceed to Savannah, Ga., for temporary duty, December 3, 1888.

VOL. LIII. SATURDAY, DECEMBER 22, 1888. NO. 25.

ORIGINAL ARTICLES.

DIABETIC GANGRENE.[1]

BY WILLIAM HUNT, M.D.,
SURGEON TO THE PENNSYLVANIA HOSPITAL.

THE literature of this subject is vast as to diabetes, and as to gangrene in general but meagre, and in some respects surprising as to diabetic gangrene. There are about twenty pages of the great *Index-Catalogue of the Library of the Surgeon-General's Office* given to each of the subjects of gangrene and diabetes. One has to search sharply for anything associating the two. The French seem to have the best of it up to 1868. There are but two monographs catalogued, one by Giron, Paris, 1881, and one by Peyrot, a student, 1878, who reports, I think, thirty-nine cases. Then ten isolated cases are reported in the French journals from 1856 to 1868; most of these cases are in *L'Union Médicale.*

These patients where the sex is given were males. Mental troubles are more than once given as a cause. Intermittence in the appearance of sugar is noted in two cases. The majority of these cases were in the better walks of life.

But the work worthy of a higher dignity of title than a monograph is by Marchal (de Calvi), Paris, 1864: *Recherches sur les Accidents Diabétiques et Essai d'une Théorie General du Diabète.* He claims to be, and with some force, an original discoverer. He places 1852 as the dividing line between the periods when, in the first, gangrene occurring during the progress of diabetes was regarded by all as a simple coincidence, and the second, when gangrene occurring among diabetics it is the result of inflammatory conditions dependent on the disease and due to the irritation of the peculiar products of it, which are thrown into the blood and tissues. This last is the so-called discovery as I understand it, and there is some discussion as to priority, for Hodgkin, of London, about the same time, as we shall see, took the same view. Marchal was, of course, criticised by his own people, one of whom was Charcot. The cases, facts, and comments are divided into two series, those published before the discovery, and those published after it. The collection is really remarkable, both as to number and as to character of cases, and especially so when contrasted with German, English, and American reports and literature on the subject up to that time.

Marchal's book has reports of one hundred and thirty-three cases of all sorts of what I may call extra lesions occurring during the progress of diabetes, collected both before and after the discovery. In the notice of three cases of Carmichael, Adams, and Marsh in the series before the discovery, these remarks occur: "The mention of these cases does not give place to any general deduction. The question to know is whether there exists a necessary relation between gangrene and diabetes, a question which appears to have been totally lost from view." Of the 133 cases, gangrene *per se* occurred in 57. The seats of it were, in the lower extremities 35, lungs 7, hand 3, pleura 2, shoulder 1. Nucha (not ordinary carbuncle) 2, nose 1 (necrosis). Plantar aponeurosis 2, ribs necrosis 1, forearm 1, back 1, gangrenous plaques 1—although the latter are reported in several other cases. I shall not pretend to particularize these cases, I refer any one interested to Marchal's book. My purpose is to show that gangrene in diabetes is something more than a coincidence. The extraordinary case No. xxxix. almost of itself sustains the position. A man of fifty-eight years came under observation. The case is given in detail, and is thus summed up by Marchal:

> "Thus in the space of six years from 1850 to 1856, the patient was attacked successively with, first, a necrosis of the first phalanx of the second toe, which was amputated; second, with a sphacelus of the whole foot and inferior part of the leg of the same limb, which was also amputated; third, with a skin gangrene of the other leg which gave place to a callous ulcer; fourth, with a gangrenous inflammation of the base of the great toe, which left a deep and intractable ulcer; fifth, with a sphacelus of the first four toes, which were also amputated."

Through all this melancholy history, no suspicion of diabetes was raised until, attention having been called to the case through Marchal's labors, the urine was examined, and the man was found to be a positive diabetic, and he was proved to have been one for years. Other multiple cases are reported.

This by no means exhausts French literature. Verneuil, Nélaton, Lizé, Peter, Charcot, Demarquay, Peyrot, Chauvel, and others have done their share in the observation of cases, and in elucidating the subject.

I will now take a short notice of German, English, and American work in this line. The great *Index-Catalogue* I referred to is dated 1882, and in going twice over those thirty-seven double-columned pages

[1] An abstract of a paper read before the Philadelphia County Medical Society, November 28, 1888.

devoted to diabetes and to gangrene, I found no monograph on diabetic gangrene in German. There is one case of it reported by W. Roser, of Marbourg, and an article by him upon it in the *Medicinische Wochenschrift*, Berlin, for January 1, 1880. Billroth, in his *Surgery*, merely mentions diabetes mellitus as a possible complication of gangrene. Hodgkin read a paper before the Harveian Society, session of 1852–53 (*Journal of the American Medical Association*, 1854, p. 915), and, aside from this, there is no notice of an English article or case in the *Index*. There is one Italian case reported.

The Marbourg professor (Roser) grasps the situation thoroughly. He says: "When an otherwise healthy appearing man has a gangrenous or ulcerous disturbance, for example, on the foot or hand, when one can think of no affecting cause, when all irritations with carbolic acid, etc., are in vain, it *is high time to think of diabetes*."

He attributes the past failures of diagnosis and consequently of proper treatment to three causes:

First. To the fixed, classic, and preconceived notions as to diabetes, viz., that an otherwise well-looking and well-nourished person cannot have it; that the usual symptoms, thirst, emaciation, etc., be present; so to say, cachexia. (These points I can practically confirm as well taken.)

And what are we to think of this?

"*Second.* In gangrenous destructive processes *now*, one takes it for granted that a rotting, generating, chink-fungus (literal, Spaltpilz) has got in from without and is the cause of all the trouble, and one is obstinately striving to stop or make impossible the vegetation of this chink-fungus, and to control the advancing sepsis by still more obstinate applications of carbolic acid (he quotes carbolic acid as the type of the germicides, for he has u, s, w in some places), and so long as one remains in this blind thought, he naturally seeks for no other etiology.

"*Third.* Even when the diabetes is discovered, the doubt is set up whether it has anything to do with the gangrenous destruction, and then it is still more strongly doubted whether a treatment appropriate to the case, both constitutional and local, can mend matters where there is a high grade of diabetes." Cases are then given, some of which are taken from Marchal. A plausible explanation of some cases of otherwise unaccountable sloughing after operations is suggested in the possible presence of diabetes. I came across some such cases. Roser supports Marchal's axiom, "One must always think of diabetes and examine the urine, when one has to deal with obstinate and repeated cases of furuncle, anthrax, diffuse phlegmon, gangrene or sphacelus, and the like affections." (This is all I shall translate, for I find there is a longer abstract from this article of Roser's in the *Chicago Medical Gazette*, vol. i., 1880.)

Since Roser's paper the Germans have paid more attention to the subject. I find that in the *Centralblatt für Chirurgie* König "points out" what this article shows has been long ago known, that diabetic patients are subject to a low grade of inflammation; and he issues the dictum, "that in all cases of spontaneous gangrene the urine should be examined for sugar, and in surgical complications of diabetes the first and most persistent treatment should be antidiabetic." In the article upon surgical diseases in the *Annual of the Universal Medical Sciences*, 1888, collated by Dr. Christopher Johnston, of Baltimore, an interesting case of diffuse gangrenous phlegmon in a diabetic is reported, and after some remarks and extracts as to the causes of the various gangrenes, this rather heavy quotation closes a paragraph: "The differential diagnosis is simplified since antisepsis has detached gangrenous septicæmia from the morbid coexistences which complicated its symptomatic category."

English and American literature on diabetic gangrene amounts to almost nothing. After Hodgkin's paper, 1852, the affection seems also to have been totally lost from view, and no one appears to have taken any especial interest in the subject. Hodgkin is the one with whom the question of priority was raised with Marchal. He reports several cases, one that of a young man who, after venesection for diabetes, developed an acute pneumonia. He died, and gangrenous softening was found surrounding tubercle. Another case, in an elderly gentleman, with symptoms of the same kind; no post-mortem. Two more with gangrenous feet. Then follows this important remark: "Reflecting upon the evident tendency of diabetes to impair the vitality of the tissues, I could not but attribute it, not to accident, but to an essential connection between the disease and the function of nutrition."

After this I found no monograph on the subject or particular reports of cases in our language. In only one of these books do the words *diabetic gangrene* occur in the index. Even the great *Index-Catalogue*, with much more significant headings about gangrene, has no heading about *diabetic gangrene*.

Whilst writing this, Schmidt's *Jahrbücher* for October, 1888, comes to hand. In it there is the latest general article on diabetes mellitus, a review, twenty-eight pages in length, by Dr. Louis Blau, Berlin. The paper opens with a list of seventy-four different articles on the subject from 1886 to date, but only three refer to diabetic gangrene; one by König, "A Revision of the Knowledge as to Capital Operations (Amputations) during the Progress of Diabetic Gangrene," and two cases (both French) of diabetic gangrene of the external genitals are reported. Blau gives credit to König for confirming the frequent tendency to inflammations giving

rise to gangrenous processes in diabetics. This (the gangrene) may appear to be spontaneous, but it calls for an examination of the urine if that has not been made. He as well as König is a firm believer in these inflammatory gangrenous affections being dependent upon specific microbes, as do other incidents of diabetes. The easy passage into gangrene is favored by the less resisting power of the tissues than when in health, and, also, it may be, the presence of arterial sclerosis.

The diabetic is at a disadvantage with the sound man, in that there is a greater tendency in him to take up the microbes in his tissues and into their fluids, as these offer a better nourishing nest for the microbes. Compare König's with Roser's views. Roser ridicules the chink-fungi as the producers of the gangrene *in situ* and from without. And, agreeing with this, König gives them a nidus within from which to operate. This is but a repetition of what I long ago stated in an address before the Academy of Surgery in this city.

The reason that a sick man is at a disadvantage as compared with the well man is that, the former is a harbor for the products of disease (molecular necrosis). These products are the food of the bacilli, and where the food is *there* they go. They do not differ in this from all other organized crea tures from man to microbe. How far they are the *causes* of disease is the business of the mycologist to find out. But little as yet has been established as a *certainty*, and, therefore, it is all the more incumbent, in practice, to guard against their possible presence and specific power. König thinks that capital amputations had better be let alone so long as the urine is rich in sugar. He also says there are cases in which the surgeon must be the judge. It may be worse to refrain from amputation, and thus let the patient contend with two serious conditions, the disease and the gangrene.

Thus up to this time but little has been added to our real knowledge of diabetic gangrene since 1852, the days of Marchal and Hodgkin. The disease was there, the theories were there, the cautions and advice and treatment. All were present but the bacillus, and he was lurking in the dark. The surprising thing is that, as in the expression already quoted, the interesting and important subject should have twice "been almost totally lost from view."

König gives the French great credit for their researches and papers and reports. He quotes one of the latest French observers, P. Redard, upon "De la glykosurie ephèmère dans les affections chirurgical" (*Revue de Chirurgie*, 1886, No. 8 and No. 9, S). He reports two most interesting cases, one aged seventy, and one forty, occurring in 1886, both having diabetic gangrene and atheromatous arteries. He amputated a thigh in each case, under strict antisepsis. Both recovered rapidly, and there was a remarkable diminution of the sugar in both, and at times it wholly disappeared. He argues to himself in this quaint way: "During the past year I took the knife in hand, for I said to myself, 'if thou continuest to treat the case in this way (the expectant), the old man, upon whom his family depends, will surely go to the ground; to be sure, he may also go to the ground after the amputation, but possibly he may live if antisepsis is strictly carried out.'" And live he did. He then issues his dictum: "When in diabetic gangrene, in spite of antidiabetic treatment constitutionally and antiseptic treatment locally, the general diabetic symptoms and the local phlegmonous appearances do not disappear or ameliorate, and a further perseverance in the treatment simply increases the danger for the patient, then a radical operation, in order to try to save the patient's life, must be performed. These operations will, as a rule, be amputation."

We will now leave the history and literature of diabetic gangrene and take up the records of experience with a few practitioners here at home.

I think any fair-minded person would say that, if we can develop so much in such a limited range of inquiry and in such a short time, and then ask himself what might be found out by further inquiry, not only among ourselves but throughout the country, diabetic gangrene is certainly something more than a mere coincidence of the disease diabetes. I sent out a small number of inquiries to physicians and surgeons in our city, selecting those whom I thought would know most about the matter, and also made personal inquiries of some. The questions were: 1. How many cases of diabetic gangrene have come under your notice or treatment? 2. What was the social standing of the patients—wealthy, medium, poor, hospital, or private—their ages and sex? The next question would appear to be rather a side issue, but it was made, in passing, to ascertain whether what is almost universally stated about diabetes is legendary, or is the result of carefully collated observation; it also bears upon gangrene of the pulmonary organs—it is: 3. How many of *all* of your diabetics had consumption, or died with it, and was there anything like gangrene of the lungs?

I received thirty-two answers, including myself; of these, seven had seen no gangrene, and twenty-five reported sixty-four cases. I was particular to eliminate double reporting, and that the cases should be known by actual examination and record to be diabetic.

The ages, where given, were: 1 between 30 and 40; 2 between 40 and 50; 11, 50 and 60; 12, 60 and 70; 10, 70 and 80; 2, 80 and 90. One exceptional case of Morton's, a diabetic aged nineteen, in whom gangrenous sloughing took place after a needle operation for cataract, is down, and one of

S. Solis Cohen's cases was a young female. Of the sexes given, 24 were females and 25 males. Of social standing, where given, 16 were wealthy, 23 medium, 9 poor, and of these 6 were in hospital. Dr. Brush reports a most interesting case of a female diabetic aged forty, a lunatic. She had large ecchymoses on her limbs which became gangrenous; she died. The autopsy revealed a gumma the size of a large pea in the floor of the fourth ventricle. The seats of gangrene were reported as: Lower extremities—below the knee 37, thigh and buttock 2; nucha (not ordinary carbuncle) 2, external genitals in female 1, lungs 3, fingers 3, back 1, eyes 1.

Had I allowed myself to include ordinary carbuncles and boils in the gangrenes, to which class they belong, the list would have been greatly increased.

We will now take up the third question: How many diabetics have consumption or die of it? Is it a legend?

Marchal says he has known of but few diabetics to die of consumption, but he is rather inclined to adopt the general view. A pamphlet published at Oxford in 1745, called "A Mechanical Inquiry into the Nature, Causes, Seat, and Cure of Diabetes, with an Explication of the most remarkable Symptoms," says, if the patient be "too far advanced by a neglect of proper remedies, the person so affected in reality dies of *a* consumption."

Here are the answers elicited by my third question.

Thus among the diabetics noted, in all 144, we find but 11 deaths from phthisis. And yet Dr. Thomas S. K. Morton in an essay on diabetes has somewhere picked up a statement, from an authority whose name he has missed, that 43 per cent. of diabetics are killed by phthisis sooner or later. Roberts, 1885, says that one-half of them die with cough, catarrh, phthisis, and other lung complications, when prolonged to the third year, and Aiken quoting him, evidently in mistake, says to first year. Dr. George B. Wood says, "In the great majority of cases the patients die of phthisis." Drs. Da Costa and Longstreth, whose opinions are entitled to great weight, make general statements in their answers, Dr. Longstreth cautiously stating it is *called* consumption. From a conversation with Dr. W. Pepper, who gives no return, he adopts the consumption view, and Dr. J. Cheston Morris coincides.

S. Solis Cohen says: "I cannot find accurate statistics as to consumption. Think at least one-third of the cases that I have seen died of pulmonary affections." Griesinger, quoted by Niemeyer, says "one-half of the cases die of phthisis." Watson says, "some think phthisis universal in diabetes, but it is not so." Flint, quoting Ogle, reports fourteen cases, with deaths from scrofulous or tubercular disease in seven of them. Niemeyer says "that pulmonary tuberculosis hastens the fatal issue." What one of latest authority, C. Hilton Fagge (1886) says, is important. "Diabetes is frequent cause of *a* phthisis" (almost the 1745 expression), which is peculiarly pneumonic in character. Its relation to ordinary pulmonic disease is still doubtful, and after giving certain facts he says, "hence it supports very strongly the opinion that the pulmonary affection in the disease is not of a tubercular origin." He kept notes of the diabetic deaths in Guy's Hospital, and in twenty years out of 40 such deaths, 17 died of phthisis.

It will be noticed how indefinite and general some of the statements above given are, without figures to sustain them. Blau, in his review in the late number of *Schmidt's Jahrbuch*, already quoted as to gangrene under the head of "diseases of the lungs in diabetics," says, in substance, "that the question whether so-called diabetic phthisis is the same as ordinary tubercular disease of the lungs is only to be settled by the proved presence in both of the same bacillus." Authorities, Inmérman, Rütimeyer, von Merkel, and von Leyden, are quoted as having observed absolute differences between the two diseases, both from examinations of sputa and also by post-mortem. A case is given in which, during life, the patient had all the symptoms of tubercular phthisis. Except that bacilli were not found in the sputum, and at the autopsy the appearances were totally different from those found in that disease, and these appearances are noted in the text. The bacillus tuberculosis was nowhere found. A case having almost the same post-mortem appearances as this one is reported by Da Costa, in the *Philadelphia Medical and Surgical Reporter*, vol. i. page 8, January, 1887. The bacillus, as in the preceding case, was absent.

This record, considering the large number of consumptives in communities like ours, would seem to show that the cases in point *are consumptives with supervening diabetes, and not diabetics with supervening consumption.* I leave the question for wiser heads to determine. Diabetics die, as my inquiries and experience confirm, with coma, œdema of the lungs, and exhaustion.

I will not report the minute particulars of my own cases. To do it would not add to the general knowledge of the subject; but I will sum them up and relate, I think, some interesting points. I have 9 cases to speak of, 5 of which were gangrenous, and 3 rapidly advancing toward it when death overtook them. One was peculiar and unverified; all are dead; one was in medium circumstances, all the others decidedly wealthy. The ages ranged from 50 to 93, 4 of them being above 70; 5 were women, 4 men. In none of them was the classical emaciation present at any time. The disease was intermittent in two. The urine in one of these cases would range as low as 1010 specific gravity, with slight traces of sugar, and then advance to 1030–

1035 with evidence of abundance of it. Another case also ranged from low to high at varying times, but not so marked as the first. This teaches us not to be too sure in saying, as we all often do, "there's no use looking for sugar in that," when the gravity is 1020 and under. Austin Flint, Jr., reports a diabetic case with the gravity of 1011½.

The seats of the gangrene in 5 of my cases were: foot and leg below knee 3, thigh and buttock 1, nucha (not ordinary carbuncle) 1.

Gangrenes, as a rule, are generally of the soft or humid kind. This, however, depends much upon the part involved. Where the tissues are succulent, the gangrene will also be of that character; where they are composed mostly of skin, tendon, and bone they will approach the senile gangrenes in appearance. The remark made by Holmes Coote is also applicable. He, speaking of the terms used in the descriptions of gangrene in general, as dry, moist, etc., says "when death of a part takes place rapidly, the vessels still contain blood and the usual fluids, and the mortified parts are moist and soft. When, on the other hand, the death is slower, there is usually a deficiency of the supply of blood, the vessels become empty and the part hardens and withers." There is this distinctive difference between the diabetic and the senile gangrenes according to my observation. The former rarely or never present the clear-cut line of demarcation between the dead and living parts that is characteristic of the latter. This fact, with a want of the decided dryness and shrivelling of the senile variety, should suggest the diabetic form, but in any case the urine should be examined.

I have this interesting observation to make about one patient:

A lady, aged ninety-three years, who did not have gangrene. This past summer she was in more than usual good health. I know positively she had no diabetes until shortly before her death; not only from the want of rational symptoms, but also from recent examining of the urine. I went with her to Newport in June, and left her there. In passing through Newport in the latter part of July I saw her; she was perfectly well, and her delight was to drive twice a day. I was at Bar Harbor in August, and received a telegram asking me to come at once to see her at Newport. She was dead before I arrived, and I learned from Dr. Cleveland, of New York, who attended her, that she was sick but eight days, and had developed an *acute* diabetes, which rapidly proved fatal. I had no hesitation in saying that had she survived the first fierceness of the attack she would have had to contend with gangrene. The opinion was given, not because of her age, but because of the diabetes.

Sugar in the urine has been developed by falls upon the head, and also in certain forms of apoplexies, but I have just made a, to me, most interesting observation; for I find none like it reported.

In January, 1885, a wealthy gentleman, a long-time patient of mine, of most vigorous constitution, then seventy-six years of age, had an apoplectic seizure, from which he reacted, and finally settled down into a chronic semi-paralytic. On the 9th of this November, 1888, in the evening, I was suddenly summoned to see him by his son-in-law, a physician. He was comatose, face very much flushed, temperature 103°, pulse 120, and had Cheyne-Stokes respiration. There was no increase of paralysis of the extremities. Basic effusion was diagnosed. Under treatment he improved, and was very much better by morning. His urine during his sickness had been repeatedly examined, and, with the exception, at times, of slight traces of albumin, there was nothing abnormal. On my morning visit, mindful of the symptoms of the night before, I proposed an immediate examination of the urine. This was done, and decided sugar reactions were produced by fresh Fehling solution.

Here was auto-physiology. Temporary pressure upon. and disturbance of the respiratory centres, and also pressure upon the diabetic regions of Bernard. As the effusion disappeared with the mending of the patient's condition, the sugar has gone with it, and now the tests give no traces of it. It will be interesting in this case, if the patient survives, to note both as to sugar and as to gangrene.

I had written thus about this case, when I had occasion to make another note. I saw the patient daily for four or five days, when it looked as though matters were about to resume their old course, and I made the next appointment for two days ahead. But on the 15th I was summoned again. The patient was in deep coma, breathing 60 per minute, pulse 150. *The urine gave sugar reactions more decided than before.* Respiration could be stopped by reflex at once—that is, by any peripheral irritation about the mouth or thorax. This would occur on an attempt to give liquids; then, after a few automatic adjustments, the breathing would go on as rapidly as before. Within two hours death took place. There was no filling of the bronchi with mucus. The patient simply stopped breathing. Pressure on the pneumogastric centres was profound. It was a quick and permanent application of the air-brakes.

In practice we all have our puzzling cases. Some we clear up during the life of the patient, while others die, and, it may be, not until long afterward does the knowledge come to us of what probably was the matter. Some similar case, or some reading or discourse may give us light. I recall one such case in the direction of the present paper. A distinguished, wealthy lawyer was attacked with an obscure disease. It was rapidly fatal. Dr. James Darrach was the physician, and I was sent for in consultation. It is not necessary to give the details. I cannot remember whether the urine was examined; certainly, I think, not for sugar. Symptoms of sepsis were marked, and among the incidents there

was enormous swelling of the abdominal walls, both anteriorly and laterally. I made free and deep incisions into the flanks, and from the cellular tissue mephitic gases and fluids, like those that flow from moist gangrenes, came in abundance. I think, in the light of what has been developed in my researches, that that patient died from an acute attack of diabetic gangrene.

There was no consumption, or even a suggestion of it, in *any* diabetic of whatever kind that I have seen, except the one I vaguely remember as being in the hospital when I was resident. I now submit, from what we have heard, whether among all the gangrenes mentioned in books and indexes, viz., traumatic, hospital, senile, symmetrical, spontaneous, puerperal, visceral, infantile, congenital, cutaneous, mephitic, spreading, exanæmic, arterial, static, dry, wet, moist, humid, white, etc., the much-neglected diabetic gangrene should not be included? We have seen that *diabetic* gangrene makes, with good reason, higher pathological claims to notice than most of the kinds above given.

It is rash to make assertions. I, however, will say I should not be surprised to find, after thorough investigation, that in *numbers*, in civil practice, diabetic gangrenes would be found to hold the second place, traumatic gangrenes, including those from frost-bite, burns, and scalds, only exceeding them.

I shall only glance at the theories of diabetes. Faults of the nervous, vascular, and visceral symptoms have been, respectively by some, and *all* together by others, considered to be at the bottom of the trouble. I incline to deranged vaso-motor effects (stasis or paralysis of the vessels, with or without atheroma or arterial sclerosis) as most explanatory. What better fact could we wish to sustain this position than the influence of the disease on virility, a condition almost absolutely dependent upon normal vaso-motor function? Men with diabetes are mostly impotent; Marchal says, always so. He gives some strange cases of marital infelicities, such as unfortunate charges of infidelity by wives against their husbands, when really the poor fellows were helpless diabetics. One of these is described as a veritable athlete, and he was an example of the fact that in this disease great and peculiar strength in one direction may for a time coexist with great and peculiar weakness in another.

The knowledge of diabetes is ancient, and, in looking over the old records, I thought that I might stumble on one of diabetic gangrene, but in this I was disappointed.[1]

[1] Coincident with the reading of the proof of this paper, I received (December 6, 1888) a copy of the Berliner klinische Wochenschrift, No. 47, November 19, 1888. It contains the first part of an article by Dr. Max Schüller, of Berlin, called "Ein Beitrag zur Kenntnisse der phlegmonösen und gangränösen Processe bei Diabetes." The author also intimates that gangrene, etc., is more than a mere coincidence in diabetes. He says: "While many cases of glycosuria—as, for example, those following experimental researches upon and injuries of the central nervous system—have found an essential clearing up, the relation between pus formations, furuncle, carbuncle, gangrenous process, and glycosuria is still quite dark. The view that these cases are essentially only complications of an unrecognized diabetes has still its adherents. I now have nothing new to offer as explanatory, and will consider this part of the subject no further."

THE DIAGNOSTIC VALUE OF HEMORRHAGE FROM THE EAR IN HEAD INJURIES.

By CHARLES D. BENNETT, M.D.,
of Newark, N. J.

The object of this paper, while admitting that hemorrhage from the ear is a frequent accompaniment of fractures of the base of the skull, and therefore of a certain value in the diagnosis of such injuries, is to show that serious aural hemorrhage may occur after severe head injury, and yet be unattended with any serious damage, such as fracture, to the bones of the skull.

If this proposition can be maintained with any reasonable evidence of truth, the value of such bleeding as a factor in diagnosis is evidently much lessened, and the difficulty of making a diagnosis of fracture of the base correspondingly increased.

Authors of works on surgery differ considerably in their estimates of the value of this sign, but, with one notable exception, a fair summary of their opinions might be given—application of sufficient force to the head, evidence of some brain injury, free and prolonged hemorrhage from the ear, with or without other symptoms; and then follows, as diagnosis, fracture of the base of the skull. It must be admitted that in a majority of cases this summary would be correct, or at least would never be disproved, for it must ever be borne in mind that a fracture of the base is always an obscure injury, even when, as usually, resulting in death; but, when followed by recovery, the justice of the diagnosis must remain in doubt, for the cases that may be verified by subsequent post-mortem examinations are so few as to be hardly worth considering. When the accident has resulted in death, an autopsy has often vindicated the diagnosis: but, on the other hand, cases are on record in which, after such a conjunction of symptoms having occurred, and such a diagnosis having been made, the post-mortem examination showed no fracture whatever, and occasionally a case occurs resulting in recovery, in which, with the above-named symptoms, is found some anatomical fact which would seem to belie the diagnosis. Such a condition occurred in a patient recently treated in St. Michael's Hospital, in the service of Dr. J. C. Young:

Paul B., aged twenty-eight, on February 3, 1888, fell in an elevator through seven stories. A roll of hides had become wedged between the elevator and

the shaft-wall, and the patient, standing on the elevator, after allowing the rope to unwind to its fullest extent had endeavored to force the car past the obstruction by jumping, so that, when the obstacle was suddenly overcome, the fall of seven stories was uninterrupted. One of the large supporting beams of the cage fell after him, striking him in the face, and causing a fracture of the alveolar process of the lower maxilla. The patient was seen within three-quarters of an hour after the accident. He was then conscious, but very irritable, and presenting no other brain symptoms. Pupils equal and normal in size. The hemorrhage was profuse from the nose, and from both ears. No paralytic symptoms were discoverable.

The next day the hemorrhage from the ears continued in lessened amount, and a patch of subconjunctival ecchymosis had appeared on the left side. General condition improved. The hemorrhage ceased during the following night. Two days later a tumefaction appeared behind both ears, which had every appearance of being inflammatory, but which disappeared in two days more by the use of cooling lotions. Seven days after the injury, the ears were examined by Dr. T. Y. Sutphen, whose report I give in full:

"After removing the clot found in both ears, I found the external canal red, and swollen slightly anteriorly and superiorly. No wound could be detected. Membrane red, but not perforated. Hearing watch four feet from each ear, or nearly normal. No hemorrhage in middle ear."

On the following day, Dr. Sutphen made a verbal addition to his report, saying that, in his opinion, the base of the skull had been fractured, and the blood had perforated at the side of the membrane, not through it.

This patient continued to improve, suffering only from occasional headache and vertigo, and with these symptoms continuing in steadily lessening severity, he was, on March 5th, discharged, practically well.

The anatomical fact spoken of is, of course, the non-rupture of the membrana tympani, and the question raised would be on the possibility of a hemorrhage, due to a fractured base, escaping from the ears past an unruptured membrane.

Hewitt, in Holmes's *System of Surgery*, vol. i. p. 629, says even if there be a fracture of the petrous bone communicating with one of the great venous sinuses, and the membrana tympani be not ruptured, there can be no bleeding from the ears, or, in other words, he denies the possibility of blood effused into the cranial cavity finding its way into the external canal, unless it flows through a tear in the tympanic membrane.

Nancrede, in the *International Cyclopædia of Surgery*, vol. v. p. 35, quotes Hewitt on this point, agrees with him, and is even more plain and positive, he expressly stating that a recent rupture of the membrane must be made out, saying, further, that if the membrane be not ruptured, and show no evidence of blood pressure from within, the fracture, if existing at all, may be said not to involve that portion of the petrous bone where lie the aural parts.

If these authors are correct, then our patient had no fracture of the base, or, at least, the hemorrhage had no connection with it. Truth, however, compels the statement that their opinions must be qualified, for Roosa, in his *Treatise on Diseases of the Ear*, mentions a case of Zaufal's, in which a fracture had run through the upper wall of the pyramid, the opposite wall of the tympanum, and the upper wall of the osseous portion of the auditory canal, leaving the membrana tympani uninjured, yet hemorrhage from the ear, due to the injury, had occurred. But such cases as that just quoted must be very rare, and, while making necessary a slight qualification of the opinions previously given, can hardly affect their general truth.

With this view other authors, so far as they consider this point, seem to agree, and I have been able to find no written opinion to the contrary, save in the *Archives of Otology*, vol. x. p. 314, where Dr. J. D. Rushmore reports a case of hemorrhage from the ear as probably due to fracture of the skull—merely a summary of Dr. Rushmore's article, not in author's language:

> The case was that of an old gentleman, previously in good health, who, while walking in the street, and having for a few minutes a peculiar, uncomfortable sensation in the head, suddenly fell backward and toward the left side, became unconscious, and lost, in a few minutes, about sixteen ounces of venous blood from the left ear. He regained consciousness in a few hours, and for several days suffered from vertigo, severe frontal headache, tenderness around the left auricle, and dulled hearing in the left ear. There was no more hemorrhage, and on the sixth day a purulent discharge appeared, the patient becoming delirious; but gradually the symptoms disappeared, and the patient became, with the exception of some impairment of hearing power, as well as before.

Here is no history of traumatism, there being no evidence of bruising, save for a slight ecchymosis below and behind the ear—and certainly fracture of the base does not occur without violence, while the peculiar sensations preceding the fall, the fact of the falling being toward the side from which the hemorrhage occurred, both of which symptoms point clearly to some lesion in the head preceding the fall, and being a cause, not the result, of the loss of equilibrium, seem to be entirely ignored. The membrana tympani was later shown to have been torn, but for the first two weeks subsequent to the accident the case had been considered as a fracture of the base, with no rupture of the membrane.

Let us, however, consider the evidence adduced to show the possibility of hemorrhage from the ear without fracture of the base, and with or without rupture of the drumhead.

Bell, in his *Institutes of Surgery*, p. 104, says, "hemorrhage from the ear may be dependent on

mere concussion," and in *Braithwaite's Retrospect* for January, 1850, p. 102, is given an abstract from an article in the *Medical Gazette*, by John Adams, as follows:

"Hemorrhage from the ear is, in my opinion, not pathognomonic of this injury (*i. e.*, fracture of the base); it is so commonly found in slight cases of injury to the head, and in cases which occur without any untoward symptoms, that I feel justified in discarding it as a sign wholly to be relied on." Again, "Separately and singly, although it is an important indication, I do not rely upon it as conclusive of the existence of such an accident."

A. H. Buck in the *American Journal of Otology*, vol. ii. p. 277, writes: "The mere fact of a copious hemorrhage from the ear does not justify assuming the existence of any such serious lesion as fracture of the petrous bone and laceration of sinus."

I have been able to find a few apposite cases in medical literature. Roosa gives (*Diseases of the Ear*, pp. 324 and 501) two cases of concussion of the brain from a blow on the head, causing hemorrhage from one or both ears, and resulting in recovery. In neither of these could any rupture of the membrane be found.

Warren, in *Surgical Cases with Observations*, p. 14, mentions a similar case caused by a fall from a horse, with bleeding from the ears and unconsciousness and ending in recovery.

E. J. Spear, in the *American Journal of Otology*, vol. ii. p. 107, reports the case of a teamster falling head first from the high seat of a furniture wagon and striking upon his chin. He became immediately unconscious, had a considerable hemorrhage from the ear at once and an oozing of blood for twenty-four hours, with steady pain in the ear but good hearing. Eight days later a fracture of the anterior inferior osseous wall of the auditory canal was discovered. The membrana tympani had not been ruptured.

Hulke, in the *Lancet*, 1879, vol. ii. p. 689, reports the case of a boy, who slipping while running, fell striking his chin on the ground. He was found unconscious and with free bleeding from one ear, which continued for five days. Perfect recovery ensued. At the end of two weeks the membrana tympani of the ear was examined, and a recent scar found. Mr. Hulke believes all the symptoms to have been caused by the violent impact of the condyles on the floor of the tympanum.

Gauthier, in an "Inaugural Thesis on Hemorrhage from the Ear of Traumatic Origin," reviewed in the *American Journal of Otology*, vol. i. p. 293, sums up the evidence, and to the reviewer's mind, at least, shows conclusively that otorrhagia after severe head injuries is not necessarily a symptom of fracture of the petrous bone. Gauthier concludes that aural hemorrhage, following a fall or blow on the head, may depend on, 1st. A lesion of the auditory canal, such as laceration of the skin of the canal, a loosening of skin and mucous membrane of the ear without rupture of the drumhead, or to a fracture of the anterior wall of the bony canal; 2d. To a fissure of the membrana tympani or of the mucous lining of the drum; and 3d. To a fracture of the squamous or petrous portions of the temporal bone.

To illustrate how hemorrhage from the ear, not traumatic, might, not unreasonably, be mistaken for bleeding due to an injury, the following two cases reported by Orne Green, in the *American Journal of Otology*, vol. iii. p. 135, may be cited.

Both were cases of vicarious menstruation, in one the blood flowing from what subsequent growth showed to be a sebaceous tumor in the meatus, the drumhead being unbroken, and in the other from the tympanic mucous membrane, the membrana tympani having been previously destroyed. Had either of these patients sustained a head injury during menstruation and fallen into strange hands, a basal fracture might very probably have been diagnosticated, but with no more justice and probably no more correctness than in Rushmore's case.

Admitting then that free traumatic aural hemorrhage may occur without fracture of the bone, let us look at the subject from another standpoint.

The notable exception, previously referred to, was Erichsen. He writes (*Science and Art of Surgery*, vol. i. p. 536):

> "Bleeding from one or both ears, after an injury to the head, cannot, by itself, be considered a sign of much importance. If, however, the hemorrhage be considerable, trickling slowly out of the auditory meatus in a continuous stream, if the blood with which the external ear is filled, pulsate, and more especially if the bleeding be associated with other symptoms indicative of serious mischief within the head, and if it has been occasioned by a degree of violence sufficient to fracture the skull, we may look upon the hemorrhage as strong presumptive evidence that a fracture of the base of the skull has taken place."

Here is a fair description of our case. The hemorrhage was copious, calling for plugging of the meati, it trickled away in a continuous stream; there were the other symptoms of severe concussion of the brain, and the man had fallen seven stories landing upon his feet, and had again been struck in the head by a heavy beam that had travelled down the seven stories after him. But Erichsen, with all these signs present, holds that the evidence is still only presumptive.

On this point Gauthier claims that after an injury from a fall upon the head, there may ensue loss of consciousness for a longer or shorter time, followed by dulness of intellect for several days, loss of hearing on one side and hemorrhage from the ear, even also a serous aural discharge, and all these symptoms be due to a ruptured membrane with no fracture

present. In support of this view he adduces nine cases.

Accepting these theories as true, it is difficult to see why our case should be diagnosticated as a fracture, and it becomes necessary in most cases of head injury to hold the diagnosis in abeyance until recovery has shown the improbability of such fracture being present, or an autopsy has positively established the truth.

The mere fact of recovery having occurred must throw a strong doubt on the diagnosis. The importance of the contiguous organs, not merely to intellect, but to life, and the force necessary to fracture the strong basal bones, with the nervous shock accompanying, must clearly justify the dangerous prognosis attached to such an injury. If such cases as have been narrated are to be styled fracture of the base, then the experience of past ages must be thrown aside and this injury be considered a light one, instead of one almost invariably fatal.

In looking over the records of St. Michael's Hospital I have found thirty cases of simple, uncomplicated fracture of the base, of which twenty-one died, one was not improved, and seven were cured. Omitting the "not improved case," which I consider must have been intended for "remaining," this gives a mortality of seventy-six per cent., certainly not a high rate for one of the most dangerous injuries in all surgery, and the inference is inevitable that some of these cases were not fractures at all.

Nancrede, in The Medical News of January 28, 1888, quotes Wagner, who claims that all his cases of fractured base who survived the first twenty-four or forty-eight hours, being twenty-three in number, recovered, and apparently ascribes his success almost wholly to the attention given to antiseptic details. Bearing in mind the promptitude with which patients with basal fracture usually die, Wagner's report might almost as well read that those cases which survived recovered, and one feels strongly inclined to doubt the accuracy of the diagnosis.

If the hemorrhage in our case was not due to a fractured base and lacerated sinus, whence did it come?

It will be recollected that a heavy beam fell after the man, striking him on the lower jaw and breaking off part of the alveolar process of one side, also that on the anterior and superior aspect of the external canal was a red and swollen spot, and it seems not improbable that the articular process of the maxilla had been forcibly driven back against its socket, and perhaps fractured the wall of the external canal.

That this explanation is not unreasonable several reported cases, proved by autopsy, demonstrate. Hewitt reports one case in Holmes's *Surgery*, and other authors give this as a not unusual cause of aural hemorrhage. The cases of Spear and Hulke are also similar. It is true that the bleeding was from both ears, and it is hardly probable that both temporal bones were fractured in this manner, yet even this supposition is not more unlikely than a fractured base when the necessarily great extent of the basal fracture is considered.

The bleeding from the nose and under the conjunctiva would indicate a fracture in the anterior fossa; the bleeding from the ears points to a fracture in the middle fossa and on both sides. Here then we have a fracture that involves the petrous portions of both temporal bones, and as fractures on the opposite sides would probably coalesce, the lines of separation would evidently course through the sphenoid and join at, or in, the substance of the ethmoid. It is hardly probable that so extensive a fracture as this would have caused so few symptoms, or would have allowed the patient to leave his bed on the third day, convalescent.

The following conclusions seem fairly deducible from the foregoing consideration:

1. That hemorrhage from the ear is, in itself, no evidence of fracture of the base.

2. That hemorrhage from the ear, even in conjunction with other symptoms, must only be regarded as presumptive evidence.

3. That no such diagnosis should be made until the membrana tympani had been examined.

4. That the membrana tympani being unbroken, the bleeding is not due to a fractured base.

5. That all the signs of fractured base may be present with mere concussion of the brain, and that therefore the two injuries cannot always be differentiated.

6. That many cases, now on record of recovery after fracture of the base, were cases of concussion only.

A CASE OF NEPHRO-LITHOTOMY; RECOVERY.

By L. D. WILSON, M.D.,
of Wheeling, West Virginia

In the *Lancet* of June 16 and 23, 1888, Mr. Henry Morris, Surgeon to Middlesex Hospital, London, in a communication "On the Surgical Treatment of Renal Calculus," reports four successful cases of nephro-lithotomy. In the general remarks upon the subject, preliminary to the detailed reports of these cases, he uses the following language:

"But though the surgical treatment of renal calculus has yielded gratifying and admirable results, and has received the approbation alike of the medical and surgical mind, it still requires to be better known before it will obtain the thorough confidence and general recognition of the profession at large. It is, of course, much to be wished that we could approach every operation for renal calculus with the same certainty that we shall be able to find and remove the stone as we feel when we operate for vesical calculus. . . . As a step toward attaining to such accuracy of diagnosis and precision of ex-

ploratory methods as this implies, it is desirable that every case should be recorded, (1) in which a renal calculus has been removed, and (2) in which a calculus having been justly suspected has been searched for, but in which subsequently it has been proved that the symptoms were due to some other cause."

It so happened that four days previous to the publication of this report I had operated on a case of renal calculus, and in compliance with the desire above expressed, a report of it is contributed.

Case.—On May 31, 1888, I saw J. A. H. P., photographer, of this city, in consultation with Drs. W. S. Fisher and John Cook, of Bridgeport, Ohio. The patient gave the following history: Age thirty-eight, married, of healthy family. Fourteen years before, while working very hard at his business, he began to pass a considerable amount of blood with the urine. This he continued to do intermittently for about six months, when it ceased, as he supposed as a result of medical treatment, and did not recur again so far as he knew at any subsequent period. About eight years later he noticed that pus began to show itself in the urine, and at the time I saw him he was, and had been for several years passing it in relatively large quantities, the proportion to the whole bulk of urine ranging from one-tenth to one-fifth. Its presence however was not constant; there being intervals as much as a month at a time when the urine was apparently normal. About three years ago he began to suffer pain in the right lumbar region, dull, deep-seated and often excruciating in character, and never entirely absent. He was subject to frequent hepatic disturbances, at which times his distress was greatly aggravated. His appetite and digestion continued good, and his bodily functions with the occasional exceptions already noted were fairly performed. During all these years he continued with only occasional intermissions to conduct his business actively, and he had taken to his bed but a few days before I saw him.

At my visit I found him considerably prostrated, countenance indicative of much suffering, daily fever and sweating, poor appetite, marked degree of emaciation, and much mental despondence. There was marked tenderness on pressure in the right lumbar region over the location of the kidney, but no redness, œdema, or fulness was noticeable. Examination of the abdominal region disclosed a rounded tumor located a little above and to the right of the umbilicus, and reaching nearly to the border of the ribs. It was smooth, tense, elastic, and tender, but gave rise to no pressure symptoms, no distinct evidence of fluctuation, but slight appearance of fulness to the abdomen and was only demonstrable on moderately firm palpation. The patient himself was not aware of its existence until it was discovered by his physician. It was flat on percussion and a narrow space of tympanitic resonance seemed to separate it from the liver. An examination of the urine showed pus to about one-tenth of the whole quantity, earthy phosphates, epithelium, occasional blood-disks and albumin in small amount. Its reaction was neutral or faintly alkaline. Sp. gr. about 1020, and normal in quantity. The diagnosis of his physician, Dr. Fisher, pyonephrosis consequent on the presence of a renal calculus, was concurred in.

Owing to the unfavorable condition of the patient, an operation was not at once proposed, it being thought best to see if it were not possible to bring about some improvement before radical measures should be undertaken. This plan was followed for a short period, he in the meantime being seen by several other physicians. Instead of improving he steadily lost ground, and as further delay offered no encouragement, operative measures were proposed and agreed to.

The operation was done June 12 at 4 P.M., Drs. W. J. Bates, R. M. Baird, Stifel, and Hoge, of this city, and Drs. Fisher, Cook, and Heinlein, of Bridgeport, Ohio, present and assisting. Chloroform was administered by Dr. Baird. The ordinary lumbar incision was made, parallel to and about an inch below the twelfth rib, and about four inches in length. The muscular structures having been divided and the perinephritic connective tissue cleared away, the thickened and greatly dilated capsule of the kidney presented. This was opened and immediately a large quantity of offensive pus poured out. On introducing a finger a large rough calculus could be felt firmly embedded in what seemed to be the dilated opening of the ureter. In attempting to remove it quite a number of fragments were broken away by the forceps before the main portion could be removed from its bed. It was finally extracted and the cavity carefully explored. The pelvis, infundibula, and calices were much dilated, but the lining was smooth. After carefully washing out the cavity, first with warm, afterward with warm carbolized water, the anterior half of the wound was closed with silk sutures, a large drainage tube inserted into the cavity, the whole dressed with absorbent cotton and the patient placed in bed.

The main portion of the stone, which measured one and a half inches in length and two and a half inches in circumference, after drying for more than two months after removal, weighed 131 grains, the fragments broken away during extraction, 37 grains; total weight, 168 grains. It was phosphatic in character, and its outer layers very friable.

Nothing of special interest occurred during the various steps of the operation. The anæsthetic was well borne. Hemorrhage, while sometimes quite free, especially during the efforts to loosen the stone from its position, gave but little trouble, one or two small vessels being twisted, pressure with sponges doing the rest. The patient was greatly prostrated and rallied slowly. The next morning, however, he had fully reacted, and his subsequent progress to recovery was uneventful. The temperature varied but a trifle from the normal; the wound drained well; the portion closed by stitches united by first intention, the dressing used being absorbent cotton to the wound, and a large compress on the abdomen over the site of tumor felt before the operation and which, of course, disappeared when the pus cavity was emptied. The drainage tube was retained seventeen days, when the discharge having become small in amount and plainly urinous in character, and the cavity satisfactorily contracted, it was withdrawn.

On the thirtieth day after the operation the patient went out driving. A few weeks later he took a trip to the lakes, and returned in September, having gained about forty pounds in weight. Since then he has actively followed his business. A small fistula remained discharging slightly until a few weeks ago, but it seems now to be permanently closed.[1]

The principal requisite to success in operations of this sort would seem to lie in integrity of the other kidney. In the *Pittsburg Medical Review* for September, 1888, is the report of a case operated on by Dr. McCann, of that city, in which the left kidney was removed by lumbar incision for multiple abscess and calculi, on July 31, of this year, the patient dying five hours afterward. The autopsy disclosed a similar condition of the other kidney. While the determination of this question even approximately, in many, if not in most cases will be beset with difficulties and involved in more or less doubt, still, in general, where the daily quantity of urine secreted, and the specific gravity do not fall much below the normal; where the amount of albumin present is not greater than the contained pus would account for; if no casts are found and no subjective or objective signs of mischief are elicited by inquiry or examination, it may be fairly assumed that the opposite kidney is at least in a sufficiently active condition to warrant an operation.

This one question out of the way, the indications and contra-indications that may exist in the other organs, and in the general state and surroundings of the patient are comparatively easy to determine.

WHEELING, November 2, 1888.

RADICAL TREATMENT OF SUPPURATING INGUINAL GLANDS.

BY THOMAS S. K. MORTON, M.D.,
ADJUNCT PROFESSOR OF ANATOMY AND SURGERY IN THE PHILADELPHIA POLYCLINIC; MEMBER OUT-DEPARTMENT STAFF PENNSYLVANIA HOSPITAL.

IT IS my object in this paper to report a typical instance of each of the two forms of suppuration to which the inguinal glands are commonly liable, and to sketch briefly the technique of radical operation thereupon.

These chosen illustrative cases will be found to present almost all of the coincident conditions which are usually found accompanying or complicating buboes thus situated.

The first case is that of Charles A., aged twenty-five, rather robust in appearance, but strumous withal. He had always enjoyed good health, but on coming under my care was somewhat depressed in constitutional vigor. Examination proved negative, except in the left inguinal region where was found a chain of large lymphatics: one of them quite softened, and all painful to touch or upon motion. No history or likelihood of infection could be elicited. He was urged to have a radical operation performed and thus secure permanent relief from all annoyance or danger from this source in the future. Consent thereto having been obtained after a just presentation of all the prognostic aspects of his case, I made a two inch vertical incision one-half inch to the outside of the central and most softened gland, and then worked my way laterally through the swollen and softened tissues until the purulent gland was reached, when, after easily tearing its capsule with the finger-nail, it was enucleated without rupture by gently shelling it from its bed with the tip of the index finger. In like manner, save that the thumb was also at times employed, every gland of the chain was removed. A thorough curetting of the gland-beds and surrounding tissues was then done, the wound washed with 1 to 1000 sublimate solution; catgut sutures were made to bring the edges of the entire opening into close contact, and an antiseptic dressing was applied. No drainage was employed. The primary dressing was not disturbed for ten days, when a firm and complete union of the entire wound was found to have occurred.

The second case is that of William N., who about six months before coming under my care suffered with a soft chancre of the glans penis, the scar of which was quite marked. The usual suppurating bubo ensued and was opened. The abscess then closed, but only again to require opening of another purulent collection shortly afterward. These abscesses had arisen and been operated upon several times, and he had passed through the hands of a number of physicians when I first saw him. This was about a week after the last abscess had been opened, and there then existed a small sinus; also a gland higher in the chain was just taking on suppurative action. Explaining to him the cause of his constantly recurring troubles, and the likelihood of their keeping up indefinitely unless the whole chain of diseased glands was excised, he readily consented to the operation.

An oval vertical incision two inches in length was made over the centre of Poupart's ligament, including the fistula, and avoiding by half an inch the degenerated gland above referred to. Through this opening every gland of the chain was removed in the same manner as in Case I., except that in this instance the most pussy gland ruptured during extrication, so it was removed, together with the remains of the one to which the sinus led, by means of the curette. As this case presented considerable swelling and infiltration of the surrounding tissue, a small catgut drain was left in. The wound was not dressed for a week, when it was found united, except that portion which the drain had traversed, where some gaping had taken place, but which was granulating nicely. A lymph-like discharge kept up for a few days longer, but then the wound firmly and permanently closed.

[1] A few days after this was written the patient was rather suddenly attacked with severe pain in the lumbar region accompanied with high fever, headache, etc. This continued several days when the fistula reopened and discharged quite freely. The symptoms at once subsided, the fistula remaining and discharging slightly, as it had done before.

The specimens secured from these cases proved, as usual, most interesting and significant in their teachings and indications. The glands had no communication with each other, in fact, when in situ were separated by morbidly thickened interstitial tissues, and hence would probably have suppurated each in turn and never have fused into one large abscess. Indeed, the history of Case II. shows what in time probably would have been the subsequent course of Case I. Several of the more superficial of the in all about eighteen glands removed from both cases, were quite broken down and not much more than pus bags, whilst *all* of those not, apparently, much more than hardened upon palpation when split open, were found to contain innumerable vari-sized foci of suppuration or minute abscess.

I would urge similar treatment for all cases of suppurative, tubercular, or specific infections of the inguinal glands. The chief points to be kept in mind are: vertical incision down to the gland capsules, if they still remain, avoiding; if possible, those most degenerated; to enucleate the latter from one or the other side; to remove every gland of the chain or neighborhood, whether enlarged or not, with the fingers alone, if they be unruptured, or with the curette, if that accident has occurred before or during the operation; and, finally, never to be content to open abscesses of the above septic, specific, or tubercular nature, without at the same time removing all the glands which are their present cause, or they may prove future sources of recurrence or constitutional infection.

NOTE ON THE COUNTING OF WHITE BLOOD-CELLS.

By JAMES K. THACHER, M.D.,
PROFESSOR OF PHYSIOLOGY AND CLINICAL MEDICINE IN YALE UNIVERSITY, NEW HAVEN, CONN.

STICKER (*Zeitschr. f. klin. Med.*, Bd. xiv. S. 91 ff., 1888) states that when the blood is diluted—*e. g.*, with sodium sulphate solution, and mixed by shaking in the mélangeur of Malassez, or similar instrument—the number of white blood-corpuscles is found to be smaller in comparison with the red than when a thin layer of pure blood is examined. He infers that a considerable number of white corpuscles have been destroyed by the mixing and shaking, and he concludes that the true number can only be found by the examination of the thin layer of undiluted blood.

The statement of Sticker will probably seem to be true to one who compares the two methods of examination experimentally. But there is some reason to question its correctness. The following observation is submitted:

Some leukæmic blood was drawn into the mixer, diluted with five per cent. of sodium sulphate solution, and shaken. One drop was then examined. Next the remaining blood was shaken more vigorously than before, and another drop was examined; again the blood was shaken up in the mélangeur and a third drop examined. An examination in this form was made on four occasions. The results were as follows:

	Drop No. 1. White-red.	Drop No. 2. White-red.	Drop No. 3. White-red.
First examination	1 to 14.3	1 to 17.8	1 to 14.4
Second examination	1 to 10 8	1 to 12.6	1 to 16.3
Third examination	1 to 12 5	1 to 11.3	1 to 9 7
Fourth examination	1 to 16 5	1 to 15.0	1 to 12.4
Average . .	1 to 13.5	1 to 14.2	1 to 13.2

The second and third shakings did not affect the ratio, and consequently did not destroy any white blood-corpuscles. But these shakings were decidedly more violent than that preceding the counting of drops No. 1; therefore, either the white blood-corpuscles are of two kinds—one very tough and the other very tender—or the counting of pure blood in a thin layer is liable to errors favoring an excessive count of the white corpuscles. When a thin layer of blood is spread on a slide and covered, we ordinarily find places where the red corpuscles are much crowded and run together in rouleaux and other places where they are separate and easily to be counted. Were the white corpuscles pretty evenly distributed over the preparation, while the red showed this tendency to concentration at points, and were we, in counting, to avoid the more crowded localities, where counting is difficult or impossible, we should obtain a number for the white blood-corpuscles in excess of what it should be.

MEDICAL PROGRESS.

The Radical Cure of Hernia.—MR. MITCHELL BANKS, at a late meeting of the Harveian Society of London, read a paper in which he divided non-strangulated hernia into two groups: (1) moderate sized herniæ, and (2) very large and enormous herniæ. This had been done, because they were by no means on the same footing, either as to danger to life from the operation or liability to recurrence of the rupture. In the statistics which he gave, the terms were used in the following manner: By "quite sound" was meant that the rupture had never come down since the operation, that there was nothing in the way of a swelling to be felt or seen, and that there was no impulse on coughing. By "partial success" was meant that the rupture had slightly returned, or threatened to return if unsupported, but that, with the aid of a truss, the patient was in safety and comfort. In many of these cases no truss at all would keep the bowel up before operation, while after it support could be effectually given. In every instance the patients placed in this category declared that they were in a distinctly better position after the operation than before it. By "complete failure" was meant that the rupture was as big and troublesome as before the operation.

Among the fifty-five moderate-sized non-strangulated

herniæ, two deaths were recorded. One was distinctly due to the operation. The other was doubtful, as the wound was all but healed, and there was no peritonitis or other lesion relating to the wound found after death. Of the sixteen very large and enormous herniæ, four cases proved fatal. Septicæmia killed two patients, and an unsuspected abscess, bursting into the peritoneal cavity after the patient was walking about and deemed sound, proved fatal in another, while in one case the operation could not be completed.

Of the twenty-two cases of strangulated inguinal hernia, one, an old man, aged seventy-seven, died from septicæmia and bronchitis.

Of the nineteen cases of strangulated femoral hernia, two died; one never recovered from the collapsed state in which she arrived at the infirmary, and another was moribund when admitted.

The statistics of permanence of cure showed that of the 100 cases of moderate-sized non-strangulated and strangulated herniæ combined, it had been possible to trace for very considerable periods seventy-seven. Of these, forty-eight remained quite sound, seventeen were partial successes, and twelve were complete failures. Of the sixteen cases of very large and enormous herniæ, it had been possible to follow up ten. Of these, five remained practically sound (though all required some support to prevent return), three were partial successes, and two were complete failures.

MR. BRYANT'S experience of those cases in which the sac was removed was that they succeeded best. After kelotomy the operation could not be considered completed until the sac had been removed. Operations on children were to be avoided, except where a truss could not be worn. Opening the sac almost quadrupled the risk. In adult life operation was inadvisable when a truss could be worn; big herniæ ought to be left alone. He had occasionally been obliged to operate upon them, but a truss must be worn afterward.

MR. EDMUND OWEN was unable to speak definitely of results; he could only say that he was satisfied with the result of his operations up to the present. He had operated upon a good many children, but he entirely agreed with Mr. Banks, that children should not be operated on unless the hernia was absolutely beyond the control of a truss, for it was an undisputed fact that, with a fair chance, children did "grow out of" their inguinal weakness. The cases which he preferred for operation were those of adults whose inguinal herniæ were associated with an atrophied or an undescended testis. In such cases the surgeon should remove the useless gland without compunction, and, having ligated and pushed up the cord, should completely occlude with sutures the inguinal canal. The objection against removal of the undeveloped testis was purely sentimental, for the gland was almost certainly of no physiological value. He did not believe in the surgeon being able to recognize during the operation the "internal abdominal ring" and the "conjoined tendon;" at any rate, though he knew them in the dissecting room, he ignored them in the hospital. He thought that it mattered little with respect to the permanency of cure whether the surgeon used silver, gut, or silk for closing the canal; but he would ask Mr. Banks how he dealt with the sac of that variety of hernia which descended into the tunica vaginalis. He (Mr. Owen) was satisfied to tie the funicular process high up, flush with the peritoneal wall, so as to leave no depression to invite the subsequent descent of the bowel; he then divided the process below the ligature, and removed an inch or so of the testicular part of it. He did not believe in the desirability of fashioning and suturing an artificial tunica vaginalis; all that might be left to Nature. The point on which he specially desired to join issue with the author of the paper was as regards the subsequent wearing of a truss. If the neck of the sac was obliterated, and the inguinal canal thoroughly closed, no bowel could descend, and the truss, therefore, was unnecessary. He always forbade the use of a truss after the operation, for he had a strong opinion that the constant pressure of the pad went a long way toward promoting the absorption of the plastic material which was thrown out in the neighborhood of the ligatures and sutures, and the definite organization of which had a considerable influence in establishing the permanency of the cure.

Mr. Banks said that removal of the sac was best because of its simplicity. He was himself inclined to operate upon those who could wear a truss, but in any case removal of the sac was essential, and repaired the irregularity of the peritoneum. He practised stitching of the rings, but it was of less importance. Umbilical herniæ contained so much adherent omentum and bowel that they were seldom suitable for operation.—*British Medical Journal*, December 1, 1888.

Lithium and Arsenic in Diabetes.—DR. VIGIER recommends the following formula for the treatment of diabetes:

℞.—Carbonate of lithium . . . 1½ grs.
Arseniate of sodium . . . $\frac{1}{20}$ gr.

For one pill. Take two a day.

DR. CONSTANTINE PAUL proposes the following:

Effervescing carbonate of lithium one dose, adding a few drops of Fowler's solution.

DR. DUJARDIN-BEAUMETZ prescribes as follows:

To a glass of carbonic water add 7½ grains of the carbonate of lithium and two minims of Fowler's solution. —*Revue de Thérapeutique*, Nov. 15, 1888.

Glycerin Suppositories.—The glycerin suppositories recommended by Dr. Boas in the *Wochenschrift* of the 23d inst., have given rise to the manufacturing of like suppositories said to be as good, if not better. As Dr. Boas now states in the *Pharm. Zeitung*, 1888, No. 80, he has been disappointed with the action of the glycerin-gelatine suppositories manufactured by Heck, as well as in the glycerin-soap suppositories manufactured by Dietrich, of Helfenberg.

Because of the too great solvency of the material employed and the great diffusion of glycerin upon the intestinal mucous membrane, Dr. Boas gives preference to the suppositories made from cocoa-butter by Sauter, of Geneva.

Dr. Boas does not consider glycerin a reliable and active aperient, and thinks that only when atony of the lower colon exists are its beneficial effects noticeable.—*Deutsche med. Wochenschrift*, Nov. 29, 1888.

Naphthol in Typhoid Fever.—At a meeting of the Bristol Medico-Chirurgical Society, DR. J. MITCHELL CLARKE

read a paper on the effects of naphthol in typhoid fever. He considered that the so-called bacillus typhosus was probably the cause of the disease, and therefore that the rational treatment was to prevent the growth and development of this germ by introducing some insoluble, and therefore non-absorbable, antiseptic into the alimentary canal, according to the suggestion of Bouchard. Naphthol β fulfilled these conditions, and appeared to have shortened the duration of the fever, prevented splenic enlargement, albuminuria, and other complications, and brought about more satisfactory convalescence. The risk of propagation was also diminished by destroying the infectious nature of the stools. In some cases naphthol β caused gastric disturbance.

Hair Tonic.—

Phenic acid		ʒss.
Tr. nuc. vomica		ʒij.
Tr. red cinchona		ʒj.
Tr. cantharides		ʒss.
Cologne water Cocoanut oil	āā q. s. to make	ʒiij.

Sig. Apply to the hair daily by means of a wet sponge.—*Les nouveaux remèdes*, November 24, 1888.

For Vomiting of Pregnancy.—Very good results have been obtained from ʒss to ʒj doses of fluid extract viburnum prunifolium. It has been tried in Bellevue and other city hospitals. In a series of eight cases, in which it was recently given in ʒj doses, a uniformly successful result was obtained. It seems to have a direct action on the uterus itself, thus preventing the reflex irritation which results in vomiting. In some of the hospitals all other remedies have been discarded.—*Canada Lancet.*

To overcome Pain along the Course of the Trigeminus.—Of the few remedies which act upon a single nerve trunk, butyl-chloral-hydrate is an example. Given internally in doses of fifteen to thirty or forty-five grains, it produces anæsthesia along the course of the trigeminus; this anæsthetic effect though is only a temporary one; large doses produce sleep.

Butyl-chloral-hydrate will be found of special use in affections of the trigeminus in which the pain is not due to a chronic condition, such as facial rheumatism, or toothache due to an inflamed pulp or to periostitis. In the filling of teeth, which appear somewhat painful, butyl-chloral-hydrate acts very effectively.

To disguise the unpleasant taste and to aid the solvency of this drug the following combination has been found useful:

℞.—Butyl-chloral-hydrate	2–3–5	parts.
Alcohol	10	"
Glycerin	20	"
Distilled water	120	" —M.

Sig. Three or four tablespoonfuls at one dose.

Size of the dose to be regulated according to the intensity of the pain and the individuality of the patient.—*Therapeutische Monatshefte*, November, 1888.

A Penetrating Wound of the Abdomen with Protrusion of the Bowel, in a six months' Pregnant Woman, caused by the Horns of an Ox.—DR. MARTIN AYUSO records in the *Clinica Navarra* the case of a woman, aged twenty-six, who was gored by an ox. As soon as able she arose from the ground and went into the house holding in both hands her protruding intestine. Drs. Cabezudo and Ayuso found her lying in bed on her right side, with her clothing on, legs flexed upon the abdomen, vomiting, and complaining of severe abdominal pain.

The wound was situated in the right iliac region, about one-sixth of an inch below the Fallopian tubes; it was a little over an inch in length, and shaped like a buttonhole, through which protruded the intestines, forming a mass as large as the head of an adult.

After having washed the wound with a five per cent. solution of phenic acid, they increased the length of the protruding intestine in order to facilitate the reduction of the hernial mass, but this proved impossible, since the continued vomiting of the patient would not allow the mass to remain in position. The patient was then put under the influence of chloroform, the intestinal mass reduced, and the operation, which had already lasted four hours, was completed. Convalescence was slow and tedious, and not without numerous minor drawbacks, but the fœtus, which was then six months old, was carried to full term.—*Gazette hebdomadaire*, November 24, 1888.

Ingrowing Nails.—DR. PATIN recommends a long-continued foot-bath, after which the nail must be carefully wiped dry. Then paint with traumaticin between the nail and the granulations for several days. The chloroform penetrates into the flesh, and, after evaporation, leaves a thin layer of gutta percha, which gradually separates the nail from the granulations, and protects the latter against external influences. Complete this protection with sticking-plaster, which must be removed only for the purpose of another painting. When the nail which must be left untouched for some time, has sufficiently grown out, its prominent portion must be cut off, the corners being rounded off. Healing will be all the safer if the patient abstains as much as possible from walking and wears very easy shoes.—*London Medical Recorder*, November 20, 1888.

Treatment of Nasal Diphtheria.—DR. KEIERSEN, in the *Nordiskt Med. Arkiv*, Bd. xix., writes that having found it very difficult to inject disinfecting fluids in the nasal passages of both children and adults, he has composed a suppository made of boric acid and cocaine. These are inserted deeply into the nasal passages, until they reach the posterior nares, through which they are made to protrude. Their action is twofold: first, they exert mechanical pressure, and secondly they act as a disinfectant, through the boric acid, which also, in dissolving, trickles down to the stomach, where it is further able to continue its disinfecting properties upon membranes which might possibly have been swallowed.—*Deutsche med. Wochenschrift*, October 25, 1888.

Diet in Bright's Disease.—The *Revue gén. de clinique et de thérap.* of October 18, 1888, gives under the above title the following:

1. *Classical diet. a.* First of all, avoid damp weather, and all sudden changes of temperature. *b.* Avoid spiced and heatening dishes, no eggs, no wines, no liquors, no beer.

2. *Diet of Dr. Sénator.* Patient may partake of all white meats, also pork; must abstain from raw meats, and confine himself as much as possible to a vegetable diet, especially of fruits, salads, and milk. For beverage —wine largely diluted with water.

3. *Diet of Dr. Semmola.* Consists in observing the foregoing rules, and of mixing with all beverages taken during twenty-four hours the following solution:

R.—Iodide of potassium . . grs. xv.
Phosphate of sodium . . grs. xxx.
Chloride of sodium . . grs. lxxv–xc.
Water . . . . . pint ij ℥iij.—M.
Take as directed.

4. *Diet of Dr. Bamberger.* Consists in enriching the milk diet, through the use of tonics and mixtures containing iron. He recommends the following prescriptions:

a. Pills of perchloride of iron. Of these pills, from 3 to 6 are taken in two or three divided doses daily. *Each* pill contains:

R.—Perchloride of iron . . . . ½ grain.
Powd. menyanthes . . . . 1/12 "
Extract of taraxacum, . . . q.s.—M.
Make one pill.

b. Pills of sulphate of iron. Dr. Bamberger takes his formula from Dr. Wiethe:

R.—Sulphate of iron . . . . 75 grs.
Bicarbonate of soda . . . 75 "
Extract of dandelion . . . q.s.—M.
Ft. 60 pills. Take 3 morning and evening.

c. Infusion of Peruvian bark.—This infusion is made as follows: take 5 drachms of the gray Peruvian bark (crushed) and adding it to two pints of water, allow it to boil for thirty minutes, then sweeten with 5 drachms of syrup of orange-peel; thus the prescription would read:

R.—Gray Peruvian bark . . . ℥v.
Water . . . . . ℥vjss.
Syrup of orange-peel . . . ℥v.—M.
Make infusion.

Dose ℥ij every two hours.

Treatment of Mania with Opium.—Prof. Jolly has tried the effects of opium in the treatment of mania, and especially in chronic mania, as recommended by Dr. Nasse, with most favorable results. He found that opium acted most satisfactorily during the period in which the patient assumes a condition of mental indifference.

As a rule, Jolly used the simple tincture of opium, which was given in increasing doses, from ten drops to fifty drops, three times daily. Only when exceptionally large doses were given did he observe unfavorable symptoms (such as digestive disturbances, vomiting, severe drowsiness, and only once interruption of pulse).

In ten cases (two-thirds), he noticed an improvement in the motor symptoms, the patients became quieter and slept sounder. So soon as the remedy was intermitted, the patient would relapse to his former condition, and improve again when the administration of opium was resumed. Of fifteen cases, five recovered entirely. Nasse also states that one-third of his cases recovered.

As to the theoretic action of opium, Jolly is of the opinion that it acts directly upon the cerebrum.—*Münchener med. Wochenschrift*, November 6, 1888.

Remedy for Toothache.—

R.—Acetate of morphia . . . ¾ grs.
Essence of peppermint . . 4 drops.
Phenic acid (pure) . . . 20 "
Collodion q.s. to make . . 1 drachm.

Apply with cotton.—*Journal de Médecine de Paris*, October 28, 1888.

Saccharin as an Antiseptic in Ophthalmology.—At a meeting of the Société de Therapeutique de Paris, October 24, Dr. Constantin Paul read a paper upon the experiments made by Dr. Trousseau to decide the utility of saccharin as an antiseptic in ophthalmology. After having convinced himself of the absolute harmlessness of this preparation in its action upon the cornea of rabbits and dogs, he tried the same in solutions of 1 : 500 and 1 : 250 upon thirty patients. From the results obtained, he concludes that daily applications of, and washings with saccharin solutions, can be undertaken without any harmful reaction. Enucleations, three iridectomies, eight extractions for cataract, and different operations upon the eyelids healed without any reaction setting in. It was found of special use in catarrhal conjunctivitis.—*Wiener med. Presse*, No. 47.

Therapeutic Treatment of Measles.—Dr. A. Montrefresco (*Arch. de Path. infant.*) gives the following results of his observations made during an epidemic of measles at Naples:

He is opposed to the use of antipyretics, as in most cases they prove to be of no avail. Antipyretics should, in his opinion, be reserved for such conditions only in which the high temperature threatens to lead to a degeneration of tissue, to a myocarditis, or to brain trouble.

With him the importance of diet is considerable. Above all, he recommends glycerine, which he prefers to alcohol, and, which, he thinks, is better able to sustain the strength of the patient, which it does by diminishing the amount of urea eliminated, and by lowering the temperature. He prescribes it in the form of a lemonade in daily doses of ½ to 1 ounce.

For broncho-pneumonia, the commonest and at the same time gravest complication, he prescribes infusions of ipecac. To diminish the cough, tincture of aconite is added to this powerful expectorant. In the capillary bronchitis of measles he administers iodide of sodium, which, combined with the bromide of the same base, regulates the rhythm of respiration, and diminishes the frequency of the cough.—*L'Abeille Médicale*, November 26, 1888.

Treatment of Oxaluria.—In a communication to the Society of Practical Medicine, D. H. Picard states that to combat the formation of lime oxalates and to prevent consequently the waste of lime salts, and the formation of urinary calculi, one must, above all, avoid those foods which constitute the formation of oxalates, such as watercresses, tomatoes, rhubarb, and fruits rich in citric, tartaric, and malic acids, especially apples and currants. Entire abstinence from champagne, Moselle wine, and strong

beers must be enforced, but in their stead cognac, whiskey, and gin may be permitted. Hard waters, if unavoidable, should be boiled before drinking.

The medicinal treatment consists in the administration of potassium, sodium, alkaline phosphates, and food rich in phosphates, such as fish roe, calf and mutton brains. If there exist any acidity of the alimentary canal, carbonate of magnesium should be prescribed.

When this last mentioned condition exists very strongly, acetate of potash, hydrochloric acid, twenty drops, three times daily, or a mixture of hydrochloric and nitric acids is indicated.

℞.—Acid hydrochloric,
Acid nitric . . . . . āā ʒiv.
Water . . . . . ʒjss.
Orange syrup . . . . ʒiv.—M.

One teaspoonful in a glass of water before each meal.

Active exercise in the open air, salt baths, sea voyages; freely partaking of warm aromatic beverages, infusions of calumba and of hops, large quantities of milk, avoidance of sugar and early retiring and rising, will be followed by good results.—*Revue de Thérapeutique*, Nov. 15, 1888.

Vaso-motor Rhinitis.—At the meeting of the International Otological Society, held at Brussels, DR. CARLO SECCHI, of Bologna, read a paper upon this subject, the conclusions of which are as follows:

1st. Simple hypertrophic rhinitis may be due to some intestinal derangement, getting better or worse according to the abdominal condition.

2d. The nasal obstruction manifests itself when the patient retires for the night; he is troubled with nightmare, and spasmodic twitching; he sleeps with his mouth wide open; and in the morning finds his tongue dry and covered with sordes.

3d. This nasal obstruction interferes with the faculty of hearing.

4th. This nocturnal obstruction can produce lesions in the naso-pharyngeal cavity of children, such as pharyngeal hypertrophy.

5th. In chronic otitis there is generally a nasal obstruction of this form.

6th. The intestinal treatment (with purgatives, etc.), has an indirect action upon the hypertrophic rhinitis.—*Archives de Laryngol. et de Rhinologie*, November 15, 1888.

Surgical Treatment of Cicatrices of the Hand.—DR. JUENGST (*Rev. des Sciences Médic.*) has performed autoplastic operations, according to the Italian method, upon three subjects aged respectively two, fourteen, and seventeen years, who were suffering from ugly cicatrices of the palm of the hand, with contraction of the fingers, due to burns.

He made one large incision into the skin, and divided the cicatricial tissue at several points, thus enabling the patients to extend their fingers. Then he took from the opposite lateral portion of the thorax a piece of skin, the dimensions of which surpassed by one-eighth of an inch the destroyed tissue of the hand; this was sewed to the hand with sutures of catgut.

The hand was then tied to the thorax, to prevent all motion for sixteen days. When the bandages were removed, the results were satisfactory.—*Revue de Thérapeutique*, December 1, 1888.

Treatment of Migraine.—DR. JAMES LITTLE highly praises the combination of salicylate of sodium and effervescent citrate of caffeine, which he has used with success in the treatment of migraine. His practice is as follows: Should the patient awake with the sensation of approaching headache, he orders him to take thirty grains of salicylate of sodium in a glass of water, which has been rendered effervescent by the addition of a dessertspoonful of granulated citrate of caffeine. If necessary, a second and third dose can be taken every second hour. The addition of the effervescent caffeine gives this mixture an agreeable taste, which would not be the case if the salicylate were taken by itself. One must not attribute the good effects obtained to the caffeine, as alone, it is ineffective, while a combined action of these drugs is immediately followed by good results.—*Journal de Méd. de Paris*, Nov. 18, 1888.

Antineuralgic Drops.—
℞.—Tincture of valerian
Elixir of paregoric
Cherry-laurel water } . . āā ʒijss.
Tincture of hemlock . . ʒjss.—M.

Take seven drops in a little water as soon as pain in stomach is felt.—*L'Union Médicale*, Nov. 18, 1888.

Erysipelas of the Nasal Passages.—At the late meeting of the International Otological Society held at Brussels, DR. SCHIFFERS of Liege, stated that he had seen two cases of this affection. The first following close upon an erysipelas of the face, brought on a rhinitis which terminated in perforation of the septum; the second case was preceded by an erysipelas of the scalp. The author remarks that erysipelas can also find its origin in the nasal passages. His treatment consists in washing the cavities with sublimate solutions of 2 : 1000 or 4 : 1000; and in tamponing the posterior nares.—*Archives de Laryngol. et Rhinologie*, November 15, 1888.

Saccharin as an Antiseptic.—DR. C. PAUL, *Courier Médical*, in his researches into the antifermentative properties of saccharin, has tried to fix the minimum dose required to prevent the development of certain microbes, with the following results: A ^{1} watery solution arrests the development of the bacterium termo; a solution of $\frac{1}{700}$ kills the staphylococcus pyogenes aureus. Applying these researches to the antiseptic therapeutics of the digestive tract, he prescribes the following in teaspoonful doses in a glass of water:

℞.—Saccharin . . . . . ʒjss.
Bicarbonate of soda . . . ʒj.
Alcohol . . . . . ʒjv.
Essence of mint . . . . gtt. xx.—M.

Gazette Médicale de Montréal, November, 1888.

Treatment of Warts.—Children often suffer from unsightly warts of the hands, which cannot be removed by caustic. DR. G. B. PULLIN, of Sidmouth, recommends in such cases the administration of two or three minims of liq. arsenicalis twice a day. In a week or ten days the warts will disappear.—*British Medical Journal.*

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, DECEMBER 22, 1888.

COMPLETE VERSUS PARTIAL HYSTERECTOMY FOR CANCER OF THE UTERUS.

IN April of last year we made extensive editorial comment upon total hysterectomy for cancer, based upon a paper by Fritsch, which had just appeared in the *Archiv für Gynäkologie*, Bd. xxix. Heft. 3, which set forth that he had then performed the operation 60 times, with a mortality of 11.6 per cent., including 2 deaths which could not fairly be attributed to the operation. Of his 53 survivals, 2 remained healthy after 3 years, 7 after 2 years, 8 after 1 year, and 3 after 10 months.

With the knowledge of these statistics, and more especially of those which have since appeared from the pens of Leopold, Martin, and others as successful, we had settled into the firm belief that total hysterectomy should be performed (certainly by those accustomed to similar surgery) in every case of cancer of the uterus, provided that no extension of the disease to the surrounding tissues could be demonstrated. Therefore we are much surprised to notice the direction which recent discussion of this subject has taken in France.

In the *Gazette Hebdom. de Méd. et de Chir.* of October 26, 1888, is contained a communication to the Société de Chirurgie from M. VERNEUIL, strongly urging partial extirpation of the carcinomatous uterus in preference to the radical or total operation, and the two following numbers of the same journal contain lengthy discussions of the paper, in which, to our further surprise, no voice is found to champion the measure which we had regarded as established. Facts thus differing so markedly from prevalent surgical opinion always demand careful scrutiny that no hitherto unknown observations and truths may escape us which might either prove us in the wrong, or, on the other hand, possibly render our tenets even more firm.

After stating that no operation save curetting is permissible, if the malignant process has infected the neighboring tissues, and that this latter cannot always be determined, Verneuil asserts that partial extirpation is one-half as dangerous in its immediate effects as is the radical operation. He reports 22 partial hysterectomies, with an immediate mortality of 4.9 per cent. C. Braun's mortality from the same operation is 6 per cent. To offset this statement we have Leopold's statistics (*Archiv für Gynäkologie*, No. xxx. Heft. 3), wherein he records 48 total hysterectomies—all but 6 for cancer; 38 of the neck and 4 of the body—with a death-rate of 6.2 per cent. from the operation, and others even more favorable if early attempts are excluded. It is more than probable that if statistics of the radical operation were confined to operations performed within the past two years, they would make a very much better showing.

It is next stated by Verneuil that recurrence takes place much more frequently after total hysterectomy than after partial, and figures are brought forward to prove this supposed fact. But what are they? Simply statistics of German operators, which include all of those early operations which were undertaken when the disease had widely spread beyond the borders of the uterus, and such as were never interfered with by the partial method, and so could not vitiate the results of the latter. And it is from these statistics that Verneuil concludes that recurrence is equal after either operation!

Is it possible or reasonable that an operation which simply removes the vaginal portion of the neck of the uterus by the écraseur is more radical and thorough than one which not only removes the whole uterus, but also the surrounding portions of the vaginal mucous membrane and proximal portions of the uterine ligaments and neighboring fasciæ? Certainly not; no more could we say that excision of a carcinomatous nipple would be more effectual than extirpation of the whole breast and the lymphatic contents of the axilla.

In addition to *not* being the most efficient and

relatively safe at our command, other objections to the partial operation are: that hemorrhage cannot in it be so readily controlled; severe atresia is apt to follow; whilst the possibility of subsequent pregnancy exists, which, should it occur, may lead to great and, probably, fatal injury. Again, the total operation probably has very seldom been performed for other than true cancer, whilst the partial, from its ease and supposed safety, has in many cases been performed where the disease was merely "suspicious."

Therefore, we still find no reason materially to change our belief, which remains: that the only thorough operation for uterine cancer is total hysterectomy, which procedure is only to be performed when no invasion of the surrounding tissues has taken place, and when the uterus is freely movable; that it is better to remove not only the uterus, but also its appendages when it is feasible; that partial hysterectomy is usually but a palliative measure, after which recurrence is much more apt to occur than when the radical operation is done, and that its mortality is but slightly below that of the most effectual, hence, safest operation.

Carcinomatous nodules have been found in the body of the uterus when, apparently, the cervix was infected with but the very earliest stages of that disease, so that if there is any radical cure for this terrible affection it would seem to be afforded by the radical operation performed at the very earliest moment possible after the diagnosis has been established.

THE DANGER OF SEPTIC INFECTION FROM NASAL AND AURAL DISCHARGES OF THE OBSTETRICIAN.

The familiar anecdote of the obstetrician who communicated septic infection to his patients from ozæna, with which he suffered, is emphasized by the report of two cases in which the media of infection were aural and nasal discharges in the obstetrician, published in the *Lancet* of November 24th, by Hewetson.

In the first case a neglected otorrhœa with retained pus had impaired the breath of a physician by continued but gradual septic absorption. On inquiry, it was learned that in his obstetric practice, which was extensive, septicæmia occurred frequently, and for which he could not account. Removal of the septic focus and the cure of the otorrhœa were followed by the disappearance of septicæmia among his obstetric patients. The second case was that of an assistant who suffered from syphilitic ulceration of the nares: attending a confinement in his preceptor's absence, the case ended fatally by septicæmia. His condition being recognized, he was immediately excluded from practice.

These instances of the direct consequence of septic matter are, unfortunately, not so rare in surgical practice as to be disbelieved by practical surgeons; and from the time of Semmelweiss the possibility of such an occurrence has been occasionally illustrated in obstetric practice. If demonstrative proof were needed, it has been supplied by Mittmann, who has examined material obtained from beneath the nails of various persons for septic germs. His results, published recently in Virchow's *Archiv*, showed the presence of micrococci in those engaged in occupations which brought them in contact with effete matter, and also in those habitually careless in the toilet.

It is quite possible that sufficient interest in the antiseptic toilet of the surgical or obstetrical case has been excited for the good of the patient; but the attention of physicians and nurses may still be directed to their personal toilet with advantage. A focus of suppuration in doctor or nurse should be promptly destroyed. The ears, nose, throat, and teeth, which readily harbor bacteria, should be maintained in a healthy and, hence, aseptic condition; the hands, as the constant medium of communication between the attendant and patient, require constant scrutiny and care; the hair and beard are troublesome appendages from the aseptic point of view, and require careful attention. Persons suffering from diseases attended by tissue necrosis should be debarred from attendance on the sick. If the physician would enjoy freedom from the responsibility of personally infecting his patients, he must pay the traditional price of liberty—eternal vigilance.

Dr. Joseph Leidy, we are glad to learn, has lately had another added to the many honors he has had conferred upon him. A recent letter from the distinguished French naturalist, Milne Edwards, brings the information that the Cuvier prize of the French Academy of Sciences has been unanimously voted to him. The letter states that the prize has never been conferred except upon the most distinguished scientists, such as Agassiz, Owen, von Baer, and Ehrenburg. The award is, therefore, all the more a great distinction.

Owing to ill-health Dr. Wittelshöfer has resigned the editorship of the *Wiener medicinische Wochenschrift*, and Dr. Adler has been appointed as his successor.

An Army Medical Board will be in session in New York City, N. Y., from May 1 to 31, 1889, for the examination of candidates for appointment in the Medical Corps of the United States Army, to fill existing vacancies. Persons desiring to present themselves for examination by the Board should make application for the necessary invitation to the Secretary of War, before April 1, 1889, stating the place of birth, place and State of permanent residence, and enclosing certificates based on personal knowledge from at least two persons of repute, as to American citizenship, character, and moral habits. Testimonials as to professional standing, from professors of the medical college from which the applicant graduated, and of service in hospital from the authorities thereof, are also desirable. The candidate must be between twenty-one and twenty-eight years of age, and a graduate from a regular medical college, the evidence of which, his diploma, must be submitted to the Board.

Further information regarding the examinations and their nature may be obtained by addressing the Surgeon-General, U. S. Army, Washington, D. C.

Dr. Landon Carter Gray was elected last week President of the Medical Jurisprudence Society of New York.

According to the *Medical Press* of December 5, 1888, the Censors of the Royal College of Physicians of London have been relieved from a position of much delicacy and anxiety, by the voluntarily tendered resignation of a member whose case has been under their consideration for some time past, and who has been accused of a breach of professional confidence in connection with the medical history of an illustrious patient whose case has excited the interest of two continents.

Sir Spencer Wells has been appointed a Deputy Lieutenant for the new County of London.

The fourth annual meeting of the Association of Ex-Residents of the Pennsylvania Hospital will be held at the Hospital, on Thursday, December 27, 1888, at 8 P.M. After a brief business meeting, there will be a social reception and entertainment, to renew and revive old friendships.

The Philadelphia Polyclinic has established a three months' Special Course in Ophthalmology, including didactic instruction and quizzing, with three hours daily of clinical work. The course will be systematic, aud is a departure from the ordinary six weeks' course that can be entered upon at any time. The necessity of the student first familiarizing himself with certain optical facts and principles, before he can intelligently study the diseases of the eye, has rendered such a departure necessary, and it will conduce to a more thorough mastery of the subject by the pupil.

The German government has issued a direction to physicians of Alsace-Lorraine to discontinue the writing of prescriptions in French. They must hereafter write in the Latin or German languages.

We learn from private sources that Prof. Waxham, of Chicago, has had ten recoveries in his last series of fifteen cases of intubation in diphtheria; twenty-two in the last series of fifty; and fifty-three in his entire series of one hundred and seventy-three—say thirty per cent. in all, with an unusually good showing, sixty-six per cent., in the last fifteen.

Finding that patients swallow well in the inclined position, with the ordinary intubation tube, Prof. Waxham has practically discarded the use of the artificial epiglottis with which his name has been favorably associated.

A new medical periodical, named the *Maritime Medical News*, has made its appearance at Halifax, N. S. It is edited by Drs. Campbell and Morrow, of Halifax, Drs. Daniel and Allison, of St. Johns, and Dr. McLeod, of Charlotte. We wish our new namesake of the seaboard every success, and especially that it may rapidly outgrow its present bimonthly form into the full stature of a weekly publication, as is becoming to all those who aspire to the guild which imparts "medical news."

REVIEWS.

A System of Gynecology. By American Authors. Edited by Matthew D. Mann, A.M., M.D. Vol. II. 8vo. pp. 1180. Philadelphia: Lea Brothers & Co., 1888.

This volume, which narrowly escapes being ponderous, completes the gynecological portion of the composite treatise. It is clearly and abundantly illustrated by 360 wood engravings and 4 colored plates, and typographically it is up to the high standard of its publishers.

While there can be no objection to a large volume treating fully of a subject in which Americans have done much

excellent and original work, yet the boundary between gynecology and obstetrics has been drawn in favor of the former. This is especially noticeable in the presence of an article on extra-uterine gestation in the present volume. That view of the limitations of obstetrics which recently led a general surgeon to read a paper to an obstetrical society, instructing its members in the performance of laparotomy for extra-uterine gestation, because laparotomy is an operation and he is an operator, illustrates the popular operative furor and marks an erroneous conception of the logical classification of medical science. Obstetrics is the science of gestation, whether intra- or extra-uterine, and the treatment of gestation is the province of the obstetrician. This topic might better have been given to one of the volumes on obstetrics.

Lee, of New York, writes in a concise and practical manner upon diseases of the vagina. He recognizes no clinical distinction between specific and non-specific vaginitis, although the frequency of specific inflammations about the tubes following gonorrhœa is admitted.

Engelmann, of St. Louis, discusses hystero-neuroses at length, citing an extensive array of cases. He considers the hystero-neuroses sympathetic affections, to be distinguished from hysteria. His is the gynecological point of view—that most of woman's diseases originate in the genitalia.

Thomas, of New York, writes upon extra-uterine gestation, holding the view that the diagnosis of tubal, abdominal, and interstitial pregnancy is possible. His record is thirty-three cases, with twenty-two recoveries. His method is early diagnosis; in early pregnancy destruction of the fœtus by electricity; in later pregnancy operative procedures. Twelve cases were treated by electricity; all recovered. He adds a table of thirty laparotomies for this condition, prepared by Harris.

Gross, of Philadelphia, contributes an exhaustive article upon tumors of the breast, written from the standpoint of the surgeon. His work in this subject is classical and standard; his conclusions are based upon the pathology of the diseases discussed and upon extensive observation. The results of his operation for mammary cancer compare favorably with any others.

Park, of Buffalo, writes upon diseases of the breast other than tumors. Pus production he regards as the result of germ-infection; phenomena of swelling, hardness, and congestion he considers caused by blood stasis, without infection.

Jenks, of Detroit, describes fistulæ and their treatment, illustrating clearly the various operations for their cure.

Baker, of Boston, writes upon the diseases of the bladder and urethra fully and clearly; his article being one of the most complete of the volume. Sutton, of Pittsburg, gives an interesting exposition of the operative treatment of non-malignant tumors of the uterus. He considers ergot valuable to check the growth of fibroids, but writes with especial fulness of surgical treatment. Electrolysis is omitted, and Apostoli's treatment is not fully considered in the former volume, in which it is mentioned under the head of electrical treatment.

Lusk's article upon malignant diseases of the uterus states the most recent data on the subject; the prognosis of total extirpation and partial removal is still undecided, statistics giving unexpected and apparently conflicting results.

Laceration of the cervix is treated at length by Bache McE. Emmet, of New York, who states the well-known views of Emmet on this subject and describes the operations for these conditions. He justly condemns the use of nitrate of silver to heal lacerations of the cervix, as advised by Ellwood Wilson. He has found lacerated cervix frequently caused by the operation of dilatation.

Busey, of Washington, describes the various methods of treatment for chronic inversion of the uterus. Kelly, of Philadelphia, treats of injuries of the perineum and pelvic floor. He disbelieves the power of nature to heal lacerations. He describes the modern operations for restoring lacerated tissues, illustrating the article by many original drawings. He considers Emmet's operation for restoring the pelvic floor best.

Goodell, of Philadelphia, contributes a valuable practical article on ovariotomy. The results of his great experience are given in his happy style, and the article may well be considered standard on the subject.

Battey, of Georgia, describes the operation which he ably claims, denying the confident assertions of Tait. His results are interesting, because sufficient time has elapsed since operation to enable a fair judgment of the permanent results. Fifty-four cases were operated upon, thirty-three cured; in fifty the menopause followed.

Coe, of New York, completes Battey's article on ovarian disease, and with Wylie, of New York, writes on tubal diseases. The latter does not believe that gonorrhœal infection is the invariable cause of salpingitis, nor would he extirpate the tubes as invariably as is frequently done. Mental disease is rarely benefited by removing the appendages, unless a positive lesion can be detected. A series of sixty-one operations without a death indicates the perfection of his operative procedures; he relies first of all upon aseptic cleanliness. Cases diagnosticated as recurring cellulitis he has frequently found to be salpingitis, caused by septic infection from instruments, tampons, or post-partum sepsis.

A timely and valuable discussion of the pathology of ovarian tumors is contributed by Howell, of Buffalo; supplemented by the clinical history and diagnosis of pelvic tumors other than uterine and tubal, by the Editor.

Harrison, of New York, completes the volume with a scholarly and interesting article upon uterine displacements, in which modern operative treatment is fully described.

The limits of this notice forbid a critical analysis of the volume; it contains the most recent knowledge upon the subjects of which it treats, fully illustrated, enriched by the practical views and experience which the extensive clinical observation of the writers enables them to offer to the reader. With its fellow, the volume gives a full and valuable exposition of American gynecology at the present day.

La Santé par le Tricicle. By Dr. Oscar Jennings, M.R.C.S., Docteur en Médecine de la Faculté de Paris, etc. Paris: O. Berthier, 1888.

The vast hygienic importance of exercise is slowly and with difficulty regaining in the estimation of moderns the place it once held in the minds of the most cultivated and powerful nations of antiquity. The signs of the times are unmistakable. Beginning with the revival of athletics some twenty-five years ago, the cult of physical exercise has spread from England to America and to France, and has greatly deepened and

strengthened the hold it already had upon Germany. The Latin races, outside of France, are also showing clearly its stimulating and beneficial influence. While we may recognize and deplore its occasional excesses, we should not blindly shut our eyes to the fact that we have in such exercise perhaps the most valuable prophylactic, and certainly one of the most useful therapeutic agencies which can be wielded by the physician of to-day. These, however, are general terms and when we come to consider the matter practically, we find that we must answer the questions: What are the indications for exercise? In what particular condition should certain exercises be prescribed? What is the evidence in their favor?

As regards Swedish movements and massage, these questions have long since been answered, but when we come to specific exercises, especially those which have the invaluable quality of interesting and amusing the patient, we find that but little has been done to systematize our knowledge and enable those of us who can not take up the subject as a labor of love, to advise or prescribe intelligently.

Dr. Jennings, in the work before us, has admirably succeeded, in the case of the tricycle, in producing a systematic description of its effects in different conditions which are usually treated by other and less agreeable methods. Beginning with a history of the machine and its employment, and considering the question of appropriate clothing for men and women, he details the various conditions under which the tricycle may be employed with benefit. Varix, hernia, hemorrhoids, gout and rheumatism, obesity, constipation and diabetes, nervous diseases, etc., receive attention and various cases are cited to illustrate the advantage of this form of exercise. Concluding chapters are devoted to the abuses of the tricycle.

The book is worthy a perusal by all interested from either a hygienic or therapeutic standpoint, in the rational employment of exercise and must undoubtedly be of great value to the enthusiasts in tricycling, whose numbers have of late greatly increased under the stimulus of the charmingly described journeys of Mr. and Mrs. Pennell. It is to be noted that in France a special journal "Le Veloce-Sport et le Veloceman" gives evidence of the widespread interest felt in that country in what is called "wheeling." Several similar journals are published in English and are constantly on the increase.

SOCIETY PROCEEDINGS.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, November 28, 1888.

The President, J. Solis-Cohen, M D., in the Chair.

Dr. William Hunt read a paper on

DIABETIC GANGRENE.

(See page 685.)

Dr. Thomas G. Morton, in opening the discussion, said that thirteen cases of diabetic gangrene had come under his observation, generally in consultation. In all instances the disease involved some part of the lower extremity, generally originating in one or more of the toes, or about the dorsum of the foot. Many years ago he witnessed a needle operation for cataract in a young girl who was known to be markedly diabetic; sloughing and gangrene of the orbital contents resulted, and death by coma occurred on the third day. With some few exceptions, the patients he has seen with gangrene in the course of diabetes, have been in good circumstances. He referred to this because it has been suggested that this disease more frequently occurs among those who are surrounded by the comforts and luxuries of life, and not among the poor. An inquiry recently made of the superintendents of our State hospitals for the insane shows that although more than twenty thousand patients belonging to the indigent class have been under the care of the present medical officers of these hospitals, there has not, it seems, been a single case of diabetic gangrene in the institutions at Harrisburg, Dixmont, Danville, Norristown, or Warren.

Gangrene in diabetes, in the cases he has seen, has generally started in a local inflammation, resulting from some very trivial cause; on several occasions he has known it to follow the operation of cutting a corn. The occurrence of gangrene in diabetes seems to be a certain indication of great nervous exhaustion, and of a general condition most critical. Although he has observed gangrene as a result of diabetic condition in parts of the body other than the extremities, notably in diabetic carbuncular disease, yet gangrene appears more often in the toes and feet, where there is but a moderate amount of cellular tissue, and where the circulation in such cases is apt to be feeble.

The surgical treatment of this form of gangrene can generally be but palliative, most of the cases he has seen have been promptly fatal. The ordinary principles of surgical treatment should be observed; all tension of parts ought to be relieved by deep, free incisions, which, by relaxing and draining the tissues, permit a better circulation; indeed, he has often arrested the rapid march of gangrene by such treatment. When a line of demarcation forms, which may occasionally happen, the question of amputation may arise. Occasionally the gangrene of diabetes is associated with most excruciating pain, not only in the affected limb, but apparently in the gangrenous parts. He has had two such cases, both females, and in each he performed nerve section, with partial relief in one, and with complete success in the other. In the first he sectioned the posterior tibial, in the other the sciatic. The latter case he saw in consultation with the late Dr. L. M. Service, of Belmont, near the Falls of Schuylkill; the patient was seventy years of age, a large portion of the foot was already gangrenous, the pain in the foot and leg as far as the knee was excessive. He sectioned the sciatic in the middle of the thigh; the gangrene, which was not apparently hastened or influenced by the operation, very slowly extended for some weeks, until a point about four inches above the ankle was reached, where a line of demarcation formed. Subsequently, Dr. Service, Jr., removed all the gangrenous parts without encroaching upon the living tissue. The patient improved, was able to move about her room with comfort, and with entire freedom from pain; eight months afterward she died from an attack of acute dysentery.

Dr. John Ashhurst, Jr., had but one recorded instance of diabetic gangrene in his personal experience.

The patient was a man of middle age, sent to the hospital with strangulated hernia of some four or five days' duration. The attending physician stated that the man had long been a diabetic. Operation was deemed imperative, and was undertaken. There was but a small patch of gangrene in the bowel, which was left in the wound after relieving the constriction, so as to allow the formation of an artificial anus. Next day not only the bowel but the edges of the wound and the surrounding tissues were gangrenous, and death rapidly ensued. It was a case, then, of rapid, moist gangrene, following a comparatively small incision.

Among the influences which predispose to spontaneous gangrene, the most common, perhaps, is alcoholism. Verneuil refers to this fact, and says that in what he calls "alcohol-diabetes" gangrene is particularly apt to occur, as there are then two predisposing causes acting at the same time. Another cause of gangrene, after amputations and other severe operations, as surgeons are aware, is the presence of certain forms of Bright's disease, the granular kidney especially. In these cases diabetes may sometimes coexist, and the presence of sugar fail to be recognized, simply because it is not looked for.

As to the treatment of diabetic gangrene, locally, the less done, as a rule, the better. He would wait not merely for the line of demarcation but for that of separation, which may appear some days or even weeks later than the former, before proceeding to amputate. In the majority of cases of spontaneous gangrene, diabetic or not, it is the better practice to trim away dead parts with forceps and scissors, rather than to attempt a radical operation. He had seen, after amputation, rapid return of the gangrene, spreading extensively and causing death.

Constitutionally, it is a suggestive fact that the one remedy of greatest value in spontaneous gangrene of any kind is a remedy which has obtained a deserved reputation in the management of diabetes, *i. e.*, opium. Opium in doses of one grain or one grain and a half, night and morning, or larger doses if needed, will often show its good effect in tending to arrest the gangrene in a short time. In many cases of spreading ulceration opium is also of value. For the treatment of diabetic gangrene then, opium internally and the less heroic treatment of the affected part seem to offer the best prospect.

Dr. James Tyson said that notwithstanding the exhibit made in the exhaustive paper of Dr. Hunt, he could not but think that diabetic gangrene is a rare disease. Taking his own experience, of fifty-five recorded cases in private practice since 1884, and probably at least twenty-five more prior to that date not so accurately recorded, and realizing as he always had, its possible occurrence, the fact that not a single case has occurred under his observation is a significant one. It is to be remembered, of course, that many of these cases passed from his notice before they terminated. Dr. Hunt had asked for a parallel to this case of paralysis, etc. He could not give an exact parallel, but one sufficiently so to justify an allusion in the same connection. A gentleman of multiplied business and financial interests came under his care for diabetes, when he was fifty-two years old. Three years later there occurred a sudden hemiplegia. Within a few days after the paralysis occurred, the glycosuria disappeared and has not returned, though nearly two years have since elapsed. The percentage of sugar had been at one time as much as seven per cent., and was constantly two and three per cent. Dr. Morton had alluded to the extreme pain in diabetic gangrene. He had observed the same thing in gangrene associated with granular kidney. He scarcely thought it should be regarded as peculiar to the gangrene of diabetes.

Dr. James Darrach had seen but one case of gangrene associated with diabetes. Two others of the legs and two of internal gangrene have also come under his notice. Those of the legs were in women over seventy years of age, and while he could not recollect about the condition of the urine in these cases, from his custom of examining the urine in old people, for sugar, it having been stated that it was not an unusual thing to find it in the urine of the aged, he doubts the probability of sugar escaping his notice.

Dr. Hunt had spoken of the more palpable and well-recognized forms of gangrene. Dr. Wm. H. Dickerson has reported that in the autopsies of five cases of diabetes he found peculiar morbid changes in the cerebro-spinal system, consisting in dilatation of the arteries and a degeneration of the nervous matter at certain points external to them occasioning destruction and excavation of the tissue around the vessel. Kaposi describes a peculiar form of inflammatory gangrene of the skin, which Dr. Darrach suggested might be owing—as has been described as the pathological condition in shingles—to necrosis of the nerve-terminal filaments. He mentioned these as a probable addition to gangrenous affections in diabetes, and would suggest that the nervous system should be examined more than has been done in autopsies of this disease.

He asked Dr. Cohen whether he included in his statement cases with small amounts of sugar, and whether the sugar was established by the cupric oxide test alone. His own examinations have led him to doubt the existence of this element in normal urine, the existence of sugar has been supposed from the reduction of the oxide of copper. This reaction is accounted for by the uric acid and kreatinin. He asked Dr. Tyson how far his examinations sustained this view.

Dr. W. Osler thought that Dr. Hunt underrated the proportion of cases of diabetes that die with pulmonary complications. In his own experience of six autopsies there were three—two of consumption and one of gangrene. Frerichs, in his monograph which contains a study of four hundred cases, states that nearly one-half of all diabetics die of lung disease. There are three forms: The most common is a rapidly fatal lobar pneumonia, very liable to terminate in gangrene. Secondly is a broncho-pneumonia, which is still more liable to be complicated with gangrene. Thirdly, and most commonly, there is genuine consumption, which is tuberculous, as demonstated by the presence of the bacillus.

Dr. Nancrede decided to add another case to the list; it was one of moist gangrene with large amounts of sugar in the urine, where the disease started in the fourth toe. In the other case he amputated the thigh high up for moist gangrene *not* due to diabetes. It illustrated the futility of amputating anywhere near the site of disease, for the artery was thrombosed to the groin. Unless the operation be done above the knee for gangrene of the foot, we are almost certain to have recurrence in the wound with rapid spread of the disease and death.

The practical outcome of this discussion should be to lay down a rule not to undertake any serious operation unless the urine has been tested for sugar, as well as for albumin. Since he assisted at an amputation of the breast in the practice of a friend, in which the urine had been found free from albumin prior to operation, but after the amputation the urine was found to be loaded with sugar, he has pursued this rule. Perhaps if the urinary examination included testing for sugar, as well as albumin, there would be fewer unexpectedly fatal terminations to operations and more cases of diabetes recognized.

DR. J. WILLIAM WHITE said that if Dr. Hunt had been able to elicit from his correspondents the facts as to the coexistence or absence of certain other conditions likely to give rise to gangrene, we could better estimate the relative etiological importance of diabetes in these cases. Thus, in one of Dr. Agnew's cases which he had the opportunity of seeing, and upon whom he performed a knee-joint amputation, the subject was a man of fifty-two years, with chronic alcoholism, and with marked atheromatous changes in the vessels. In this case we had, therefore, two conditions, either of which was competent to produce gangrene without the concurrent diabetes. Dr. Hunt's admirable and otherwise exhaustive paper would, perhaps, have been more conclusive had it been possible to include these points.

DR. S. SOLIS-COHEN said that Dr. Nancrede's remarks suggest an explanation of the comparative meagreness of hospital records of diabetes, and of its supposed rarity among the poorer classes. Urinary analysis is not as general or as thorough as it ought to be. In the Medical Clinic of Jefferson Medical College Hospital, where it is the invariable rule to examine the urine of every patient, no matter how trifling the complaint, not a year passes that one or more cases of unsuspected diabetes, or at least glycosuria, are not discovered. Further, he would suggest that out-patient clinics or dispensaries, and not hospital wards, are the places to search for public records of diabetics of the poorer class. The Jefferson Clinic has from five to ten or more cases of diabetes annually, in a service of about four thousand new cases. At the Philadelphia Polyclinic, during nine months of this year, between three and four hundred patients have been treated in the Medical Department, of whom three have been cases of diabetes. Considering the aggregate number of diabetics at these two clinics, of which he has personal knowledge, and remembering that urinary examinations are not as thorough as they should be in private practice among the poor, and that diabetics, as a rule, are walking cases until near the last; and, therefore, not to be looked for in hospital wards, he must doubt the force of Dr. Hunt's social distinction.

In reply to Dr. Darrach, he said that dependence was never placed upon a single test, and there was little probability that uric acid and kreatinine had been mistaken for sugar. One disadvantage of dispensary practice in these chronic cases was the inability to keep patients under observation for more than a short time. They wandered elsewhere, and might possibly be doubly or trebly reported.

DR. THOMAS S. K. MORTON desired to make more especial point of what the practice of antisepsis enables the surgeon to accomplish in dealing not only with diabetes, but with all sorts and conditions of depraved system, when upon them have been engrafted complications which, with modern methods of wound treatment, are at least entitled to have some attempt made for their relief. Under this heading would be included diabetes, Bright's disease, the graver infectious and contagious diseases, ataxia, and all other serious nutritional alterations dependent upon nerve or other change.

Now the dangers principally to be dreaded in undertaking operations in persons subject to such diseases are those of *infection*. Little need be feared until this dire calamity has occurred. The most innocent forms of senile or other gangrene may at any time become so infected and change their nature to one of greatest malignancy. On the other hand, even large areas of necrotic tissue will not putrefy nor infect the system until bacterial decomposition takes place in them. He was convinced that infected gangrene existing without skin lesion usually has derived that complication from noxious bacteria lying deep in the various appendages of the skin. Hence the evident advisability of protecting a part about to become sphacelated by antiseptic covering; preferably by a carbolic, or combined carbolic and sublimate dressing, for in such cases carbolic acid is a necessary constituent of the dressing that the fat and other skin glands may be deeply penetrated and disinfected by its influence —a property not possessed by sublimate and other disinfectants.

When infection takes place in a case of one of the above-mentioned diseases, the already depraved tissues are powerless to resist the onslaughts of bacteria, and frightful pillage and destruction are the result. Especially is the system unable to cope with the attacks of bacteria when diabetes is present, for then is provided, in addition to the other favorite pabula of bacteria, glucose, which, in tissue solution, affords a most capital medium for the culture and dissemination of poisonous and tissue-destroying microörganisms.

We must then have ever in mind, that in dealing with surgical complications of any of the diseases which have been quoted, but more especially in the case of diabetes, that our object should be:

1. To prevent infection of a part about to become gangrenous, by instituting disinfection and subsequent protection: and, above and beyond all, never to apply a poultice.

2. Only to interfere surgically when absolutely necessary.

3. To operate only with thorough and powerful antisepsis—asepsis will never answer in these cases.

4. To relieve tension absolutely, and to eradicate as much of the diseased tissue as possible, and to disinfect thoroughly and to render sterile all that cannot be so treated; for unless this be accomplished, a favorable result, or arrest of the destructive process, cannot be expected.

5. In suturing or dressing, to make no great traction upon any portion of the wound or its surroundings, and to provide most liberally for drainage.

6. To dress the wound in such a way as to prohibit subsequent infection, and to redress it upon the slightest indication.

7. To remember that non-union and non-healing will probably result, but that we may be bold in doing what seems indicated, for local harm cannot come save by infection.

Dr. De Forest Willard could not agree with the suggestion to make incisions to relieve the tension. He considered any interference injudicious in slow gangrene. The only safe plan is to wait for the line of demarcation. Some months since, a man almost moribund came to the hospital with gangrene of the leg, and wtih crepitation extending as high as the hip-joint. Under excessive stimulation, twenty-four ounces of whiskey daily, the patient rallied, and he cut away the parts with scissors, through the knee-joint. A quick operation, or one near the part, would have caused death. Recovery has taken place, though a spot is now making its appearance on the toe of the remaining leg.

Dr. Tyson was very glad to hear Dr. Darrach's remarks. He did not believe that sugar is ever present in normal urine. The copper-reducing substance in such supposed cases is most frequently the uric acid.

Dr. Ashhurst said in regard to the recommendation to amputate at a very high point in cases of spontaneous gangrene, the general consensus of surgical opinion is against it. In traumatic gangrene, of course, the case is different. There the proper course is, to amputate as soon as possible, at a point well above the limit of the gangrenous portion.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, December 4, 1888.

The President, George W. Jacoby, M.D., in the chair,

Dr. M. P. Jacobi presented a case of supposed

TUMOR OF THE PONS.

The case was that of a child, ten years of age, the illness dating from a fright three years before. The immediate symptoms had been trembling lasting two weeks. A little later the child had commenced to walk as if intoxicated and to have difficulty in using the hands. About three months after the seizure headache had been complained of for a number of weeks. The child had also commenced to grow fat and the head had increased in size. During the past summer the circumference of the head had increased one-third of an inch. At the present time the child was very fat, the chest and abdomen being particularly large. There was no actual paralysis. All of the muscles would respond to faradism, the peroneal muscles only requiring a current particularly strong. There was, however, a progressive paresis. The child could not sit upright and the head fell to the right side. She could walk only if supported, and all of the finer movements of the hands had been lost. There was intermittent external strabismus in the right eye and choked disk in both eyes, referred to a descending degeneration. The appetite was abnormally increased. There had been no pain throughout excepting the headache referred to and no sensory disturbances.

The case of the tumor of the pons reported by Dr. Hun, of Albany, had presented strikingly similar symptoms. In this case the pons has been uniformly enlarged by a slowly infiltrating gliomatous growth.

Dr. Sachs felt especially indebted to the author of the paper for the opportunity of renewing an old acquaintance with this interesting case, which he had seen and lectured upon at the Polyclinic, in April. At that time the size of the head had been about as at present. The general condition was as now, but the patient had been able to walk better She had been able to walk across the floor with the assistance of her father, moral rather than physical support being required. The gait however had been uncertain and the patient had reeled, he thought, to the right side. He had also found the paresis greater upon the right than upon the left, and had noted an apparent paralysis of the right abducens. The changes which he remarked were a progressive paresis of the arms and legs, and slight increase in the size of the head. In the spring, the speaker's diagnosis had been tumor of the cerebellum, favored by the paralysis of the abducens, which had a long course along the ventral aspect of the cerebellum, and might be affected by pressure from the growth. Such a fact would also explain the intermittent character of the symptom noted by Dr. Jacobi. He had not appreciated the objections to this diagnosis toward which the reeling and the vomiting certainly pointed. The knee-jerk was more marked upon the right side. The ankle clonus had been obtained upon the left and not upon the right at all. Dr. Hun's had been a very rare case. The majority of cases of tumor of the pons, had presented different symptoms. He made these remarks simply to justify his diagnosis. Dr. Jacobi had gone more fully into the case and possibly had developed further evidence.

Dr. W. A. Hammond asked why a multiple lesion was excluded.

Dr. Sachs suggested that if one lesion could not be definitely located, the indications for a multiple lesion must be even more obscure.

Dr. Hammond inquired as to the condition of the intelligence.

Dr. Jacobi thought that the intelligence was normal. The child could relate the circumstances of the initial fright very clearly, and had made inquiries in regard to the prognosis in her case.

Dr. Hammond noted a tendency to staccato speech. He had seen a number of cases of tumor of the cerebellum. He referred especially to the case reported by Dr. Gibney. The distinctive symptom of tumor of the cerebellum when uncomplicated with pressure upon the pons, was incoördination without paralysis, while that of pons lesions was a gradually increasing paresis. He had seen also, a good many cases of injury to the cerebellum by arrow wounds, bullet wounds, etc.—perhaps twenty cases in all. These were more likely to furnish indications in regard to the functions of the cerebellum than cases of tumor, where the effects of pressure complicate those of the destructive lesion. He had never seen a case of either tumor or injury of the cerebellum, without vertigo and nystagmus.

Dr. Jacobi closed the discussion. The diagnosis had been studied between an intracranial tumor and a diffuse hypertrophic sclerosis of the brain with a generalized lipomatosis. The latter was excluded by the absence of the more distinctive symptoms of pseudo-muscular hypertrophy and by the existence of the choked disk, the latter, pointing positively to intracranial disease. Diffuse sclerosis was, among other symptoms, invariably attended by convulsions, which had been entirely absent in this case. Intracranial tumor was diagnosticated therefore by exclusion as well as by the positive symptoms and by further analysis, located in the pons.

The speaker had not known that the case had been previvously seen by Dr. Sachs, or that a clinical lecture had been delivered upon it. The latter stage of the affection accounted for the main difference between the symptoms reported by her and those noted by Dr. Sachs. She had not, however, referred to a paralysis of the external rectus but to an intermittent spasm. The muscle could at all times be readily exercised. The history of vomiting too was limited to two occasions in May, and was not more marked than might have been accounted for by some digestive disturbance. Further, there was not only incoördination in this case, but complete incapacity. In lesions confined to the cerebellum, standing was simply difficult. In this case standing was impossible.

Dr. W. A. Hammond followed with a paper entitled

WEAK HEART AND ITS TREATMENT.

The paper referred simply to weakness of the muscular structure of the heart, uncomplicated by dilatation or valvular disease. The affection was very common, and while it might be fatal in its result, it might also be entirely relieved by treatment which could be resolved into medicinal, gymnastic, and dietetic.

Digitalis was the main medicinal remedy. The author had never observed the so-called cumulative effect of this drug. He thought, on the contrary, that it required increasing doses. He administered the infusion in two drachm doses for two weeks, when he increased the dose one fourth, repeating the increase at the end of the second fortnight. Convallaria he considered uncertain and unreliable. Strophanthus he thought of more value. Where there was intolerance to digitalis, this drug might be given. Strychnine was a valuable remedy in weak heart. He prescribed one grain in one ounce of dilute phosphoric acid, ten drops three times a day. Cocaine was a valuable remedy, one-fifth grain being given three times a day. It had been his custom to add two grains to one pint of Malaga wine, a wineglassful being used at a time.

Inhalations and hypodermatic injections were required often in the weak heart of disease. Hypodermatically he had used brandy, digitalin in $\frac{1}{20}$ gr. dose and nitrite of amyl, two drops diluted with thirty drops of glycerine.

Glonoin was useful in $\frac{1}{100}$ gr. dose. Hedicatin was, however, only temporarily useful. Exercise was required for the permanent relief of this condition. Mounting stairs was mentioned as a convenient form of exercise. People living in the country might mount hills. The physician should however be in attendance, and the exercise should be suspended when the action of the heart had accelerated fifteen beats per minute, to be resumed upon its tranquillization. The author's Sanatorium in Washington would contain a modified treadmill in which such exercise could be taken.

The dietetic treatment of weak heart referred particularly to ingested liquids, the quantity of which should be limited. By lessening the amount of liquids ingested, the total amount of blood in the body was diminished and the work of the heart lightened. In some cases he had reduced the daily quantity to twelve ounces, with marked improvement within forty-eight hours. The diet was further modified so as to reduce the amount of fat where this was excessive. He was aware of the work of Oertel and others. He presented the matter, however, as approved by his own experience and observation.

Dr. Leale referred to the numbers of recently enlisted soldiers who fell in the grand review in Washington, their previous occupations having been largely sedentary and predisposing to weak heart, which failed them in response to the demands for the unusual exertion of this occasion. In five hours ten ambulances had been filled, the speaker having been detailed to pick up those who thus fell by the way. The weak heart of typhoid fever and diphtheria was briefly alluded to. The weak heart of adolescence was often encountered, the child, from close school attendance or other sedentary habits, having failed to develop heart muscle sufficient to accommodate the growing frame.

Dr. Heinemann had been very much interested in Dr. Hammond's paper. He was interested to know of the Sanatorium referred to. He had during the past year visited a number of these institutions in Europe, and thought it to be regretted that in this country we had so generally failed to avail ourselves of the peculiar advantages which they afford.

Weak heart is one of the most common conditions met with in medicine; it is almost as common as dyspepsia. While actual disease of the heart may not be detected in connection with the condition, the sounds will be found not what they should be, and the radial artery will be found never more than half filled with blood. The causes for weak heart, are often dyspepsia, lithiasis, and excesses of various kinds—alcoholism, tobacco, and excessive coitus. The treatment should be directed first, toward the removal of the cause, bad hygienic surroundings, anæmia, or whatever it may be. Iron or the oxygen treatment are often efficacious.

In regard to digitalin, he could say that he had seen the cumulative effect, although not, perhaps, the cumulative effect of the materia medicas, which he thought was exaggerated. He had seen the pulse under the influence of digitalis one day eighty or ninety, and the next day forty or fifty, as strong or stronger than before. Convallaria, was he thought, useful combined with digitalis in the cases of heart failure in children and in cardiac dilatation. Cocaine was valuable in curing anæmia, as well as for its direct action upon the heart. In a recent case he had prescribed the wine of cocaine, intending to combine it with iron, but at the end of a week had found the anæmia so much improved, that the iron was considered unnecessary.

In the diagnosis of the weak heart of adolescence alluded to by Dr. Leale, it is well to bear in mind the condition of congenital narrowing of the aorta, to which, attention has been directed by Fränzel. This is not infrequently a cause of sudden death in young people. The speaker would not pretend to diagnosticate the condition except by exclusion.

In regard to the question of exercise, he hoped that treatment would not be systematized upon the plans in vogue in Europe. In the Black Forest, there are paths specially designated for pulmonary diseases, and other paths for other complaints. He had seen a sign on one of these paths reading "This is the end of the Oertel treatment." There is a rule too, that a Sanatorium for pulmonary affections should be built at the foot of a hill, so that the patient having taken his exercise in climbing the hill can easily get back. There is also conflicting

evidence as to the value of these "Cures." The Oertel treatment was antagonized by the Brothers Schott, who substituted a system of resist ' ovements, a species of wrestling with the nurse under the supervision of the physician. Cardiac calisthenics is the appropriate title of these exercises.

DR. HAMMOND closed the discussion. He was pleased to have called out so many interesting remarks. One interesting point in etiology had however, he thought, failed of recognition. This was, that a normal heart under ordinary circumstances, might become a weak heart by simple increase in the general body weight. He had a personal experience on this point. His ordinary weight was two hundred and forty pounds. When it increased to two hundred and sixty pounds, which it did about twice a year, he was troubled with weak heart. He was then accustomed to apply his own prescriptions as to diet and exercise. In this way he could reduce his weight thirty pounds in thirty days. He then again ate and drank what he pleased. When he went up to Mackinaw this summer he had been suffering from weak heart. When he returned he could climb anywhere and was perfectly comfortable.

It might not be out of place to add that the eminent surgeon, recently diseased in this city, had lost his life from this cause. The case had been at first reported as one of cerebral hemorrhage, but hemorrhage except into the medulla does not instantly destroy life, and subsequently the condition of heart failure had been reached.

THE PRESIDENT expressed the indebtedness of the Society to Dr. Hammond for coming from Washington, in order to be present at this meeting.

PHILADELPHIA ACADEMY OF SURGERY.

Stated Meeting, December 3, 1888.

THE PRESIDENT, D. HAYES AGNEW, M.D., IN THE CHAIR.

DR. DE FOREST WILLARD reported a case of

OPERATION FOR OPEN URACHUS.

The condition is so rare that he desired to place on record a case which occurred to him three years ago in a child then two years old. The urine had escaped from the umbilicus ever since birth. There was a spot two inches in diameter about the umbilicus with excoriated epithelium from which there was an offensive discharge. About half a drachm of urine escaped in the course of the day. The part had been cauterized several times with nitrate of silver, but it had not closed. The child was a female. The urethra was free from any obstruction, save that the labia minora were adherent in front of the orifice. The catheter could be carried to the top of the bladder, but a probe could not be passed through the urachus to the bladder. He cut down on the umbilicus, freshened the edges, and attempted to get primary union. The union was perfect, but in the course of a month a small papule formed, which subsequently opened and discharged urine, but only a few drops during twenty-four hours, and only when the bladder was allowed to become full. He again cut down and found the bottom in an unhealthy condition. This he scraped, applied chloride of zinc, and inserted a drainage tube. An occasional stimulating application was made and healing was perfect, the drainage tube being cut off as was extruded by the advancing granulations. There has been no return of the trouble. He considered the advisability of retaining a catheter during these operations, but decided that it was preferable to have the child pass water every two hours. After the second operation he emptied the bladder every hour.

This condition of open urachus is an exceedingly rare one, and is discussed in only one or two text-books, Agnew, in his *Surgery*, has a few lines in regard to it. He refers to one case of open urachus, and to another in which, while the urachus was not open, there was a cyst at the umbilical opening which became distended when the urine was retained and which disappeared when the bladder was emptied. He mentions a case of umbilical fistule in which urine was not passed, but in which hair and bone were discharged as a result of extra-uterine pregnancy. In Ashhurst's *Encyclopædia of Surgery*, umbilical fistula is mentioned. It is there stated that there may be various forms of dilatation of the urachus. There may be two or three patent filaments, one of which may become cystic. Tait speaks of urachal cysts of immense size, which have been mistaken for ovarian tumors, the correct diagnosis not being made until the abdomen had been opened.

DR. J. EWING MEARS reported a case of

FRACTURE AND DISLOCATION OF THE VERTEBRAL COLUMN.

in which he performed an operation with the view of affording relief.

June 18. E. F., female, æt. twenty-nine years, single, was brought to St. Mary's Hospital, having fallen from a third-story window, probably while in an epileptic fit, to which she was subject. She had one epileptic attack while being brought to the hospital. Examination showed that there were fracture and dislocation in the lower dorsal or upper lumbar region. There were paraplegia, incontinence of urine and feces, and aching pains in the lower extremities, but no loss of sensation. The day following admission an attempt was made to relieve the deformity by extension and counter-extension. This was without result. A broad binder was then applied around the abdomen which gave some relief. She was ordered fifteen grains of bromide of potassium three times a day. The urine was phosphatic, very turbid and deposited considerable sediment. There was pain in the hypogastrium.

20th. The bladder was washed out with a weak boracic acid solution. A small dark greenish spot appeared on the outer side of the left foot, increased suddenly, and finally disappeared. The urine was very ammoniacal, lower limbs were cold, and there was no return of motion. After consultation with the surgical staff, an operation was decided upon. An incision was made five inches in length to the left of the spinous processes in the region of injury. There was found dislocation between the first and second lumbar vertebræ with fracture of the body of the first vertebra. The dislocation was so fixed that, with all the effort it was thought advisable to make, it could not be reduced. Dr. Mears then cut away the articulating process, and also the lamina of the first vertebra, exposing the canal. He then passed a finger in front and found a fracture directly through the body of the vertebræ. This operation relieved the compression to a certain extent. The wound was then drained, sutured,

and dressed antiseptically. The urine following the operation was bloody and purulent and continued so for some time. The incontinence continued. Two weeks after this operation the patient was suspended and a plaster jacket was applied. No benefit seems to have been derived from the jacket, as it was removed and not reapplied under the direction of the surgeon who followed Dr. Mears's term of service.

August 5. Urine offensive and purulent, but not bloody. The bladder has been washed out at different times with nitrate of potassium, boracic acid, and quinine solutions. The internal treatment consists of quinine, iron, iodide and bromide of potassium.

6th. Massage was instituted and continued for three weeks; under this there was some return of motion in the left leg.

An examination made December 2d shows that the patient can flex and extend the left foot, move the toes and flex the left knee slightly. There has been slight return of motion in the right leg. She had a bed-sore early in September, from which she has recovered. She has had another for the past three weeks, but this is also healing. She is able to sit up in a chair and to move herself in bed. There is still incontinence of urine and of feces.

The return of motion in the left leg under massage is encouraging. Possibly the results would have been better if the patient had been suspended and the plaster jacket had been applied immediately after her entrance to the hospital. Since the operation Dr. Mears had received a paper from Dr. Burrell, of Boston, who refers to a number of cases in which decided relief has followed the application of the plaster jacket, and he records a number of cases in which operation has been performed. It is to be noted that he removed the articulating process and the lamina on the left side, and it is on that side that motion has returned. This seems to indicate that if the operation had been extended to the right side, still greater benefit might have been afforded. In regard to the effect of the accident upon the epileptic seizures, he would state that the patient has had but one attack since her admission into the hospital, and that occurred some three weeks since.

Dr. William Hunt said that in these cases he thinks that we should not confine our attention wholly to the injury of the spinal column. He has no doubt that at the time of many of such accidents violence is also often done to the sympathetic nerves and ganglia, and that the injury will prove fatal in a shorter or longer period, according to the power of endurance of the patient. The chief diagnostic signs of the sympathetic being coincidently injured with the spinal column and cord, are the effects upon breathing upon the intestines and bladder, as indicated by tympany, obstinate constipation, and retention or incontinence both of feces and urine. Priapism through vaso-motor disturbance is also often present and indicates injury to the sympathetic. It is a very unfavorable sign.

Dr. John B. Roberts said that the case described was under his care after Dr. Mears's term of service had expired. He thought that the motion in the left leg and foot improved while he was on duty. He gave her large doses of iodide of potassium, and endeavored to get rid of the cystitis by the use of intravesical injections. He saw an interesting case at Blockley Hospital, two months ago, in which Dr. J. William White cut away the spinous processes and laminæ of three or four vertebræ in searching for the cause of a paraplegia which it was thought might be due to the pressure of a tumor. By this means the cord was readily explored. No tumor was found. There were some adhesions between the dura mater and the pia mater. These were broken up. There has been, he understands, some amelioration of the symptoms. These two cases, with one operated on by Dr. Deaver, are the only three operations of this kind which have been performed in this city, so far as he knew.

CORRESPONDENCE.

INFLUENCE OF ANTIFEBRIN ON THE SECRETION OF MILK.

To the Editor of The Medical News:

Sir: In your issue of December 8th, I notice a report on the "Effect of Antipyrin on the Secretion of Milk." It has called to mind a case that I attended during the month of July, in which the administration of *antifebrin* seemed to have the opposite effect. I used antifebrin at irregular intervals, in the case of a lady with mild typhoid fever, with a view of controlling the temperature. The dose was five grains two or three times in twenty-four hours. At the time she was nursing a child, between five and six months of age. As the fever developed the secretion of milk developed very much, but I found after the administration of each dose of antifebrin, when its effect began to show itself on the temperature, that there was a sudden accumulation of milk in both breasts, to such an extent as frequently to demand relief by mechanical means. I do not regard this as a direct effect on the mammary gland, but suppose it to have been indirect by lessening the fever and by promoting secretion generally as a result, as a sweat would occur at the same time. Recollection of this fact may, however, be of service in other cases.

Reasoning from analogy (provided the explanation of its action given above is correct), we have good cause to think it would be especially indicated in so-called milk-fever, with high temperature and delayed establishment of the mammary secretion. Very truly yours,

W. R. Cushing, M.D.

NEWS ITEMS.

Glanders.—The following letter by Dr. George M. Sternberg, U.S.A., upon the subject of glanders as an infectious disease, and the propriety of killing animals suffering from said disease or farcy, as soon as recognized, has been published by the War Department, for the information and guidance of the army.

Glanders is an infectious disease in which the infectious agent has been demonstrated to be a living microörganism—a bacillus.

The bacillus of glanders was discovered by the German bacteriologists Löffler and Shutz, in 1882, and the discovery has since been confirmed by several other competent bacteriologists. It is found in the nasal secretions and ulcers of the mucous membrane, in the "farcy-buds," pustules, and enlarged lymphatic glands of infected animals, and it is probable that it is also sometimes present in the urine. It is a slender rod, somewhat simi-

lar in appearance to the well-known tubercle bacillus, but more uniform in size and somewhat broader. In preparations stained with fuchsin or with Löffler's solution of methylene-blue, clear spaces are often seen in the rods which have been thought by some authors to be spores, but this is doubtful, as Löffler has found that no development occurs after the bacilli have been exposed to a temperature of 55° C. (131° F.) for ten minutes.

Pure cultures of this bacillus have been shown to produce typical glanders in horses and asses, and it is recognized by bacteriologists as the cause of the disease. The disease may also be transmitted by inoculation to guinea-pigs and to field-mice, which animal (preferably guinea-pigs) may be used as a test of the infectious character of the nasal secretions of a suspected animal.

Exact experiments have shown that the bacillus of glanders is killed by exposure for five minutes to a five per cent. solution of carbolic acid, or by 1 to 5000 solution of corrosive sublimate. In practice it will be best to rely upon boiling water for the disinfection of all articles which can be immersed in it without injury—rope halters, blankets, curry-combs, bits, etc. To keep on the safe side, half an hour may be fixed as the standard time during which articles to be disinfected shall be immersed in boiling water, or exposed to steam at a temperature of 212° F.

Articles of leather should be repeatedly washed with a five per cent. solution of carbolic acid or a 1 to 1000 solution of corrosive sublimate; or immersed in such a solution for at least one hour. If the solution can be used hot, say 180° F., without injury to the material, this will be desirable.

All exposed parts of an infected stable should be thoroughly and repeatedly (three or four times) washed with a hot solution of one of the above-named disinfectants. The carbolic acid solution (five per cent.) will be preferable on account of the poisonous nature of the solution of the bichloride of mercury; but the latter is less expensive, and under proper supervision there should be no special danger in using it. After its use, feeding-troughs, etc., should be thoroughly scrubbed with hot water to remove all traces of the poisonous salt. The application of a lime-wash to all surfaces, after complete disinfection, will be desirable.

Stables occupied by infected or suspected horses should be disinfected daily by washing exposed surfaces with a five per cent. solution of carbolic acid, and nose-bags, halters, buckets used for drinking water, etc., should be carefully washed with the same solution or with boiling water.

In view of the reliability of known measures of disinfection, when properly executed, it is not necessary or justifiable to destroy Government property of value which has become infected by contact with animals suffering from glanders.

The propriety of killing animals suffering from glanders, as soon as the nature of the disease is recognized, is undoubted.

Killing the Yellow Fever Germs.—A press despatch from Jacksonville, dated Dec. 2d, states that F. E. Smith is busily engaged in building the steaming and drying rooms to be used for disinfecting bed clothing, carpets, and clothing. The rooms are tight compartments, ten by twelve by six and a half feet in dimensions, and are closed by trap-doors which are raised by means of pulleys. There is one steaming room and two drying rooms. The floors of the rooms are covered with steam pipes, those in the steaming room being perforated every six inches to allow of the escape of fine jets of steam. Mr. Smith expects to begin operations on Dec. 4th.

For blankets and such other articles of bedding as can be saved, three large cylindrical vats have been prepared, where they will be thoroughly purified with boiling water, after which they will be put through a steam wringer which revolves with great rapidity, forcing the water out.

Tin Foil.—Chocolates, confectionery, dried fruits, cheeses, and other alimentary products are very often wrapped in what appears to be, and is described as, tin foil, but is really an alloy containing lead. This dangerous practice is now prohibited in France, and the tin foil destined for this use must, under penalty, be composed of "fine tin," that is, an alloy containing at least ninety-seven per cent. of tin. Here is a subject which may be worth the investigation of public analysts.—*British Medical Journal*, December 8, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING DECEMBER 15, 1888.

PENROSE, THOMAS N., *Surgeon.*—Ordered for examination, preliminary to promotion.

OBERLY, A. S., *Medical Inspector.*—Ordered before the Retiring Board.

DICKSON, S. H., *Passed Assistant Surgeon.*—Detached from the "Richmond," and ordered to the "Pensacola."

ASHBRIDGE, RICHARD, *Passed Assistant Surgeon.*—Detached from the "St. Louis," and ordered to the "Richmond."

AUZAL, ERNEST W., *Assistant Surgeon.*—Promoted to Passed Assistant Surgeon.

WIEBER, F. W. F., *Assistant Surgeon.*—Promoted to Passed Assistant Surgeon.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM DECEMBER 11 TO DECEMBER 17, 1888.

By direction of the Secretary of War, JEDEDIAH H. BAXTER, *Colonel and Chief Medical Purveyor*, will proceed to St. Louis, Mo., and Hot Springs, Ark., on public business connected with the Medical Department; on completion thereof, to return to his proper station.—Par. 13, *S. O. 289, A. G. O., Washington*, December 12, 1888.

LA GARDE, LOUIS A., *Captain and Assistant Surgeon*.—Is granted leave of absence for one month, with permission to apply for an extension of three months.—Par. 15, *S. O. 290, A. G. O., Washington*, December 13, 1888.

By direction of the Secretary of War, NATHAN S. JARVIS, *First Lieutenant and Assistant Surgeon*, is relieved from duty at Fort Leavenworth, Kansas, and will report to the commanding officer at Fort Lewis, Colorado, for duty.—Par. 14, *S. O. 290, A. G. O., Washington*, December 13, 1888.

CHAPIN, ALONZO R., *Captain and Assistant Surgeon* (U. S. Army).—Is granted leave of absence for fourteen days, to take effect on or about December 24, 1888.—Par 1, *S. O. 261, Headquarters Division of the Atlantic, Governor's Island, New York City*, December 11, 1888.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL ARTICLES.

THE TECHNIQUE OF OVARIOTOMY AS PRACTISED AT THE UNIVERSITY HOSPITAL, BY PROF. WM. GOODELL.[1]

BY LEWIS H. ADLER, JR., M.D.,
RESIDENT PHYSICIAN AT THE UNIVERSITY HOSPITAL, PHILADELPHIA.

ALTHOUGH the general plan of treatment about to be described agrees with that laid down in Professor Goodell's *Lessons in Gynecology*, yet in some essential features it will herein be found to differ. For instance, opiates are never given now unless positively indicated. They were formerly used in every case, with the result of nauseating and constipating the patient, as well as checking all the secretions and excretions of the body.

Again, the habit of giving cracked ice has been abandoned, unless specially called for, as it tends only to create thirst and hinders digestion.

Likewise, food, which for a long time was given as soon after the operation as the patient could bear it, is not given now until after the lapse of twenty-four hours, nor is anything given by the mouth for this period of time if it can be avoided. By the adoption of this plan, the stomach of the patient is allowed to recover from the effects of the irritation induced during etherization, so that when food is given she is not made sick by the sight of it, as well as for the more important reason that intestinal peristalsis is not set up, and the consequent risk of peritonitis involved.

In the preparation of a case for operation, great care and attention must be exercised to secure a favorable result. All the emunctories of the body should be active; medicines of a tonic nature should be given, if indicated; moderate exercise indulged in, if the patient is able to stand it; and a good, substantial, easily digested diet required.

Some surgeons state that it makes no material difference whether a patient be operated upon during menstruation. Prof. Goodell, with the majority of operators, is inclined to think that midway between the "periods" is the time for an *operation of election;* though any time before, during, or after this may be taken, if the urgency of the case requires it.

On the day previous to the operation the patient is given early in the morning a full dose of *castor oil*, preferably, or else *compound liquorice powder*, or a dose of *Epsom salts*. During the afternoon of the same day the abdomen is thoroughly scrubbed, previous to which the patient has taken a warm soap-bath. After the abdomen is thoroughly cleansed, clean clothes are put on and she goes to bed. The following morning, the day of the operation, she is given an enema of soap and water, to empty the lower bowel. This is followed by another bath, together with a vaginal douche of bichloride of mercury, 1 to 2000. A carbolized towel is then placed over the abdomen and covered with waxed paper. This is retained in place by a roller bandage or binder.

Formerly it was the custom to shave the pubic region on the day preceding the operation; but as this needlessly alarmed the patient, Dr. Goodell defers this until after the anæsthetic has been administered.

Should there be a tendency to sleeplessness the night previous to the operation, some hypnotic should be given, such as potassium bromide, chloral, or the like; but not opium.

To avoid vomiting during or after the operation, a light breakfast is given upon the morning of that day.

The time for the operation having arrived and everything being in readiness: the instruments immersed in boiling water, in which a solution of carbolic acid has been placed; the hands of the operator and assistants chemically cleaned; the abdomen re-washed with a 1 to 1000 solution of corrosive sublimate; and the patient thoroughly etherized—the operator, standing upon the right side, begins the operation by an incision in the median line of the abdomen, cutting through the skin and fat with the intention of hitting the linea alba beneath. This latter is not always an easy matter, especially when the walls of the belly are not distended by a tumor. An excellent way to find this line is that employed by Prof. Goodell, who passes a probe across the rectus muscle, to the right and to the left, and the nearest point of arrest indicates the linea alba. The dissection is cautiously continued until the peritoneum is reached, which lies behind the recti muscles, separated by a cellulo-adipose tissue. A grave error which I once saw committed elsewhere is the mistaking the peritoneum for the walls of the cyst, and peeling the same off as you would the cyst from its connection.

[1] Read before the D. Hayes Agnew Surgical Society.

It is not always an easy matter to distinguish the two, but, as a rule, the peritoneum is not as pearly a white as the sac of a cyst, and it is always covered with a layer of peritoneal fat.

Before opening the peritoneum the hemorrhage incurred thus far is to be checked with catch forceps made for this purpose, after which, by means of the dissecting forceps, it is picked up and gently cut through, care being taken to avoid any stray loop of the intestine; after which, by inserting two fingers of the left hand in the opening thus made, the wound is enlarged to the necessary extent.

The opening in the abdomen does not complicate the case any by being made as large as desirable. Should necessity require it, the wound must be enlarged, as is sometimes done, even to the ensiform cartilage. When the incision extends beyond the umbilicus, it should be made to go directly through the navel. Some operators afterward cut out the umbilicus; but the plan first mentioned is, upon the whole, the safer method.

If a cyst is discovered bound by adhesions to the abdominal walls, it should be separated by the finger, and thereby avoid as much of the subsequent hemorrhage as possible, for it sometimes is a very troublesome thing to control. Should much hemorrhage ensue, it should be controlled by ligatures or catch forceps, as much of the success of the operation depends upon this apparently minor point.

When all the reachable adhesions have been severed the cyst is ready for tapping: the trocar and canula, thoroughly clean and previously dipped into a solution of carbolic acid, are plunged into the interior of the tumor at the upper part of the wound. The trocar is withdrawn, when the fluid flows into the vessel prepared for its reception. When the sac contains more than one cyst, it will be necessary to push the trocar into each cyst until all have been drained. If any of the fluid escapes into the abdominal cavity, as it often accidentally does, antiseptic precautions promptly taken will, as a rule, prevent any subsequent harm.

The empty cyst is now pulled out through the abdominal wound, and severed from its attachment; previously to which, strong forceps with a firm grip are passed one on each side of the pedicle of the tumor to control the bleeding and to secure the same, for ligaturing. I say *ligaturing*, for Dr. Goodell prefers the silk ligature, carbolated, which in time, he says, becomes disintegrated and absorbed, to any of the other methods proposed by ovariotomists. It is a subject—this final treatment of the pedicle of the tumor—upon which, at the present day, there is much disagreement. Among the methods proposed are the clamp, the ligature, the cautery, and the écraseur. This last method is the only one I believe which is almost universally condemned. So that with this exception, any of the plans, according to the exigencies of the case, and the preference of the operator, may be used. Dr. John Homans, in relating his experience in 384 laparotomies, says that he considers the actual cautery, when properly used, sufficient in almost all cases of ovariotomy to secure the pedicle. He objects to the silk ligature, saying that it is not always absorbed or encysted. In proof of this statement, he mentions a case in which a silk ligature escaped two years after it was fastened to a pedicle, with the knots and cords of same in perfect condition.

The pedicle having been firmly secured, it is returned to the abdominal cavity, where in most cases —as shown upon the post-mortem table—it becomes encysted or encapsulated, and finally absorbed.

The wound in the abdominal walls is now ready to be closed. First, however, the abdominal cavity must be thoroughly cleansed, particularly in Douglas's pouch and the peritoneal fold between the bladder and the womb, as otherwise septicæmia or peritonitis may result. After this has been done a large, flat sponge is placed over the intestines, under the wound, in order to catch the blood that issues from the suture tracks. Each suture is double-threaded —that is to say, has a needle upon each end—which allows its being passed from within outward. Each needle is inserted about a quarter of an inch away from the edge of the wound, and it is well, if possible, to include in the sutures all the layers of the parietes, cutaneous, muscular and aponeurotic, peritoneal.

I would mention particularly the muscular layer, because many ovariotomists think that by including the recti muscles abscesses are apt to follow in the suture tracks. Dr. Goodell is of the opinion, and rightly, that it is better to run the risk of a stitch abscess, than the more serious and grave one, of ventral hernia. His rule is to include these muscles in the suture, whenever they are exposed to view.

When all the sutures have been inserted, the flat sponge, previously placed underneath to catch the blood escaping from the punctures, is removed, and the abdomen reëxamined to see if any oozing has occurred; then, if all is dry, the operator catches in one hand all the sutures on his side; his assistant does the same upon the opposite side, and the edges of the wound are brought firmly together, and, at the same time, all the air is expelled from the abdominal cavity. Each suture is now tied by means of the surgeon's knot.

When the whole wound is closed, the ends of the sutures are gathered together and cut off several inches from the knots. If any superficial stitches are needed they are now put in, after which the wound is ready to be dressed. First, however, it is thoroughly cleansed and dried. Iodoform is then liberally sprinkled over the surface of the abdomen, particularly into the umbilicus; upon this a fifty per

cent. iodoform gauze is placed and over this several layers of dry carbolated gauze, over which adhesive strips of rubber plaster are fastened. Next comes a wad of cotton wool which has been thoroughly baked, in order to destroy any germs, and finally over all a flannel binder.

Formerly it was the custom of Prof. Goodell to use an opium suppository at this stage of the case; but for reasons already stated this practice has been stopped, and it is now the exception, rather than the rule, to use an opiate to relieve pain in these cases.

Hot bottles are now applied to the body, care being taken that they do not come in too close contact with the skin, as the burns which they make are unusually severe. Absolute quietness must be observed and no one allowed to see the patient but the nurse and the physician.

When the case is one requiring a drainage tube, the fluid in the same must be removed every two hours for a day or so after the operation, and to prevent injurious pressure upon the bowels by the tube it must be lifted up and turned around occasionally. It can be removed entirely, whenever the fluid is colorless, or nearly so, and does not exceed in quantity a couple of drachms. This is usually about the third or fourth day.

The subsequent treatment of the patient, after the operation, needs the most careful attention. She must not be left alone at any time; the pulse, respiration, and temperature must be carefully noted at least every two hours. If the patient be greatly shocked, every effort must be made to secure reaction; which, in part, is accomplished by the hot water cans already applied, and by hypodermatics or enemata of brandy and the like. Should obstinate vomiting occur, ice should be given or sinapisms applied to the epigastrium. If these fail, it is stated by some authorities that minute doses of calomel and morphia, repeated at short intervals, are efficacious. If there is much flatulence, it must be relieved by inserting a flexible catheter high up into the rectum, by enemata of turpentine or by turpentine combined with soap and water.

As a rule, it is necessary to catheterize a woman for a day or so after the operation; but it is a good plan to avoid this as much as possible, as the too frequent use of the catheter is likely to cause an irritable bladder, and one which is slow to respond to treatment. For the first twenty-four hours nothing whatever must be given the patient—by the mouth, especially—unless indicated. Even cracked ice is avoided by Dr. Goodell, though it was his former practice to give it, as stated in his book recently published. On the second day, half an ounce of milk is given every two hours, and the quantity is increased gradually as the patient's condition demands.

If the temperature is high, 101° or over, ice should be applied to the head, the body sponged, a saline cathartic given, or some of the popular anti-febrifuges administered.

The bowels are to be freely opened on the fourth or fifth day after the operation, with castor oil, or if, for some reason, this drug cannot be given, compound liquorice powder is a good purge, and being agreeable to the taste, most persons will readily take it. If these fail to act, they must be supplemented by an enema of soap and water.

From a week to eight or nine days, the dressing first put on is ready to be removed, and the stitches taken out. The wound is first washed with some antiseptic solution, then with alcohol, after which the stitches are removed, and the abdomen re-washed and dressed as before; but with the addition of adhesive straps. To prevent any possibility of hernia at the site of the wound, the patient is kept in bed from two and a half to three weeks, and then for months has to wear some kind of a close-fitting binder or abdominal supporter. I might state that some ovariotomists are opposed to this long wearing of the binder, one of the principal objectors being Mr. Frederic Treves, a London surgeon, who states that by an over and prolonged use of an abdominal support, the parietes are weakened, and that the secret of success in preventing ventral hernia is not to allow the patient to get out of bed too soon—a month or longer not being an unreasonable time.

The subsequent dangers of ovariotomy likely to arise are collapse, hemorrhage, septic poisoning, and peritonitis.

Collapse usually occurs immediately after or during the operation. The treatment has already been alluded to in detail.

Hemorrhage, when internal, will require the wound to be reopened, and the bleeding vessels sought for and tied.

Septic poisoning is indicated by a frequent pulse, an elevated temperature, feebleness, mild delirium, and, at times, marked chills. The treatment is a brisk saline cathartic, and the administration of large doses of quinine. This complication of the case, as a rule, ends fatally.

Peritonitis is the greatest cause of the mortality in this operation. Its symptoms are well known: a wiry pulse, extreme abdominal tenderness and distention, etc. The prognosis in a case of peritonitis complicating ovariotomy is not usually grave. Saline cathartics, poultices over the abdomen, and stimulants are called for, and is the treatment usually pursued.

In concluding this article, I wish to make a few remarks about *menstruation after both ovaries are removed*, and to discuss briefly the question, *whether ovariotomy, after puberty, unsexes a woman.*

It is an undoubted fact that some women do menstruate after their ovaries are extirpated. There is a case in the University Hospital now who, for two years and two months after her ovaries were removed, saw regularly her monthly sickness. Some authorities explain this unexpected condition by saying it is due to force of habit, to a law of periodicity; others, to some fragment of ovarian stroma left behind by the operator; whilst a few claim its existence to be due to a third or supernumerary ovary. Any of these theories might be accepted, for they are all plausible enough, but the exact truth is not known, and probably never will be.

Finally, as to a woman being unsexed by the operation of ovariotomy. I think most authorities agree to the fact that, after the removal of the ovaries, a woman's sexual feelings gradually lessen, but are at no time entirely lost.

Dr. Goodell replies so aptly to this question that I cannot do better than quote his own words upon the subject: "So far as can be ascertained, spaying after puberty does not unsex a woman; at least not more than castration after puberty unsexes a man. In the one, the ability to inseminate is lost; in the other, the capability of being inseminated; but in both, the sexual feelings remain pretty much the same."

NOTES ON THE USE OF STROPHANTHUS.

By J. Y. DALE, M.D.,
of Lemont, Pa.

Last summer I was called upon to treat a case of exophthalmic goitre, in a married woman aged about thirty-five, the mother of half a dozen children. The disease, which had been of several months' duration, was progressing rapidly, and, as a result, the patient was very nervous and anæmic. The action of the heart was so tumultuous and irregular that the sounds could not be differentiated, nor could the frequency of the pulse be accurately determined, though when the patient was at rest it did fall below 120.

Tincture of strophanthus was prescribed in doses of five drops t. i. d., to control the action of the heart, which it did effectually—at least after two weeks' employment the heart became regular in rhythm, though not in force, the pulsations were reduced to 80, and the murmur in the goitre lessened in intensity. At that stage of the disease I gave a mixture containing six drops of tinct. ferri chloridi and two drops of liquor. arsenici chloridi, at a dose, three times daily, but in three days such general and extensive anasarca had developed that it was omitted. Under the continued use of the strophanthus, and of tonics, with the faradic current applied to the goitre, there was a decided amelioration of all the symptoms; the action of the heart became steadier, the goitre lessened in size, the appetite improved, and the strength increased. Unfortunately, after being so much benefited, my patient declined to submit to further treatment.

Amongst the cases of typhoid fever treated during the past season, I had eight patients in whom, after the first few days, a condition of apyrexia supervened, continuing, unless there was a relapse, until the commencement of convalescence. These cases were usually mild, though several of them had most of the prominent symptoms of the disease, excepting, of course, the elevation of temperature; but they were nearly all lingering, some lasting four weeks before the tongue cleaned. They were mostly attended by cardiac weakness, shown by breathlessness after slight exertion, feeble heart sounds, a slow pulse, sometimes under 60, coldness of the extremities, and often of the entire surface of the body, necessitating the use of artificial heat. When prescribed in these conditions strophanthus exerted a most happy effect. I have also used the drug under other circumstances, when it seemed to be indicated, with apparently excellent results.

Judging from my very limited experience, strophanthus would seem to have considerable power as a heart tonic, but to test the value of a remedial agent requires prolonged and careful trials by many different observers; and to aid in this good work, I wish to contribute my mite to the recorded experience of the profession respecting the merits of this new candidate for therapeutic honors.

A CASE OF ARSENICAL NEURITIS.

Reported by H. C. WOOD, M.D.,
professor of materia medica and therapeutics and clinical professor of diseases of the nervous system in the university of pennsylvania.

The following case is perhaps worthy of record as an illustration of the value of persistent careful treatment in nervous degenerations due to metallic poisonings. At the time when the woman first entered the University Hospital, the symptoms were so severe that it seemed impossible that a good result could be achieved. The thighs and legs below the knee could almost be spanned with one hand.

I would call attention to the large doses of strychnine employed; the effects of the alkaloid were not so pronounced and brilliant as in cases of lead poisoning, but I believe distinctly conduced to recovery.

L. B., aged twenty-five, mother of one child, enjoyed good health until June 1885, when she ate "rough on rats" spread on bread which had been put in the closet to kill rats. After this there was some discomfort in the stomach; but according to her own statement, not until five hours had

elapsed were the symptoms very marked. She then vomited matters having a metallic taste, and during the following night vomiting was repeated several times. There were also violent pains in the stomach and all over the body. The next day there was repeated vomiting, with great epigastric tenderness, and violent pain produced by taking water or other substance into the stomach, also diarrhœa. She was in bed for several days, then got up and was about until the 9th of July. There was, however, persistent irritability of the stomach with frequent vomiting; great abdominal pain and tenderness; no appetite; small ulcers in the mouth; obstinate constipation, and, according to her assertion, some days after taking the poison, puffy face followed by general swelling of the body; and, subsequent to this, the appearance of a red rash with small watery blisters followed by an outbreak of large and small boils all over the body. The secretion of the urine is said to have been very scanty. By the end of the eighth week the skin eruptions had disappeared, but had left the skin harsh and desquamating. Along with these symptoms there were neuralgic pains in the limbs and progressive emaciation, and she did not begin to improve or gain flesh until September.

She entered the University Hospital on the 21st of January, 1886. At that time she was pale, emaciated, with the legs and arms very thin and flabby; tongue furred, marked with shallow transverse fissures and slightly tremulous. The appetite and digestion good with no evidences of gastric discomfort. Pulse 92, but weak; heart sound weak, but normal; very slight tenderness over the epigastrium. Menstruation, which had not occurred for several months after the poisoning, had reappeared. The movements of the arms could be executed, although very feebly. The fingers were numb and somewhat distorted in their habitual position. She could not button her clothes with the eyes shut, and could, with difficulty, when the eyes were open. The legs were excessively wasted and covered with long, harsh, black hair, much more pronounced below than above the knee. According to her statement, this hair had developed after the poisoning. She habitually lay with the knees drawn up, and the hamstring tendons tense, and on attempting to straighten the legs, pain was caused just above the patella. She complained of a feeling of picking and stinging in the legs, and when she was touched of a soreness as though she had been bruised; there was also much pain in the toes and occasional sharp cutting pains shot down the nerve trunk to the legs; the nerve trunks were tender. Specific gravity of the urine 1019; no albumin. No response of the leg muscles could be obtained in the ward to the faradic current, and the case was referred to Dr. Lloyd for a study of the electrical condition of the muscles. He reported as follows:

Right leg. Peronei muscles much diminished. 16 milliampères cause slight contraction. C C C = A C C, also nodal changes. Gastrocnemius about the same. Degeneration reaction of the adductors and vastus internus. Rectus femoris, no response.

Left leg. Condition about the same as right leg.

Right arm. Marked diminution in response in the median nerve; some of the flexors do not respond at all, some show nodal changes. Extensor and ulnar muscles do not show De R to any extent; the changes are rather nodal than serial.

Left arm. Similar to the right.

To the faradic current there is marked diminution in median group, slight diminution in ulnar and extensor group.

Deltoids. Both normal; slight increase in response to galvanism.

There was no anæsthesia to be discovered by means of a single point; but in all of the body, and especially the legs, there seemed to be hyperæsthesia. (Examinations of the sensation by the æsthesiometer or of temperature sense, if made, were not recorded.)

After sitting up, feet would become swollen. On putting the feet and legs in hot water for ten minutes, then rubbing them with ice, and then reimmersing them in the hot water, a glow was created in the feet, but the pale color of the legs did not change. She was ordered massage, treatment with the galvanic current, the practice of the hot water bath with the ice rubbings, daily; the iodide of potassium, one grain, three times a day with tonics.

By January 1st there had been no distinct improvement in the legs, but some in the arms. It was noted that the current from a battery of forty cells produced good contractions in the arm muscles, but the current from sixty cells caused in the leg very little effect except pain, although some contraction could be obtained in the adductors and the anterior tibial muscles. In addition to the previous treatment, she was given hypodermically one-thirtieth of a grain of strychnine in the arms and legs twice a day. A few days later it was found necessary to stop the injections of the strychnine on account of local irritation produced by them, and she was ordered the alkaloid in ascending doses by the mouth.

February 19, 1886, it was noted that she had been slowly improving, and that "at present the application of the constant current elicits contractions from the muscles of the legs; also that she is taking five grains of the iodide of potassium and one-third of a grain of strychnine per diem."

March 11th, it was noted that great improvement had taken place in the hands, but less in the lower extremities. An attempt was now made by attaching weights to the feet about one-half hour daily to aid the massage in straightening the lower extremities. Hypodermic injections of atropine into the flexors of the thigh were also given daily before the attachments of the weights.

April 5th, it was noted that the limbs were somewhat straighter than a month before; that she was able to propel herself around the ward by a wheel crutch which had been obtained for her a few days previously, but that in the crutch she supports almost all her weight by the arms. The daily dose of strychnine had reached three-fifths of a grain.

March 28, 1886, it was noted that she had free use of her arms and hands and thighs; on the wheel crutch she could use her feet enough to propel herself with ease, and she could stand by a table. There was still, however, constant abnormal flexion

of the knees. Her appetite and general health were good, and she insisted upon being discharged from the hospital.

October, 1888, a sister-in-law of Mrs. B. came to my office as a patient: she stated that three or four months after Mrs. B. left the hospital she became pregnant, and was in due time delivered of a healthy child; that for a long time after leaving the hospital she gradually did more and more of her housework sitting in a chair, but that little by little she began to use her legs more freely, and is at present restored to her health, walking about doing her various household duties, etc.

MEDICAL PROGRESS.

The Uses of Creolin during Labor.—DR. MINAPOULUS read a paper at the Munich Gynecological Society, giving the results obtained from the use of creolin during labor, at the clinic of Professor Winkel. The irrigation of the vagina was begun with a ½ per cent. solution, then increased to a 1 per cent. and later to a 2 per cent. solution in conjunction with the use of two pints of lukewarm water at each sitting. These irrigations were made immediately before and after delivery, and were used in the subsequent lying-in period only, when the temperature rose to a fever point. In every instance the mother would complain of a slight burning sensation, no doubt due to some lacerations of the mucous membrane, the result of labor.

Before each examination the hands and instruments were thoroughly disinfected with creolin.

Of 140 cases thus treated, 2 were severely infected, 1 dying, and 19 were less severely infected.

The two septic cases were treated with the ½ per cent. solution, and only during labor, and not immediately before nor after delivery. Of the remaining 19, 2 were examined in their own dwellings, and, no doubt, were already infected when they came to the institution. There thus remain 17 slightly infected cases.

Of 140 cases treated with a ½ per cent. sublimate solution, 3 were severely infected, with 1 death, and 13 less severely.

The author concludes that the results obtained with creolin are as favorable, if not more so, than those obtained with corrosive sublimate. Cases of abortion, in which the secretions had a gangrenous odor, were treated with excellent results, with a 1 per cent. solution of creolin. Vaginal tumors healed quicker when treated with a concentrated solution of this drug, than when treated with the ordinary bichloride of iron applications. Creolin, it is claimed, will prove a valuable substitute for corrosive sublimate and carbolic acid, as it posseses all their advantages with none of their disadvantages.—*Wiener med. Presse*, November 25, 1888.

For Dyspepsia accompanied with Palpitation.—

R.—Compound tincture of cardamon . ℥ij.
Aromatic spirits of ammonia . ℥ij.
Bicarbonate of soda . . . ℥j.
Infusion of gentian . . q.s. ad ℥vj.—M.

Sig. One teaspoonful when required.—*Revue de Thérapeutique*, December 1, 1888.

Spasm of the Glottis of Nasal Origin.—DR. ALBERT RUAULT, in his monograph upon this subject, comes to the following conclusions:

1st. Certain lesions of the mucous membrane lining the nasal passages, such as mucous polypi or hypertrophic rhinitis, can reflexly provoke repeated paroxysms of spasm of the glottis, which, in certain cases, have proved grave enough to necessitate tracheotomy.

2d. These attacks of spasmodic laryngeal dyspnœa can occur at long intervals (as many as twenty years or more intervening) and will baffle all treatment, until attention and medication are directed toward the intranasal trouble which is the cause of the dyspnœa.

3d. It would seem that women, and especially those who are predisposed to attacks of hysteria, are more liable to this affection than men, but instances have occurred in which this trouble showed itself in both men and women without either being of hysterical diathesis.

4th. Spasm of the glottis of nasal origin can attack children as well as adults.

5th. General bronchial spasm is often observed in conjunction with spasm of the glottis, and at times one can observe, between the paroxysm, a more or less spasmodic condition of the entire respiratory tract.

6th. Voice troubles due to phonic laryngeal spasms are also frequent complications of this disease.

7th. The prognosis is very favorable when the cause of the trouble is recognized, but unfavorable if not recognized or if due to a hypertrophic rhinitis.

8th. The diagnosis is to be made by exclusion of all causes known to bring on spasm of the glottis, and by a rhinoscopic examination, aided by the sound and by painting the nasal passages with a solution of cocaine, which in spasm of the glottis of nasal origin, not only overcomes this spasm, but also any spasm of the bronchial tubes.

9th. The treatment of the paroxysm if grave, consists in painting the nasal passages with cocaine, in the administration of chloroform, and finally in the opening of the trachea, if the patient's life is menaced.

10th. The treatment of this affection consists in treating the nasal passages, which are the main seat of the trouble.—*Archives de Laryngol. et Rhinologie*, November 15, 1888.

Phenic Acid in the Treatment of Diseases of the Skin.—DR. BERTOLUS (*Thèse de Lyon*, August, 1888) gives the results of his observations on the therapeutic action of phenic acid in skin diseases, in the following *résumé*.

1st. Taken internally, phenic acid is an excellent remedy for the prurigo of Hebra. Not only does it diminish the pruritus, but acts also upon the papules.

2d. It modifies the exudative eczemas, and those resembling lichen.

3d. It seems to act directly upon the nerve extremities.

It is useless to allow the daily dose to reach above five to eight grains in the young, and between seven to thirteen grains in the adult, as larger doses will not produce any greater benefit, if, in fact, they do not do harm. Small doses can be continued for weeks or months with good results.—*Revue de Thérapeutique*, December 1, 1888.

Helleborein, the glucoside of helleborus niger and helleborus viride, has been used as a substitute for digitalis.

Drs. Victorio and Ehridia have discovered that it is an efficient local anæsthetic; when used in a one per cent. aqueous solution, three or four drops placed in the eye of a dog or rabbit produce anæsthesia of the cornea, lasting about thirty minutes, without producing disagreeable secondary effects.—*Apoth. Ztg.*, 1888; *Amer. Journ. Pharm.*, December, 1888.

Treatment of Ozæna.—Prof. Cozzolino, of Naples, recommends the following treatment for ozæna:

R.—Salol	. . . . .	75 grs.
Boric acid	. . . . .	45 "
Salicylic acid	. . . . .	7½ grs.
Thymol acid	. . . . .	3 "
Powdered talc (℥ij)	. . .	2 drachms.

Or

R.—Bichlor. of mercury	. . .	1½ grs.
Resorcin	. . . . .	22½ "
Benzoic acid	. . . . .	30 "
Boric acid	. . . . .	3 drachms.

These powders are applied to the nasal passages, after having irrigated the same with carbolic or salt water, using, in so doing a Weber's douche. At the same time the following preparation is to be applied to the nose morning and evening:

R.—Distilled water	. . . .	℥iv.
Alcohol	. . . . .	1½ ounces.
Chloride of zinc	. . . .	30 grs.
Thymol acid	. . . .	3 "
Menthol	. . . . .	4½ "

—*Wiener med. Presse*, November 4, 1888.

Fifteen Gold Pieces Swallowed.—Dr. Siotis (*Bull. médicale*) had occasion to treat a patient who had swallowed fifteen gold pieces. The patient complained of great pain in the epigastric region. On auscultation, the patient making some motion, one could plainly hear the noise made by the clashing of the money.

The administration of purgatives was followed with negative results. The author then administered pills containing laudanum and belladonna, which resulted in the finding of three of the fifteen gold pieces in the evacuation the following morning. The next day four more pieces were discharged; a severe pain was felt in the right iliac fossa, percussion over which gave forth a metallic sound. By degrees the rest of the money was evacuated, and the patient made a rapid recovery.

This case is interesting, first, on account of the number of pieces swallowed, and second, in that it demonstrated that where cathartics have to be discarded, belladonna and laudanum give the best results.—*L'Abeille Médicale*, December 3, 1888.

Creasote in the Treatment of Phthisis Pulmonalis.—Dr. Austin Flint, in a paper upon creasote in the treatment of phthisis pulmonalis, presents the following conclusions based on ten cases treated in his service during the past summer at Bellevue Hospital, with inhalations of creasote by a method suggested by Dr. Beverley Robinson. The improvement noted in these cases, when Dr. Flint took charge of the wards, was so considerable that he directed the treatment to be employed in all the cases of phthisis pulmonalis in the male wards, with the exception of a few in the last stages of the disease. This report will be read with interest in connection with Dr. Robinson's paper in the number of *The American Journal of the Medical Sciences* for January, 1889.

The records of ten cases reported show that creasote by the stomach and the inhalations, in cases of solidification without cavities, effect prompt and decided improvement in all phthisical symptoms, with increase in appetite, weight, and strength, even with surroundings much less favorable than would obtain in many cases in private practice.

In cases with small cavities much less improvement is to be looked for, but some benefit may be expected.

In cases with large cavities the treatment seems to have little more than a palliative influence.

The observations here recorded are defective as regards the influenee of the treatment upon the bacilli. In one case, with large cavities, it was noted that the number of bacilli was diminished. No other examinations for bacilli were made during or after treatment.

No estimate was made of the relative value of creasote taken into the stomach. As regards the inhalations, it is assumed that the chief benefit was derived from the creasote, the spirit of chloroform and the alcohol rendering this agent more volatile, and soothing the mucous surfaces. The inhaled vapor undoubtedly penetrated by diffusion as far as the air-cells. It is by diffusion that fresh air, anæsthetic vapors, etc., penetrate the lungs, and cases of pneumonokoniosis illustrate the fact that even solid particles may be carried to the pulmonary vesicles.

Dr. Flint has employed the method of inhalation here described, conjoined with other treatment, in private practice, with good results. In a case of irritative cough of several months' standing, with slight bronchitis and emphysema, but no signs of phthisis, which resisted ordinary treatment, three inhalations produced complete relief, and the cough had not reappeared at the end of four weeks.—*New York Medical Journal*, Dec. 8, 1888.

For Uterine Hemorrhage.—

R.—Extract of Indian hemp	. .	7½ grs.
Fluid extract of ergot	. .	1 drachm.
Fluid extract of hamamelis, Tr. of cinnamon	. .	āā ½ ounce.—M.

Sig. One teaspoonful three times daily.—*Revue de Thérapeutique*, December 1, 1888.

Simple Test for Arsenic.—To the suspected liquid is added, in a test tube, a solution of caustic potash or soda, and then a fragment of aluminium. The mouth of the tube is then closed with paper moistened with a solution of nitrate of silver. If arsenic be present, the paper turns black. Aluminium is preferable to zinc, for the latter may contain arsenic, whilst aluminium is always free from it.—*Farm. Ital.*; *Arch. de Pharm.*; *Amer. Journal Pharm.* December, 1888.

Magnesium-silicate in Chronic Diarrhœa.—This preparation is administered by Dr. Debove, in twenty-five to sixty grain doses. In the diarrhœa of phthisis, if given with milk and for a prolonged period, it will overcome the diarrhœa, and improve the appetite and digestion.—*Deutsche med. Wochenschrift*, November 22, 1888.

Injections of Lemon-juice in Epistaxis.—After having vainly tried all remedies recommended to overcome

epistaxis, DR. GENEUIL resolved to test the value of lemon-juice. The results obtained were surprising; nasal hemorrhages which had lasted from twelve to fifteen hours, and which had resisted all known hemostatics, were brought under immediate control.

His mode of procedure is as follows: With the aid of a small glass syringe, he first washes the bleeding nasal cavity with fresh water, in order to remove all possible clots, and directly afterward injects a syringeful of fresh lemon-juice. Within less than two minutes hemorrhage ceases; if not, the injection is repeated.

The author does not attribute the resultant good action to citric acid (as he, on two occasions, made use of a concentrated solution of citric acid with negative results), but rather to the *ensemble* of substances contained in the lemon.—*Bulletin de Thérapeutique.*

Accidental Rashes in Typhoid Fever.—In a paper upon this subject read before the Section of Medicine of the Royal Academy of Medicine in Ireland, DR. JOHN WILLIAM MOORE sums up his conclusions as follows:

1. Not infrequently, in the course of typhoid fever, an adventitious eruption occurs, either miliary, urticarious, or erythematous.

2. When this happens, a wrong diagnosis of typhus, measles, or scarlatina respectively may be made, if account is not taken of the absence of the other objective and subjective symptoms of these diseases.

3. The erythematous rash is the most puzzling of all; but the prodromata of scarlet fever are absent, nor is the typical course of that disease observed.

4. This erythema scarlatiniforme is most likely to show itself at the end of the first, or in the third, week of typhoid fever.

5. In the former case, it probably depends on a reactive inhibition of the vaso-motor system of nerves; in the latter, on septicæmia, or secondary blood-poisoning; or both these causes may be present together.

6. The cases in which this rash appears are often severe; but its development is important rather from a diagnostic than from a prognostic point of view.

7. Hence, no special line of treatment is required beyond that already employed for the safe conduct of the patient through the fever.—*Dublin Journal of Medical Science*, December, 1888.

Diphtheritic Conjunctivitis.—DR. ABADIE speaks of the efficacy of lemon juice, as recommended by Dr. Fienzal in the treatment of diphtheritic conjunctivitis, of which affection he had lately three cases to treat. Being not then acquainted with the powerful action of lemon juice, he tried the juice in one case, and antiseptics, galvanocautery, and iodoform in the remaining two cases. It was not long before he was convinced that lemon juice held the same place as a specific for diphtheritic conjunctivitis as does nitrate of silver in purulent ophthalmia. —*Bulletin Gén. de Therapeutique*, November 30, 1888.

Spasmodic Cough resembling Whooping-cough, cured by Chloride of Methyl.—DR. GAREL (*Annales des Mal. du Larynx*, etc., August, 1888) reports the case of a girl thirteen years of age, affected with spasmodic cough. The voice was hoarse, the vocal cords rosy red, the glottic functions appeared normal. Different medicaments, especially antispasmodics, had been employed without effect. A strong spray of chloride of methyl, applied to the neck and the upper part of the back and anterior surface of the neck cured the condition.—*Journal of Laryng. and Rhinology*, December, 1888.

Terpin in Bronchitis.—This remedy seems to have been largely prescribed of late by Parisian physicians. CHÉRON'S preparation has been most frequently used; its formula is given as follows in the *Monde Pharm.* of October 5th:

R.—Terpin . . . . . 75 grains.
Glycerin . . . .
Alcohol (of 95 per cent.) } āā 2–2½ ounces.
Syrup of honey . .
Vanillin . . . . . 4 grains.—M.

One tablespoonful contains about seven grains of terpin. Two tablespoonfuls are given daily to loosen and finally diminish expectoration. In the above doses it is not liable to cause gastric disturbance, especially if given after meals.—*Amer. Journal of Pharm.*, December, 1888.

The Biniodide of Mercury in Ophthalmic Surgery in New York.—MR. DAVID WEBSTER writes to the *International Journal of Surgery*, October, 1888, that the use of bichloride of mercury solutions in ophthalmic surgery has been abandoned at the Manhattan Eye and Ear Hospital, on account of corneal opacities following a certain number of cataract operations wherein those solutions were employed. The surgeon of the Royal Ophthalmic Hospital about the same time reported a similar experience. In March last, he gave up the bichloride in surgical cases having corneal relations, and now uses Panas' fluid in all iridectomies and cataract extractions. The formula for this fluid is biniodide of mercury 1 part, absolute alcohol 400 parts, pure water 20,000 parts. The results under this plan have been unusually satisfactory.

Treatment of Scarlatinal Diphtheria.—PROFESSOR O. HENBUER, of Leipzig, treats the diphtheria of scarlet fever with injections of three to five per cent. solutions of carbolic acid into the tissue of the tonsils from which it passes into the lymphatics. The injections are to be continued until the lymphatics are reduced in size and the temperature has fallen nearly to normal.—*Med. Chirurg. Rundschau*, December 1, 1888.

Myrtol in Tuberculosis.—DR. EICHHORST recommends the internal administration of myrtol to overcome putrefactive processes of the air-passages. This preparation is administered in two grain capsules, two of which are taken every two hours. It can be continued for weeks, without causing any bad after-effects. Not only does it ameliorate the gangrenous odor of the expectoration, but diminishes also the quantity of the expectorated material. It does not stay the progress of the tuberculosis.—*Münchener med. Wochenschrift*, November 27, 1888.

For Dysmenorrhœa.—DR. J. SHAW recommends a mixture of belladonna and hyoscyamus for the relief of dysmenorrhœa. It is particularly in the so-called neuralgic or spasmodic form of the affection that this mixture seems to afford the greatest amount of relief.—*Lancet*, September 22, 1888.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

INDISCRIMINATE LAPAROTOMY.

"A GENERAL Summary of Conclusions from a Second Thousand Abdominal Sections," by LAWSON TAIT (*British Medical Journal*, November 17, 1888), affords interesting material for the consideration of the profession in general as well as the laparotomist. Practitioners who care for the health of families are called upon to treat a considerable number of cases of pelvic or abdominal disease in women, and it not infrequently happens that ordinary methods of treatment fail, and a disease not fully understood and possibly threatening life seems developing. The decision of the time when palliative and expectant treatment is no longer justifiable, and when the pressure of threatened danger is assured, is a difficult problem and generally requires especial skill and experience.

Mr. Tait's results furnish the most favorable showing possible for the radical specialist in gynecology, who does not hesitate to perform laparotomy for diagnostic purposes. The range of his experience has been phenomenal; his results correspond to his experience, and he hopefully draws attention to the diminished mortality of his second series, and admits his improvement in judgment, power of diagnosis, and operative skill with increased experience, with the confident expectation that his gains will continue. Diagnosis by exploratory incision, in Mr. Tait's hands, shows a mortality of 3.7 per cent., while the operative treatment of abdominal and pelvic disease results in 5.3 per cent. mortality.

While these results are a most gratifying exhibition of special scientific work, they should not mislead the profession. If an experience of 2000 operations by an expert is required to obtain these results, the tyro may well hesitate to perform a radical operation until every means of diagnosis at his command has been exhausted, and ability in diagnosis and experience superior to his have been summoned. The brilliancy of such statistics minimizes the technical difficulties to an inexperienced man, who is thereby led to underestimate the responsibility which is first entailed upon him: that of making a correct diagnosis.

To attain skill in treatment a thorough logical analysis of cases from the standpoint of pathology is requisite. A statistical, operative ambition must be subordinate to the less brilliant study of the processes of the disease. The profession must realize that it is not the performance of a given number of laparotomies nor the proprietorship of a certain number of hospital beds devoted to patients treated by laparotomy which constitutes a specialist in gynecology; but diagnostic power, operative skill, and sound judgment, which can only be obtained by special training in early professional life, with a thorough education in the pathology of the regions of the body and organs treated. The possessor of these qualifications will not fail to receive the cooperation of the practitioner and the honorable position which scientific work deserves; his aid will be summoned intelligently and, therefore, reasonably, and the best interests of the profession and the patient will be furthered. In contrast to indiscriminate laparotomy, discriminating laparotomy is one of the brightest laurels of modern medical science, as exemplified by Mr. Tait.

GOVERNMENTAL RELATIONS TO YELLOW FEVER IN FLORIDA.

A BILL has been introduced in the United States Senate authorizing the appointment, under the Marine-Hospital Service, of a special sanitary inspector, known to be an expert in yellow fever and inland quarantine. This proposition appears to emanate from Florida, many of whose citizens are desirous of securing the valuable services of Dr. James Y. Porter in some responsible relation to the sanitary needs of that State.

It is not impossible that this kind of legislation may result in good, but we are persuaded that it is not in this way that the key of the situation, so far

as the prevention of yellow fever is concerned, is to be found. We hold that the right thing to do, that almost the only thing to do, is for the Legislature of Florida to take measures, at the earliest practicable moment, for the establishment of a State Board of Health having ample powers and a liberal endowment. On this point we have already spoken, with some emphasis, in our issue of the 8th instant, stating, in brief, the grounds for this urgent demand in behalf of the welfare of that State and of thousands beyond its boundaries. We take occasion here to add our conviction that if the correct legislation shall be enacted, there will be found in Florida physicians and sanitarians competent to administer it vigorously, intelligently, and with success.

The complete stamping out of yellow fever, the happy issue for which the whole country devoutly prays, will not be accomplished by any half-way measures, but by a thorough observance of the known precepts of sanitary law.

PROFESSOR W. OSLER, of the University of Pennsylvania, last week delivered three lectures on "Cerebral Localization," at the University of Toronto Medical College. The lecture theatre was crowded by the students of the College. The Faculty and many members of the profession were also present at the lectures, which were a most able exposition of the subject. Dr. Osler received an enthusiastic welcome—an ovation in fact—in this University in which he began his medical studies.

A PRESS dispatch states that Dr. James E. Reeves, of Chattanooga, Tennessee, has been studying the tissues of the liver and kidneys from patients who died with yellow fever at Decatur, Alabama, and claims to have discovered a microörganism that closely resembles a specific germ. The finding of such a microörganism, however, is a long way from the demonstration that it is the specific cause of the disease.

ACCORDING to this year's catalogue of the University of Pennsylvania, the number of professors in the Department of Medicine, including the hospital service, is 71, and of students 458. The course in medicine has been partially extended, and the following information concerning the innovation is given: "The course of study earnestly recommended to students extends over four years, but the course is also arranged for three years, at the end of which the degree may be conferred. For the fourth year, almost wholly practical in character, a certificate is granted in addition to the diploma, to those who pass a satisfactory examination in the studies of that year."

WITH profound regret we record the death, on the 20th inst., of Caspar Wister, M.D., of Philadelphia, in the seventy-first year of his age. Dr. Wister was widely known in the profession through his connection with the American Medical Association as its Treasurer and the trusted manager of its finances through the long period of twenty-three years, extending from 1854 to 1877. He was also Treasurer of the International Medical Congress, held at Philadelphia in 1876. He was a man of cultivated mind and scholarly tastes, and was held in the highest respect and esteem by all whose privilege it was to know him.

A DELEGATION of Munich physicians, headed by the burgomasters of that town, recently presented Dr. von Pettenkofer, in honor of his seventieth birthday, with a purse of 10,000 marks, to be devoted to the foundation of a prize, bearing his name, the income of which is to be awarded for original scientific research in hygiene. The city of Leipzig sent the additional sum of 5000 marks for the same purpose. Dr. von Pettenkofer also received congratulations from the Prince of Bavaria, universities, corporations, and numerous friends and eminent personages.

SOCIETY PROCEEDINGS.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, December 6, 1888.

THE PRESIDENT, T. M. DRYSDALE, M.D., IN THE CHAIR.

DR. WILLIAM GOODELL showed a specimen of what he deemed to be an

EXTRA-UTERINE FŒTATION.

A healthy lady, æt. thirty-three, had been married thirteen years without conceiving. Her catamenia had always been regular up to two months before he saw her, when they were delayed for over two weeks. A few days before they reappeared, she was seized with a violent pain, "like cramps" in the pelvis, "shooting upward like knives." This was followed by syncope. Hypodermatics of morphia were resorted to, and she was left with a pelvic soreness that kept her in bed for several days. During the flow of this delayed period, a second attack of pain occurred analogous to the first, but not quite so severe. In about a week another hemorrhage came on. A few days later, she had a third attack of

pain and of syncope, which took place at night. A third hemorrhage now occurred, which was also followed three days later by a severe pelvic colic. This seized her as she was in the act of getting out of bed. The last attack took place on November 18th, and she was left for several days very weak and nervous. On the 25th, she consulted Dr. Goodell about the pelvic colics, irregular hemorrhages, painful defecation, and occasional pains running down the left leg.

He found a small womb pushed forward and to the right, by a boggy tumor, lying to the left in Douglas's pouch. The diagnosis of extra-uterine fœtation was made; its dangers explained, and an early operation insisted upon. Both the lady and her husband were so shocked by this discovery, and seemed to be so incredulous, that Dr. Goodell deemed it best for them to get the opinion of another physician. He sent them to Dr. Joseph Price, who confirmed the diagnosis.

Very early in the morning of November 29th, while she was in his private hospital, a fifth attack of pain of a "bursting feeling," aroused her out of a sleep. This was followed by faintness. At nine o'clock, about six hours after this attack, laparotomy was performed. As soon as the cavity of the abdomen was opened, a large amount of black blood, of the consistency of thin molasses, welled out of the incision. Several knuckles of intestine were also forced out, which could not be wholly kept in during the operation. The right ovary was sound, but the left could not be discovered. In its place was found an irregular cavity, within which was found a tumor about the size of an egg, containing within its sac layers of coagulated blood. It was attached to the broad ligament, which was tied and cut off. A very large number of old clots and shreds of fibrin were flushed out of the abdominal cavity by means of a syringe, six quarts of water being used for this purpose. A drainage tube was put in and the wound dressed with iodoform gauze. So much hemorrhage occurred later through the tube, that he spent several hours by the side of his patient, fearing it would be needful to reopen the wound. But, by dint of keeping the blood from collecting in the tube, the bleeding points were kept dry, and the hemorrhage ceased spontaneously. The tube was removed on December 3d, and the patient thus far has had an uninterrupted convalescence. Dr. Goodell had not been able to examine the specimens carefully, but Dr. Baldy, who was present at the operation, had cut it open and he would like him to describe it.

DR. BALDY said that the history of the case had been rather typical of extra-uterine pregnancy, and the escape of dark-colored blood from the abdominal incision at the time of the operation seemed to confirm this opinion. The mass, which had been shown, was brought to the surface and cut away, after being tied. This was apparently all that was to come away, there being nothing left but a sac, filled with old blood-clots, which sac was formed by adherent intestines, and uterus, and pelvic walls. The mass itself contained a semi-fluctuant tumor the size of a small egg, which he felt confident contained the fœtus, before it was opened. On being laid open, it appeared like a large blood-clot, parts of which had undergone degeneration, presenting a mottled appearance. A small portion of normal tube seemed to run directly into this mass, and as it reached it, spread its coats out over the mass. The ovary was nowhere to be found. He believed that the mass was a blood-clot, but could not explain its occurrence. The fœtus was not found.

On motion of Dr. Baer, the specimen was referred to the Committee on Morbid Growths.

DR. JOSEPH PRICE read a paper on

TUBAL DISEASE A PRIMARY CAUSE OF INTESTINAL OBSTRUCTION.

In reporting cases he has repeatedly called attention to the frequency of adhesions occurring between the uterine appendages and some parts of the intestines, and his purpose in this brief note was to emphasize the importance of recognizing the danger of obstruction of the intestine arising from inflammatory conditions of the pelvic viscera. In glancing over the cases he has operated on during the past year, he finds that in more than fifteen per cent. there were noted "dense, firm adhesions" between the intestines and uterus and appendages, malignant cases not included. In every case, with a single exception, as far as he could determine from the history, symptoms, and operative developments, the inflammatory conditions causing the adhesions originated in the uterine appendages. He did not intend to discuss the pathology of inflammations in the pelvis, nor to present distinct evidences, nor to cite numerous authors who have recognized these lesions, as Greig-Smith and others, for the few general observations he desired to make. And, first, as to the form or kind of obstruction likely to occur. The inflamed serous surface of the diseased tube, or ovary coming in contact with a loop of intestine, or an edge of omentum, provokes inflammation there, and with characteristic promptitude these surfaces cohere. If the process is not severe and of slight duration, these adhesions may disappear as promptly as they occurred, by the enormous absorptive power of the peritoneum, and hastened by the mild influence of the peristalsis of the bowel. If, however, the inflammation is severe, or assumes a chronic condition, these adhesions gain in extent and strength, and give rise to all the variety of conditions classified by Treves as "strangulation by bands." In most cases in which these adhesions occur, there is a history of constipation. It is probably due as much to the pain caused by defecation as to interference by the condition. Again, the pain is often so great as to mislead the physician into thinking that a more virulent inflammation exists than really does. But the pain is not always proportionate to the amount of mischief. He has seen cases in which a mere omental adhesion has caused most agonizing pain. For instance, he recently saw a case in consultation, a woman who had had the appendages removed for backache, some time before, and who suffered excruciating pain, especially on defecation. In this case, the only lesion found was the omentum firmly adherent to the original incision. The omentum here was much elongated, and the transverse colon was dragged below the level of the umbilicus. In like manner he has seen the omentum adherent over the entire pelvis, dragging the transverse colon so out of place that a twist or kink of the bowel could be very easily found. It is not at all rare to find the vermiform appendix glued fast to the uterine appendages, while almost any loop of the small intestine may become adherent to the inflamed pelvic viscera.

These adhesions vary in extent and density from those that will tear like wet tissue paper, to those so well orga-

nized that it requires the scissors to release them, and it is not rare in pus cases for the bowel to be almost gangrenous about these points of adhesion, and, in fact, to tear through. That adhesions do not cause complete occlusion at the time of their formation, oftener than they appear to, is no reason for regarding them lightly, for Mr. Treves tells us in the series of cases he studied, that the average duration of the interval between the causation and the obstruction was three years; the shortest period being five weeks, and the longest twenty-one years. In view of these general considerations, it is hardly necessary to insist upon the release of the intestine whenever and to whatsoever extent adhesions exist. For if the surgeon leave adhesions when he closes the abdomen, he leaves a probable cause of future serious trouble. Louis reports a case in which an ovarian cyst when emptied by the trocar, so dragged upon an adherent bowel that intestinal obstruction developed. He is prone to believe that some of the deaths from intestinal obstruction after operation, are due to leaving old bowel adhesions undisturbed.

DR. WM. GOODELL said that his experience in ovariotomy, led him to say that it is a mistake to postpone the opening of the bowels to a late period. He used to follow the old plan of not giving a cathartic until the eighth day, but he was confident that he had had death result from this practice in consequence of the formation of intestinal kinks from adhesions, making it impossible for the bowels to be moved. He now, almost always gave an aperient or an enema on the fourth day, and earlier if any symptoms, such as vomiting and tympanites, present themselves.

DR. B. F. BAER said that, up to a few years ago, he had also followed the plan of keeping the bowels confined after laparotomy, but now he had them moved on the second or third day, rarely as late as the fourth day. That good plan of quenching the thirst by allowing a pint of warm water to flow into the rectum, facilitates the passage of flatus and feces. Intestinal obstruction was likely to result, as well as adhesions. But this question must be settled by the requirements of each case. He had a case four years ago, in which very serious collapse occurred at the end of the second day. Stercoraceous vomiting occurred, and large quantities of flatus were passed by the mouth, but none by the anus. These symptoms were thought to be due to obstruction, and reopening was considered, but not done. The patient recovered, although she did not pass flatus for five days. Should such a case occur again, he would open the wound and would have the endorsement of most operators for so doing. Large doses of salines are advised in such cases, but he wondered if there was not some danger of rupture of the bowel in these cases of adhesion after serious operations, and he related the following case: An ovarian cyst was closely adherent to the large intestine for a considerable distance, and on the evening of the third day symptoms of septic peritonitis developed. A large dose of Epsom salts was given. The next morning the general condition was better, but he found that liquid feces were flowing from the wound. He reopened the wound and tried to find the point of rupture and close it with sutures. Even after having enlarged the original opening, the ruptured point could not be found on account of its depth in the pelvis and the amount of lymph thrown out. He then closed the wound, without drainage, but freshened the surface of the drainage tube tract and closed it, hoping that the freshened edges would unite. In two days fecal matter again appeared, symptoms of collapse developed and she was expected to die. She however finally recovered. The fistula has entirely closed. The lesson he learned from the case was, that when rupture of the bowel occurred under similar circumstances, the best plan is to let it alone.

DR. PRICE had referred to two cases in which he reopened the abdomen for pain and found the omentum adherent to the line of incision. It is unfortunate that we do not know of some means to prevent these adhesions, but it is a wonder that they do not more frequently occur in the line of the incision, and to the raw surface left after separating adhesions. He knew of no better way to prevent this accident than by the early use of laxatives. Probably much of the pain complained of after operations is due to adhesion, and it is unfortunate that we should be called upon to reopen the abdomen in order to release them. Would it not be wise to give nature time to adjust matters, since there is danger of the formation of other adhesions from the second operation.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, December 18, 1888.

SECTION ON THEORY AND PRACTICE OF MEDICINE.

R. C. M. PAGE, M.D., CHAIRMAN.

DR. J. C. MINOR read a paper on

THE TREATMENT OF THE ACUTE STAGE OF TRAUMATIC TETANUS.

This, he said, was a study in toxicology, a question of poisons and antidotes, since he assumed at the outset that the disease itself was the manifestation of a poison due to the tetanus germ, and produced by the formation of ptomaines as a sequence of its germ origin. The discoveries of Nicolaier, in 1884, and the subsequent investigations of Carle, Ratione, Rosenbach, Terari, Hocksinger, Shakespeare, and Brieger, had demonstrated that tetanus was a blood disease, infectious, inoculable, and having its origin in a bacillus, and that from germ cultures, at least three poisonous substances or alkaloids could be separated, viz.: *tetanine*, which produces tetanus; *tetanotoxine*, which gives rise to tremors, paralysis, and convulsions; and *spasmotoxine*, which gives rise to tonic and clonic spasms. These facts bearing upon the modern aspect of the etiology and pathology of the disease, served to substantiate the observation that in the treatment of tetanus we had to deal with a toxic condition. As to the prevention of the disease, the fact that a high temperature destroys the tetanus germ pointed to a possible local prophylaxis in the primary dressing of wounds.

The healthy working of a nervous centre, as has been well said, required two equally necessary qualities, namely, a power to act when called into play, and a power of remaining at rest. In tetanus the latter was lost; inaction becoming impossible because excitation was constant. Even when the tonic contractions diminished in force nervous energy accumulated during the remission, to be discharged later on as a paroxysm of increased tension or spasm. The disease has a duration, in average cases, of three or four weeks. There seemed

to be a definite limit to the production of toxic material, and the disease, having run its course, terminated in recovery, under certain conditions. That these conditions are not often fulfilled was shown by the mortality, which Gowers placed at nearly ninety per cent.; a rate that was a sufficient warrant for better and more systematic methods of treatment. The fact that the disease was self-limited should encourage the hope of a successful treatment, provided the patient could be protected against its force for a definite period, and the mortality lists show that this definite period consisted of the first and second weeks of the disease, the acute stage of tetanus. Recovery, therefore, depended mainly upon the treatment during this time.

It was admitted that we could neither eliminate nor destroy the poison of tetanus, and that the disease, once started, was beyond the reach of direct methods of antagonism. But when we consider the limitation of the disease and the fact that its activity was expended upon the cord and medulla, we were led to the inference that if we could so act upon the central nervous system that the force of the disease would be spent upon a benumbed tissue, if we could so modify the functions of the cord as to diminish materially its reflex excitability until the nerve storm has passed, we should accomplish the most essential end of treatment. The problem before us, therefore, was how to put the cord and medulla "in splints," physiologically, to do this in the shortest possible time, and to maintain this condition of modified function for at least two weeks.

Dr. Minor did not believe it possible, except by profound anæsthesia, to obtain complete relaxation of all the muscles in the first period of an acute case of tetanus without incurring as much danger from the remedies used as from the disease. The object of treatment was, not to abolish the manifestations of the disease, but to control them to such a degree as to maintain a relatively safe condition long enough for the disease to expend itself. The effect of the disease upon the muscular system was the main point of clinical significance.

Beginning with mere stiffness of the jaws and neck, the muscular tension increased, and subsequently involved the muscles of the abdomen and chest. At times a sudden increase in the degree of this tension occurred, as a paroxysm or convulsive spasm affecting the whole muscular system, producing opisthotonos or other distortions, and threatening death by asphyxia from tonic contraction of the muscles of inspiration. It was to be noted that one had a period of remission and one of exacerbation, with a certain rhythmic rise and fall of nervous excitability. This condition, during the first or acute stage of the disease was one of increasing violence—the spasms growing more severe, and the remissions shorter or less pronounced, until, in from one to two weeks, the disease culminated in a spasm of extreme violence that usually ended the case. The termination was not always fatal, however, as this might be the critical discharge, from which the patient, if he survived, would pass at once into the declining stage of the disease. Other causes of death might occur in the form of simple exhaustion, cardiac failure, or accidental complications.

It appeared, then, that if one could eliminate these convulsive paroxysms from the disease, it would cease to yield such a frightful mortality, and the aim of our treatment, consequently, should be to prolong the remissions, and modify or absolutely prevent the paroxysms. Now, it was a well-known fact that when the functions of the nervous system were under the control of any agent that modifies them, they were not easily affected by any other agent; and in tetanus we had a toxæmia, of which *tetanine* was the genetic agent. This poison produced a marked influence on the functions of the cord, increasing its reflex excitability, and if we attempted to counteract this effect by agents that depress the functional activity of the cord, we should find that ordinary doses produced little or no effect, because the nervous system was already under the control of a powerful modifier of function. Hence, toxic doses would be required to produce therapeutic effects. On the other hand, if we once obtained control of the nervous system, and maintained that advantage, by using our remedies in doses sufficient for the purpose, neither *tetanine* nor any other agent would easily regain control of the functions thus modified.

Assuming that all remedies useful in the treatment of tetanus must possess the power of depressing the functional activity of the cord, the choice of remedies was not of more importance than the method of using them; and a poor remedy well used was better than the best of remedies inefficiently given. The main object being to intoxicate the spinal cord, so as to depress its normal excitability, it was evident that quite a wide range of drugs was at our service. The ones to which Dr. Minor gave the preference were Calabar bean, chloral, and the bromides, with an occasional resort to chloroform. Each of these remedies, he said, appeared to have a special place and purpose in clinical use. Chloroform, Calabar bean, and chloral were the most efficient in the first period of the disease and at its crisis or climax; while the bromides, and also the salicylates come into use during the declining stage.

In the first stage there are three indications to be fulfilled: (1) to lessen muscular rigidity; (2) to prevent convulsive spasms; and (3) to carry the patient through the crisis. The three remedies mentioned are not equally adapted to the purpose in view. Chloroform, for instance, had only a limited use; but within its range of adaptation its action was unrivalled. It was to be employed in those cases of rapid development, occurring soon after an injury, in which the violence and frequent recurrence of the paroxysms threatened an early and fatal termination. Again, it might be necessary in cases of slower development, in which the disease, either from neglect or inefficient treatment, had been permitted to get under full headway. Under these conditions, chloroform was of immense value. Its action was sure and rapid, and carried to the degree of narcosis it gave us complete control of the functions of the cord, abolished reflex excitability, and held the disease in check. This point attained, anæsthesia was to be continued long enough to transfer the control of the functions of the cord to some other and safe agent. During anæsthesia, then, we might administer chloral, Calabar bean, or any remedy suitable for hypodermatic or rectal use, and, after waiting twenty or thirty minutes for absorption to occur, suspend the chloroform.

Of the two agents mentioned, Calabar bean was preferable, because its action was confined to the same field in which the tetanus poison operated, and it was the nearest approach to a physiological antidote to *tetanine* that was at our command. The variable character of

the drug, as usually found, rendered it very unreliable in practice, however, and it was better to use the salicylate of eserine than to depend upon the solid extract of Calabar bean. Chloral was not so good a remedy, or so perfect an antagonist of tetanine, but it was a better drug, and practically of greater service. If Calabar bean was used, chloral would be needed to supplement its action as the disease approached its climax; while if chloral was used, the bromides would serve in the same relation. As to dosage, we should start with the maximum quantity, and be governed as to its subsequent increase by the effect observed upon the muscles. Verneuil advised doses of not less than ʒj of chloral to adults, and not less than ʒiv daily. He considered it necessary to keep the patient in a kind of continuous coma for at least fifteen days, and then gradually to reduce the amount of chloral daily. It, of course, had its dangers, as well as its advantages, and there was, in fact, no such thing as a perfectly safe method of treating the disease successfully. Twice, Dr. Minor said, he had succeeded in carrying cases to recovery with much smaller doses of chloral than those mentioned. He believed that a semicoma was not the best condition for the tetanine patient, and that smaller doses were equally effective if combined with or supported by the action of other remedies. If about the end of the first week the bromides were superadded to the chloral, we should increase the action of the remedy without adding to the danger of its use.

The use of Calabar bean required far more care and attention to detail than the chloral treatment, and he recommended that the initial dose should not be less than half a grain, if the solid extract was used; the question of repeating this amount or not, being determined by the effect produced. The object was to regulate the doses in such a way as to anticipate the condition of muscular tension, and thus prevent the occurrence of spasms. Under the use of Calabar bean the periodicity naturally incident to the disease became more marked, because the remedy contributed to a more pronounced remission during its action. Two grains of the solid extract might be sufficient to obtain this relief for two hours at a time, during the first week of the disease, but three or four grains were usually necessary before the end of the second week; and the increasing violence of the disease would bring these doses closer together. As the crisis approached, the patient was in great danger from both the disease and the remedy, as both were cumulative in their toxic action; and at this stage both these dangers would be materially lessened by bringing chloral into use, and rapidly diminishing the amount of Calabar bean.

During the period of increase of the disease, no matter what remedy was given, it was necessary to increase the dose in proportion to the work it had to do, and when the crisis came we had to choose between the danger of an excessive dose of our remedy and an excessive dose of *tetanine*. We choose the first, because if toxic symptoms appeared we might antidote them, with the probability that the disease had spent its force at this point. To pass this crisis successfully signified recovery.

Having referred to the toxic symptoms of Calabar bean, and their treatment by atropia and morphia, Dr. Minor said, in conclusion, that to use our remedies timidly was to permit the disease to kill the patient. To use them recklessly was to perform that office ourselves. The impossibilities assumed by the physician in the treatment of traumatic tetanus were precisely the same as those belonging to the surgeon who conducted a dangerous and difficult capital operation. As to the general management of these cases, rest and nourishment were so important in their relation to the successful issue of treatment that, no matter how careful and thorough the therapeutic methods might be, they would certainly fail unless the strength of the patient was properly supported, and his nervous system protected against undue excitement.

THE PHILADELPHIA NEUROLOGICAL SOCIETY.

Stated Meeting, November 26, 1888.

The Vice-President, Charles K. Mills, M.D., in the chair.

Dr. J. P. Crozer Griffith reported a

A CASE OF ARTHRITIC MUSCULAR ATROPHY.

S. K., twenty-two, single, American. Father died of consumption, and a paternal uncle has had rheumatism for the last ten years. In other respects the family history is negative. The patient had typhoid fever when about three years of age. Some time in his fourth year he had a fall, injuring his back; and soon after this a posterior curvature developed, which progressively increased up to the age of fifteen, since which time it has remained stationary. About two years after the commencement of the curvature he became unable to walk, and remained so for two or three years; after this time, however, he was able to walk perfectly well, and to attend to his business, which was that of a huckster. The present illness began about a year ago with a rheumatic inflammation of the left knee, for which local remedies were employed, and which did not hinder him from going about. In a few months, however, all the larger joints grew swollen and painful. Six months ago he became unable to walk, and went to the Hospital at Scranton, where he seemed to get better for about two weeks, but after this little improvement could be noticed. While in this hospital he began to waste, and says that in about two months he was as much atrophied as when Dr. Griffith first saw him. He states distinctly that on entering the hospital his limbs were not at all wasted.

The following brief notes were made upon his case at the time of his admission to the University Hospital, June 13, 1888:

The patient complains of constant pain in the larger joints, increased by motion. He is anæmic, and his face is thin and has a delicate appearance. The arms are much wasted, and are held flexed, being more comfortable in this position. The elbows are swollen and painful and there is a tendency to abrasion from pressure on the condyles. There is some degree of contracture of the flexors of the forearm, especially on the right side. Motion of the shoulder-joints is painful. There is extreme kyphosis, occupying all the lumbar and most of the dorsal regions. The vertabræ are not tender on pressure. The hip-and knee-joints are held flexed, but are not fixed. The left knee-joint is somewhat swollen, the right little if at all so. The legs and thighs are greatly atrophied; the thigh measuring only seven and a half inches at its upper third. The ankle-joints appear nearly free from disease. The patellar reflex could not

be obtained. The examination of the thoracic and abdominal viscera was negative, except for a few râles in the lungs, and a faint systolic murmur in the heart.

The course of the case while in the hospital is interesting, inasmuch as the various plans of treatment tried during the four months appeared to have little or no influence upon the disease.

The diagnosis of the case was, however, of great interest, for atrophy developing so rapidly and reaching such a degree, with the coexistence of a posterior curvature of the spine, raised the question whether the disease of the joints might not be of the nature of a spinal arthropathy. Yet, the long immunity which the patient had enjoyed from any evidences of disease of the nerves or cord, and the manner in which the affection of the joints had developed and progressed, rendered it much more probable that it was of a rheumatic nature, and that the case was a well-marked instance of arthritic muscular atrophy, *i. e.*, as Paget explained it, "a reflex atrophy, due to the disturbance of some nutritive nervous centre irritated by the painful state of the sensitive nerve fibres." Nevertheless, some doubt is thrown upon the genuineness of this case by the presence of decided wasting on the distal sides of the affected joints, and by the absence of patellar reflex, both of these being rather more characteristic of a neuritis, while the reflexes are usually increased in arthritic muscular atrophy. It is possible, however, as Bury has pointed out, that in addition to the joint inflammation, or independently of it, there might have developed a rheumatic neuritis of certain nerves

Dr. F. X. Dercum reported

A CASE OF ARTHRITIC MUSCULAR ATROPHY OF GONORRHŒAL ORIGIN.

H. L., a man aged thirty-six, of average stature and rather slight build, presented himself at the University Hospital with the following history. Fourteen years ago he had a small venereal sore which healed rapidly, was not followed by secondary symptoms and was probably benign in character. Previous to and since this time he had been entirely well. In the middle of April last (1888), however, he contracted gonorrhœa. The attack does not seem to have been of more than ordinary severity and ran an average course. Three weeks after its commencement he noticed great pain and some swelling in the right elbow. One week later the right knee became similarly affected and he was obliged to take to his bed. One after another the various joints of the extremities were attacked though the patient no longer remembers their sequence. He simply tells us that shortly after the appearance of pain in the right knee, both ankles, the opposite knee, both shoulders, and the joints of the left arm were affected

Four weeks after the involvement of the right elbow, wasting of the muscles of the upper arm on the same side was noticed. Next the muscles of the opposite arm and of the legs were observed to be growing smaller. Gradually in an order which the patient unfortunately cannot recall, the bulk of the muscles of the upper and lower extremities were involved.

He was confined to bed some eight weeks, when the pain, in a measure, subsided. It persisted, however, and is still marked at the present time. At first the weakness of the muscles was so great that even walking was impossible. In the beginning of July, however, he had improved so as to be able to take a few steps. Since that time he has gained sufficiently to walk short distances and to ascend a stairway, though the latter is still a difficult feat.

Though the pain in the joints had for a long time been insufficient to interfere with movement, his arms continued until lately to be almost useless. A constant attendance of a relative was necessary to assist him in eating, dressing, and the ordinary acts of life.

His present condition is as follows: All of the muscles of the upper and lower extremities and some of the back appear to have suffered. The wasting is most marked in the shoulders and upper arms. The face has not been attacked. The affection is quite symmetrical except in the back, where there is extreme wasting of the lower portion of the trapezius and the rhomboid muscles of the right side are contracted with but slight wasting of these muscles upon the left. Fibrillary tremors are readily observed in various situations. No change is noted in the myotatic irritability, unless it be that the knee-joint is slightly increased. Electrical examination shows that no qualitative change has taken place. Slight diminution to both currents is, however, noticeable. If the statements of the patient are to be trusted, he is undoubtedly improving. He tells us, for instance, that he has had a distinct gain in the arms during the past month.

Dr. F. X. Dercum also exhibited a patient with

A SUBCUTANEOUS CONNECTIVE TISSUE DYSTROPHY.

This case is one which has been described in full in the *University Medical Magazine*, and it is therefore unnecessary to give the details of it here. It is a case of dystrophy of the connective tissue. Here we have enormous hypertrophy of the connective tissue which is in an embryonal state, with this there are associated many of the symptoms of myxœdema. The woman noticed some three years ago, that the arms were increasing in size. Some six months later she began to have pain in the right arm and this symptom has been confined almost entirely to the right side. The pain is not in the nerve trunks alone, but diffused through the mass of tissue. Upon the right side there are also some anæsthetic patches variable in extent. These are present both on the arm and leg. There are other sensory symptoms, such as impairment of vision, diminution of hearing and decided impairment of taste and smell. These are all most marked on the right side. The muscles of the palm are a little wasted. There are qualitative changes in the reaction to the galvanic current.

The bulk of the enlargement is due to mucous tissue. She is the subject of crises of pain which are similar to those found in myxœdema and these attacks are attended with hardening of the part where the pain is located. There is at present a little mass in the posterior cervical triangle of the right side, which forcibly reminds one of the supra-clavicular swelling described by writers on myxœdema. Dr. Dercum could not feel the thyroid gland. While there is marked dystrophy of the subcutaneous connective tissue and some changes in the muscles, the skin is not involved. This is a distinguishing feature between this case and myxœdema proper. In the early history, however, sweating was scanty or absent. Slowness of thought or slowness of movement are not

marked. There has, however, been decided speech involvement a number of times which has appeared to be associated with the crises. Not only would the neck and arms swell, but the tongue and soft palate would also swell. There has also been bleeding from various mucous surfaces as the mouth, throat, bronchial tubes, and stomach. The case, therefore, presents many of the symptoms of myxœdema. His explanation of the hardening of the tissue, is that there is some obstruction to the lymph outflow. Punctures made during the attacks of pain resulted in the appearance of lymph-like fluid.

Dr. H. C. Wood said that the wasting of muscles about an inflamed joint has long been noted. It is seen in almost every case of chronic rheumatism. Charcot has pointed out that this is independent of the extent of the joint inflammation. It may occur after very slight injuries. It is almost always the extensors that suffer, as was illustrated by the case shown by Dr. Dercum. He is thoroughly in accord with those who insist upon the necessity of amalgamating the various so-called nervous diseases. He thinks that there are very few, possibly not more than eight or nine, organic diseases of the nervous system. We make one disease of chronic inflammation or degeneration of one tract of the cord, and when the same change is found in another tract it is given a different name, or if two of the regions happen to be affected together, we have still another disease. We must, of course, for the sake of convenience, talk about locomotor ataxia and lateral sclerosis, etc. But, in doing so, we must understand that these are not, properly speaking, distinct diseases—but simply clinical groups of cases, each group characterized by certain symptoms due to the original position of the lesion—but the lesion identical in character and occasionally so situated as to make cases whose clinical features partake of those of several groups.

Dr. William Osler regarded one of the cases of Dr. Mills as a characteristic example of amyotrophic lateral sclerosis. The spinal form of progressive muscular atrophy in its later stages, usually shows signs of lateral sclerosis, and the picture presented by the patient of wasted arms and spastic legs is extremely common. In chronic cervical pachymeningitis the clinical features are very similar. The condition of the neck is no evidence that there is anything the matter with the cervical vertebræ.

There is one practical point in regard to the arthritic atrophies. He has frequently seen good results follow the use of massage, electricity, rubbing, and the like, if used early. If, however, the condition is allowed to go on for months, it may, and often does, result in permanent disability and uselessness of the joint.

It is not improbable that the case presented by Dr. Dercum may be allied to reported instances of neuritic and spinal trouble following gonorrhœa. Many years ago, Gull and others called attention to spinal troubles to which they gave the name of reflex paraplegia, in association with genito-urinary disorders. Many of these cases have been shown to be forms of myelitis, such as occur in other microbic affections.

Dr. F. X. Dercum regarded the case which he presented as one of atrophy following gonorrhœal rheumatism. He thought that we must agree that we have two forms of inflammation or degeneration in the cord, one which originates in the connective tissue, and one which originates in the nervous tracts. We are so in the habit of speaking of the inflammation of the columns that we are apt to forget that these affections are really forms of degeneration. Doubtless in these tract degenerations the essential factor is frequently a feeble vitality impressed upon the parts during the development period. We must, he thought, make a distinction between diseases affecting the sensory and those affecting the motor tract, but whether we make a distinction between degeneration of the upper and of the lower segment of the motor tract, seems to him to be immaterial. In tabes dorsalis we have degeneration of the sensory tract, and in the myelopathies degeneration of the motor tracts.

Dr. James Hendrie Lloyd said that Dr. Osler had referred to the view he took of one of the cases presented by Dr. Mills, a traumatic focal lesion with secondary degeneration. If we are to assume that this is a case of amyotrophic lateral sclerosis, it differs from many cases of that affection which he had seen, in its etiology, at least. In this case there was a distinct history of traumatism, the patient being thrown by an explosion upon a pile of iron, striking the back of his neck and his arm. This was followed in a few months by rapid atrophy of all the muscles of the shoulder and arm on both sides. Later, this was followed by paralysis of a peculiar character of the neck muscles. This is followed by a descending degeneration, evidently in the lateral tracts, shown by exaggerated patellar reflex, distinct ankle-clonus and rectus-clonus, without atrophy of the muscles of the legs.

His view is, that there was a local injury of the cervical portion of the cord, causing atrophy of the cells in the anterior cornu, and that possibly from the injury he has had a descending lateral degeneration through the motor tract. There is at present another case, very similar to this one, in the Philadelphia Hospital. It is the case of a man who fell from a scaffold, and has never walked since. He has progessive atrophy of the neck and upper extremities, with the symptoms in the legs of lateral sclerosis. The cause, in his case, is distinct, and can scarely be denied.

CORRESPONDENCE.

ON THE PROPER USE OF THE PERINEAL, OVARIOTOMY, AND OBSTETRIC PADS.

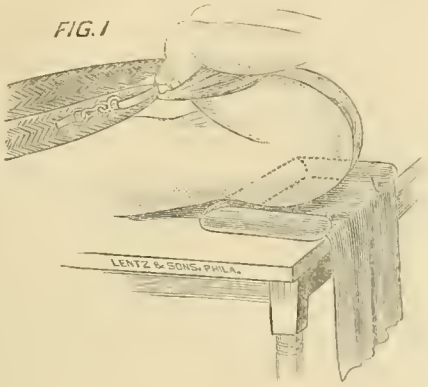
To the Editor of The Medical News,

Sir: I feel that it is important to call attention, through your journal, to the proper methods of using Dr. Kelly's perineal, ovariotomy, and obstetrical pads, having occasionally heard complaints that they have been found unmanageable. This has been due, as I know from observation, to a neglect of attention to a few of the simplest details in their use, as both the perineal and ovariotomy pads are in constant satisfactory use at the Kensington hospital, as well as in many clinics throughout this country and Europe, and the obstetrical pad has for some time been used in all confinements attended by Dr. Kelly and myself, proving itself an indispensable comfort and convenience. I feel, therefore, that my labor is not lost in describing a little more in detail the few points to be observed in using the pads.

The perineal pad should first be stiffly inflated with air, and then placed on the end of the table, with the

full length of the apron hanging vertically from the edge with its lower extremity lying in the bucket on the floor. The patient is placed upon the pad, as shown in Fig. 1,

FIG. 1

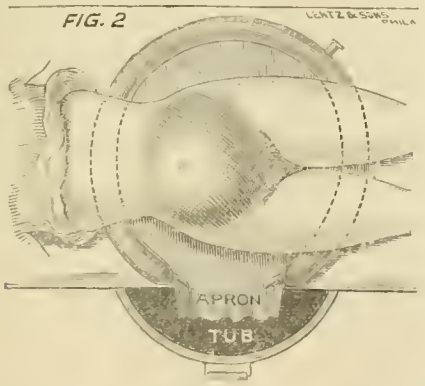


in the lithotomy position, with buttocks brought to the edge of the table, and with the clothes drawn well above the small of the back; enough air is then allowed to escape from the inflated rim by unscrewing the valve, to make it slightly flaccid, when it fits the back neatly, thus preventing the patient from suffering any painful effects from prolonged pressure. All fluid now used on the buttocks or genitals must of necessity run down on the pad, and be directed by the rim, which keeps the clothing and linen dry, on to the little flaps at the edge of the table, which turn it on to the apron and thus into the bucket.

To clean the pad, it should be douched under a faucet and wiped dry with a clean cloth immediately after use, giving especial attention to the folds under the edges of the inflatable rim.

The ovariotomy pad should be placed so as to drain off the side of the table nearest the operator. It thus *drains at right angles* to the patient's body. The apron must *not lie on the table at all*, but hang vertically at the

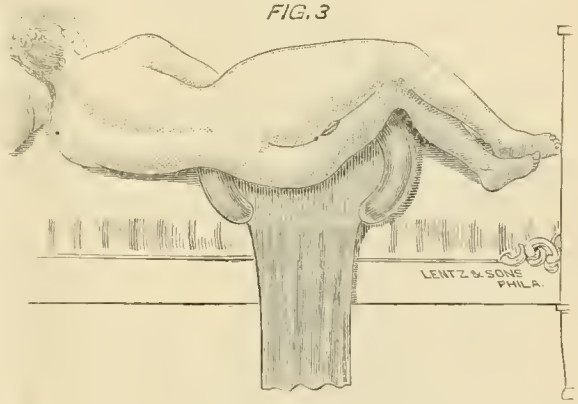
FIG. 2



side from the edge of the table, carrying fluids into the tub beneath. When inflated and properly placed, as in Fig. 2, the patient's abdomen lies in the middle of a large circle built up by the inflated rim on all sides, except the narrow opening at the edge of the table allowing the escape of fluid. Place the patient on the pad, as shown in Fig. 2, with the clothes drawn well up under the shoulders, and the apron hanging vertically as shown, and not diagonally or running the length of the table, there will then be no difficulty in using the pad.

The obstetrical pad is designed for use in confinement cases, and has a higher rim than either the perineal or ovariotomy pad, to compensate for the unevenness of the bed, and ought to be inflated to its full extent. It has proved invaluable, and of the greatest comfort in insuring a clean bed and clean clothes immediately after labor. The patient placed upon her side, or in the dorsal position with the clothes drawn, as shown in Fig. 3.

FIG. 3



above the hips and properly protected by bed-clothes below; the apron hangs over the edge of the bed into a chamber or bucket carrying off liquor amnii, blood, douching, etc., and receiving the child and placenta.

It is of especial service when any obstetrical operation is to be performed, leaving bed and clothes clean and dry, obviating the need of the "change," always troublesome and sometimes even dangerous to the patient, more often incompletely performed and then attended with all the risks of incomplete removal of discharges.

These pads may be obtained of Charles Lentz & Sons, No. 18 North Eleventh Street, Philadelphia.

Hoping that these suggestions may prove of service to the many friends of the Hospital using the pads, I am,

Respectfully yours,

HUNTER ROBB, M.D.,
Assistant-Surgeon to the
Kensington Hospital for Women.

NEWS ITEMS.

New York State Medical Society.—The eighty-second annual meeting of the New York State Medical Society will be held in the city of Albany, on Tuesday, Wednesday, and Thursday, February 5, 6, and 7, 1889.

The following papers have been promised. It will greatly facilitate the labors of the Business Committee if members or delegates desiring to read papers will immediately forward their names, with the titles of their proposed articles, to Dr. D. B. St. John Roosa, 20 East Thirtieth Street, New York, Chairman of the Business Committee:

"The Etiology of Croupous Pneumonia," by George M. Sternberg, U. S. A.

"A Clinical Study on Alopecia Areata and its Treatment," by L. Duncan Bulkley.

"Chronic Headache," by C. L. Dana.

"Vertigo, its Causation and Therapeutics," by J. Leonard Corning.

"The Medical Treatment of Diseases of the Urinary Organs in Children," by A. Jacobi.

"The Treatment of Typhoid Fever," S. S. Burt.

"Management of Cardiac Dilatation, based on its Etiology," by A. L. Loomis.

"The Municipal Control of Diphtheria," by Charles Storer.

"The Prevention of Summer Diarrhœa among Infants Viewed in the Light of the Lesions," by L. Emmet Holt.

"Some Sanitary Suggestions," by L. E. Felton.

"Diagnostic Value of Spinal Rotation," by Bernard Bartow.

"The Uses of Galvanism in Gynecology," by W. E. Ford.

"The Management of Hip-joint Disease," by A. M. Phelps.

"Treatment of Hypertrophies at the Base of the Tongue," by W. C. Phillips.

"Recent Advances in the Treatment of Hernia," by W. B. DeGarmo.

"A Plea for the Employment of Köller's Method," by C. A. Powers.

"The Orthopedic Treatment of Tubercular Disease of the Knee in Children," by V. P. Gibney.

"A Contribution to Surgery," by L. S. Pilcher.

"Contribution to Surgery of the Spine," by Robert Abbe.

"The Disorders of Menstruation," by Andrew F. Currier.

"The Treatment of Acute Inflammation of the Middle Ear," by Gorham Bacon.

"Operative Treatment of an Hyperostosis of the External Auditory Canal," by T. R. Pooley.

"The Use of Prismatic Spectacles for the Relief of Asthenopia caused by Insufficiency of the Ocular Muscles, with Reports of Cases," by D. Webster.

"Considerations Concerning the Operation for Hard Cataract," by Henry D. Noyes.

"Membranous Rhinitis," by Frank H. Potter.

"The Spectroscopic Examination of the Blood and Certain Diseases of the Eye," by Lucius Howe.

"Purulent Conjunctivitis and Blindness in the State of New York," by Lucius Howe.

Titles unannounced: W. S. Ely, George H. Fox, E. Gruening, Edward H. Parker, James B. Hunter.

The names of those who have promised to take part in the discussions will be announced later.

A Hospital built by Verdi.—The *Gazzetta Musicale* of Milan contains an interesting account of a hospital recently opened at Villanova and entirely built and supported by Verdi, the composer. Villanova is situated about twenty miles from Piacenza and in close vicinity to the Villa di Sant' Agata, the country seat which Verdi has made his home and where he lives in the manner of a farmer, abandoning all music from his thought, and without so much as a piano in his house.

The new hospital, an unpretentious but large building, lies in a commanding situation overlooking the Po and with a distant view of the Apennines. There are two wings—one for women, the other for men, and a separate ward is set aside for contagious cases; there is also a hydropathic establishment, and most elaborate arrangements have been made for the disinfection of linen and other sanitary purposes. An efficient staff of nurses and attendants is also provided, and Signora Verdi has made the housekeeping department her special care. The large sums required have been contributed by Verdi, who has also deposited sufficient funds for the maintenance of the hospital.

The munificence of the great composer is only equalled by his modesty. The opening ceremony, which took place on November 6th, was of the simplest kind, only Verdi and his family, the physician, and the Sindaco of Villanova being present. No speechifying was allowed, Verdi remarking that the only inauguration necessary was the admission of the sick and ailing, twelve of whom were received then and there.

The Sindaco proposed that the new building should be called "Verdi Hospital," but to this also the donor objected, and the name Hospital Villanova was finally adopted.

Therapeutic Value of Odor of Cows.—The *New York Analyst* reports that the supposed remedial agency of the odor of cows and cow-stables in cases of consumption is to be tried at Reinickendorf, near Berlin, on a unique scale. A vast circular building has been erected, in the basement of which several hundred cows will be kept, and the odor of the stables will be conducted to the rooms in the upper stories. In the centre of the building is a large yard, for which a whey-cure, bathing-rooms, etc., are planned.—*Boston Medical and Surgical Journal*, December 6, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM DECEMBER 18 TO DECEMBER 24, 1888.

ALEXANDER, CHARLES T., *Lieutenant-Colonel and Surgeon.*—Detailed for duty on the Army Retiring Board, to meet at Vancouver Barracks, Washington Territory, at the call of the president thereof.—Par. 22, *S. O. 292, A. G. O., Washington, D. C*, December 15, 1888.

KILBOURNE, HENRY S., *Captain and Assistant Surgeon.*—Detailed for duty on the Army Retiring Board, to meet at Vancouver Barracks, Washington Territory, at the call of the president thereof.—Par. 22, *S.O. 292, A. G. O., Washington, D. C.*, December 15, 1888.

By direction of the Secretary of War, the leave of absence granted to *Captain and Assistant Surgeon* WILLIAM F. CARTER, S. O. No. 116, November 12, 1888, Department of Texas, is extended five months.—Par. 4, *S. O. 292, A. G. O., Washington*, December 15, 1888.

MCCREERY, GEORGE, *Captain and Assistant Surgeon.*—Is granted leave of absence for one month.—Par 4, *S. O. 265, Headquarters Division of the Atlantic, Governor's Island, New York City*, December 15, 1888.

HOPKINS, WILLIAM E., *Captain and Assistant Surgeon.*—Is detailed as a member of the Army Retiring Board, to meet at San Francisco, California, vice Major and Surgeon Henry E. Tilton, relieved.—Par. 3, *S. O. 294, A. G. O., Washington*, December 18, 1888.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*
